Help your students learn to
Think Like a Nurse with new
digital learning resources in
Concepts Nursing!

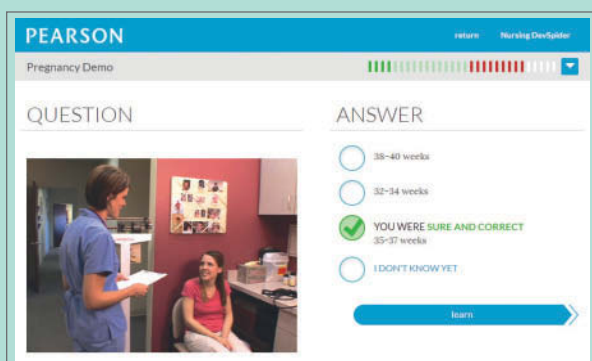

MyLab® Nursing

MyLab Nursing helps students master key concepts, prepare for success on the NCLEX-RN® exam, and develop clinical reasoning skills.

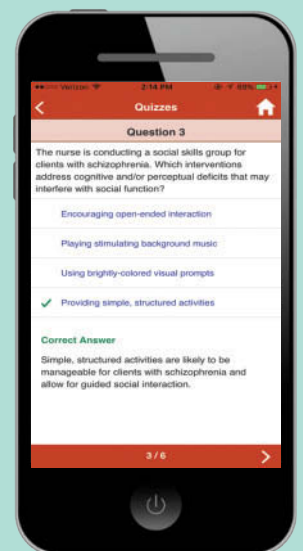

NEW! Adaptive, mobile-enabled Dynamic Study Modules with personalized learning and remediation help students focus their studies and retain information over the long term.

Learn more at pearson.com/mylab/nursing

NEW! Concepts Connection in Nursing App

The Concepts Connections in Nursing app helps students make important connections between concepts in nursing and exemplars or alterations. Understanding these key concepts and the connections between them enables students to focus on the critical thinking and decision-making skills necessary for successful clinical practice. Now available on both the Apple App Store and Google Play.

Pearson's Concepts Solution

Nursing: A Concept-Based Approach to Learning is the number one choice for schools of nursing that use a concept-based curriculum. It is the *only* true concept-based learning solution and the *only* concepts curriculum developed from the ground up as a cohesive, comprehensive learning system. The three-volume series, along with MyLab Nursing, provides everything you need to deliver an effective concept-based program that teaches students to think like a nurse and develops practice-ready nurses.

Nursing: A Concept-Based Approach to Learning, Third Edition, represents the cutting edge in nursing education. This uniquely integrated solution provides students with a

consistent design of content and assessment that specifically supports a concept-based curriculum. Available as a fully integrated digital experience or in print format, this solution meets the needs of today's nursing student.

Starting with the cover, our goal for the Third Edition is to help students learn the essential knowledge they will need for patient care. The cover, a Möbius strip, represents the relationships among the concepts and how they are all interconnected. By understanding important connections of concepts, students are able to relate topics to broader contexts.

What Makes Pearson's Solution Different?

As demonstrated with the previous two editions of *Nursing: A Concept-Based Approach to Learning*, Pearson's program has successfully met the needs of tens of thousands of students and instructors in concept-based education programs. The Third Edition builds on our commitment to excellence: Every page, every word, every feature has been examined—all to help enhance the learning and teaching process. The result is an integration of content and features that *you*, our customer, have asked for and that you will not find anywhere else.

Pearson's program includes:

- Everything instructors and students need in one package: all concepts, all exemplars, all assessment tools.
- Content designed by instructional designers for conceptual learning that includes learning and enabling objectives for every main section and measurable outcomes for each.
- Content that covers the lifespan from pregnancy and birth, through childhood and adolescence, and into young adulthood and middle and old age.

Why Teach Concept-based Learning?

University and college nursing programs across the United States have begun evaluating how their programs can meet the needs of today's nursing students. The vast array of new knowledge in the "information age" has left nursing students feeling overwhelmed by the quantity of knowledge and skills they must gain in order to become practicing nurses. In light of this, many programs are moving to the model of concept-based learning in an effort to meet the challenges facing nursing students and new nurses today. Aside from creating a streamlined approach in response to content overload/saturation in nursing education, there are a multitude of reasons for nursing programs to consider a concept-based program.

This model provides the impetus for educators to transition away from traditional methods of faculty-centered teaching and passive learning toward active, focused,

participative, and collaborative teaching and learning. Pearson's *Nursing: A Concept-Based Approach to Learning*, Third Edition, is designed to assist nursing faculty in providing students with a broader perspective while promoting a deeper understanding of content across the lifespan in a focused, participative, and collaborative learning environment.

What are the benefits of conceptual learning? Some of the often-referenced benefits of conceptual learning in nursing programs are that it:

- Focuses on problems
- Fosters systematic observations
- Fosters understanding of relationships
- Focuses on nursing actions and interprofessional efforts
- Challenges students to be excellent learners.

Organization and Structure of the Third Edition

The basic structure of the Second Edition was retained for the Third Edition. There are:

- Five parts:
 - I: The Biophysical Modules (in the Individual Domain)
 - II: The Psychosocial Modules (in the Individual Domain)
 - III: Reproduction (in the Individual Domain)
 - IV: The Nursing Domain
 - V: The Healthcare Domain
- Fifty-one concepts
- One hundred fifty-eight exemplars

The Concepts were chosen after surveying numerous concept-based curricula and finding the common elements. Some Concepts were added or revised in response to requests by users. The result is a comprehensive set of Concepts that cover the essentials of nursing education.

The Exemplars were chosen based on selected national models and initiatives such as those of the Institute of Medicine, *Healthy People 2020*, The Centers for Disease Control and Prevention, The Joint Commission, the National Institutes of Health, the National Institute of Mental Health, the NCLEX Test Plan, The Centers for Medicare and Medicaid, the Occupational Safety and Health Administration, and Quality and Safety Education for Nurses, among others. Prevalence rates were considered for the biophysical and psychosocial exemplars, with more common disorders prioritized over less common ones. Certain Exemplars were

chosen because they lend themselves to teaching across concepts or across the lifespan. In the Third Edition, some Exemplars that focused on a particular stage of the lifespan, such as Diabetes in Children, have been folded into the Lifespan Considerations of another exemplar. Now there are two separate Exemplars on diabetes: one focusing on type 1 diabetes mellitus and the other focusing on type 2 diabetes mellitus. In the Third Edition, nine new/expanded Exemplars have been added:

- Cystic Fibrosis
- Delirium
- Environmental Quality
- Nurse Safety
- Patient Safety
- Sexual Dysfunction
- Traumatic Brain Injury
- Type 1 Diabetes Mellitus
- Type 2 Diabetes Mellitus

For the Third Edition, as shown in the Module Outline and Learning Outcomes listed at the beginning of each module, each main section has a dedicated learning outcome. Our editorial and instructional design teams worked to create consistent, accurate, challenging, achievable, and measurable objective statements based on objective-driven design practices to better engage students, improve performance, increase student gains, and promote deep learning.

Module Outline and Learning Outcomes

The Concept of Acid–Base Balance

Normal Acid–Base Balance

1.1 Analyze the physiology of normal acid–base balance.

Alterations to Acid–Base Balance

1.2 Differentiate alterations in acid–base balance.

Concepts Related to Acid–Base Balance

1.3 Outline the relationship between acid–base balance and other concepts.

Health Promotion

1.4 Explain the promotion of healthy acid–base balance.

Nursing Assessment

1.5 Differentiate common assessment procedures and tests used to examine acid–base balance.

Independent Interventions

1.6 Analyze independent interventions nurses can implement for patients with alterations in acid–base balance.

Collaborative Therapies

1.7 Summarize collaborative therapies used by interprofessional teams for patients with alterations in acid–base balance.

Acid–Base Balance Exemplars

Exemplar 1.A Metabolic Acidosis

1.A Analyze metabolic acidosis as it relates to acid–base balance.

Exemplar 1.B Metabolic Alkalosis

1.B Analyze metabolic alkalosis as it relates to acid–base balance.

Exemplar 1.C Respiratory Acidosis

1.C Analyze respiratory acidosis as it relates to acid–base balance.

Exemplar 1.D Respiratory Alkalosis

1.D Analyze respiratory alkalosis as it relates to acid–base balance.

Structure and Features of the Concepts

The Concepts feature a consistent design throughout the program. This allows students to anticipate the learning they will experience. Special features, which students can use for learning and review, recur in each Concept. The basic structure of the Concepts is shown below with visuals and annotations describing the content. Note that each **red heading** has a corresponding learning outcome.

Normal Presentation ... Each Concept starts with a review of normal, healthy function, including subsections on Physiology Review and Genetic Considerations where appropriate.

Physiology Review

Genetic Considerations

Alterations ... The second section of each Concept focuses on alterations, including subheads on Alterations and Manifestations, Prevalence, and Genetic Considerations and Risk Factors. A standard feature in this section is the Alterations and Therapies table.

Alterations and Manifestations

Prevalence

Genetic Considerations and Risk Factors

Alterations and Therapies			
Oxygenation			
ALTERATION	DESCRIPTION	MANIFESTATIONS	INTERVENTIONS AND THERAPIES
Hypoxemia	Decreased level of oxygen	<ul style="list-style-type: none">Chest wall in-drawing (early manifestation)Cyanosis (late manifestation)	<ul style="list-style-type: none">Identify and treat the underlying cause.Administer oxygen if O₂ saturation level falls below 90%.
Dyspnea	Labored breathing or shortness of breath	<ul style="list-style-type: none">Clearly audible, labored breathing; anxietyDistressed facial expressionNasal flaring	<ul style="list-style-type: none">Identify and treat the underlying cause.Administer oxygen if O₂ saturation level falls below 90%.
Apnea	Absence of breathing	<ul style="list-style-type: none">Lack of respiratory effort that can lead to respiratory arrest	<ul style="list-style-type: none">Identify and treat the underlying cause.Administer respiratory stimulants, as appropriate.
Tachypnea	A respiratory rate greater than 20 breaths per minute for children and adults, 60 breaths per minute for an infant	<ul style="list-style-type: none">Excessive rapid breathingRapid breathing at restShallow breathing	<ul style="list-style-type: none">Identify and treat the underlying cause.
Orthopnea	Difficulty breathing when lying down	<ul style="list-style-type: none">Dyspnea while lying down	<ul style="list-style-type: none">Identify and treat the underlying cause.Elevate the head, neck, and chest while sleeping.
Pneumothorax	Lung collapse caused by the collection of free air within the pleural space	<ul style="list-style-type: none">Chest painShortness of breath	<ul style="list-style-type: none">Identify and treat the underlying cause.Observe the patient.Use needle decompression or chest tube insertion.Surgery

Case Studies

Each Concept contains a three-part unfolding case study to help students apply what they are learning to a sample patient.

Case Study » Part 1

Dennis Welborn is a 52-year-old man who visits his primary care physician with complaints of severe pain in his back and abdomen and painful urination with hematuria. As the nurse working at the clinic, you take Mr. Welborn's medical history and make a preliminary assessment. Mr. Welborn is 6'2" tall and weighs 265 pounds. His vital signs include temperature 100.8°F oral, pulse 95 bpm, respirations 22/min, and BP 140/92 mmHg. Mr. Welborn rates his back and abdominal pain as 9 on a scale of 0–10, and his midline abdominal pain level is a 7 when he is urinating. When asked about his diet, Mr. Welborn admits that as a widower, he often eats out with coworkers for lunch and picks up fast food on the way home for his evening meal. He usually drinks three cups of coffee in the morning and diet soda throughout the afternoon and evening. When he gets heartburn, he chews several antacid tablets for relief. An abdominal assessment reveals a distended bladder. Mr. Welborn states he delays urination as long as possible because of the pain. When he does urinate, he has noticed that he has a weak stream and continues to feel the urge to urinate when he has finished. The medical care provider orders lab tests, so a blood

and urine sample are obtained for analysis. Mr. Welborn is transferred to the radiology department to have an abdominal x-ray. The x-ray reveals a large stone (1.2 cm) in Mr. Welborn's proximal right ureter, and the urinalysis indicates the presence of small calcium crystals, RBCs, and bacteria. The blood test also detects high blood calcium levels.

Clinical Reasoning Questions Level I

1. What risk factors does Mr. Welborn have for developing urinary calculi?
2. Other than a distended bladder, what findings might you discover?
3. How many?

Clinical Reasoning Questions Level II

What?

How?

Why?

Refer

ment

Case Study » Part 3

After 3 days in the hospital, Mr. Welborn is discharged to home. His urinary catheter has been removed, and he states that he can urinate without pain. However, the nephrostomy tube remains in place. In addition, his IV morphine has been discontinued, and he now receives acetaminophen (1000 mg q6h). With consistent ambulation and discontinuation of morphine, Mr. Welborn had two bowel movements before discharge.

Clinical Reasoning Questions Level I

1. What methods can you teach Mr. Welborn to help prevent future renal calculi?
2. Describe the patient teaching you will provide Mr. Welborn about caring for his nephrostomy tube.
3. What assessment should be performed on Mr. Welborn before discharge?

Clinical Reasoning Questions Level II

4. What medications might the healthcare provider prescribe for Mr. Welborn upon discharge?
5. What follow-up appointments should you schedule for Mr. Welborn? Why?
6. How would a referral to a nutritionist benefit Mr. Welborn?

Case Study » Part 2

Mr. Welborn's physician consults with a urologist, who suggests that Mr. Welborn be admitted to the hospital for a percutaneous nephrolithotomy. The urologist prescribes intravenous (IV) morphine for pain and schedules the surgery for 8:00 the next morning. The procedure is successful, without complications, and a urinary catheter and nephrostomy tube are put in place during surgery to drain urine. Postoperative pain is again managed with IV morphine, and Mr. Welborn states that his pain is manageable. He is confined to bed until 1 day postsurgery. The day after surgery, Mr. Welborn reports that he did not have his normal morning bowel movement. When he sat on the toilet, he was unable to defecate, and he was afraid to push too hard because of his surgery. He was also unable to have a bowel movement the previous morning because of anxiety about the surgery, and his abdomen is feeling full. Abdominal assessment reveals diminished bowel sounds and dullness to percussion.

Clinical Reasoning Questions Level I

1. What factors may have contributed to Mr. Welborn's constipation?
2. What independent nursing interventions can you implement to help Mr. Welborn eliminate feces?
3. What patient teaching can you provide to help Mr. Welborn prevent constipation in the future?

Clinical Reasoning Questions Level II

4. What effects might Mr. Welborn's constipation have on his urinary problems?
5. What complications may develop as a result of Mr. Welborn's constipation? What assessments should you perform to detect these complications?
6. What side effects of the percutaneous nephrolithotomy may Mr. Welborn experience related to his urinary system?

Concepts Related to Immunity		
CONCEPT	RELATIONSHIP TO IMMUNITY	NURSING IMPLICATIONS
Comfort	Painful conditions, such as swelling and skin reactions, often occur during immune response.	<ul style="list-style-type: none"> Assess related symptoms, such as edema, rash, malaise, loss of appetite, and trouble sleeping. Be alert to topical and latex allergies that could worsen symptoms. <i>Anticipate:</i> Additional assessments, comfort measures
Infection	Patients with alterations in immunity can experience acute or chronic infections.	<ul style="list-style-type: none"> Assess area of suspected infection (see Infection Assessment section in the module on infection). Educate patients regarding the importance of immunizations and encourage their use. Educate patients regarding the importance of avoiding situations that could increase exposure to infection. Practice standard precautions, proper hand hygiene, and aseptic/sterile technique with all procedures. Assess complete blood count (CBC) results; be alert for elevated WBC count.
Inflammation	Movement of fluid and cells to the site of injury or infection causes inflammation during an immune response.	<ul style="list-style-type: none"> Assess for fever, skin warmth and redness, edema, and generalized pain. Be alert for abscess formation, purulent exudate, and increased WBC count. <i>Anticipate:</i> Aspirin, antipyretics, cold packs
Managing Care	Patients with alterations in their immune system can greatly benefit from participating in managed care and have more positive health outcomes.	<ul style="list-style-type: none"> Assess the needs of patients to identify actual or potential problems related to care. Advocate for patients in relation to their care needs.

Concepts Related to ... Enhanced for the Third Edition, the Concepts Related to section and feature are designed to help students make linkages between and among different Concepts.

Health Promotion ... New to the Third Edition is a focus on health promotion, one of the foundations of nursing. Many Health Promotion sections include a Patient Teaching feature. Examples of subsections include.

Modifiable Risk Factors

Care in the Community

Patient Teaching

Health Promotion for Cancer Prevention: Modifiable Risk Factors

- Discourage smoking or use of other tobacco products.** Emphasize the importance of patients protecting children and themselves from exposure to tobacco smoke. This is one of the most important health decisions an individual can make.
- Encourage patients, especially children, to consume a healthy diet.** This should include a minimum of five servings of fruits and vegetables daily as well as whole grains, iron-rich foods, and foods that are rich in vitamin B₁₂. Teach patients to limit their consumption of processed meats; drink alcohol in moderation; and choose fewer high-calorie foods.
- Explain the importance of maintaining a healthy weight and being physically active.** Physical activity helps to control weight. Together, these factors may lower the risk for various types of cancer.
- Teach patients effective ways to protect themselves from ultraviolet radiation.** Early excessive exposure to sun and one or more severe sunburns during childhood increase the chances of skin cancers developing in adulthood. Patients who work outdoors, athletes, coaches, and others who spend time outside regularly should use sunscreen daily (SPF 15 or greater), regardless of the climate in which they live. Emphasize the importance of avoiding midday sun, when the sun's rays are strongest. Instruct patients to cover exposed skin and wear a hat with a wide brim. They should avoid tanning beds and sunlamps.
- Explain the importance of avoiding risky behaviors.** Practicing risky behaviors such as needle sharing or unsafe sexual contact can increase the risk of developing certain cancers.
- Suggest that patients have their homes tested for radon and explore their exposure to harmful chemicals.** Patients may be exposed to hazardous substances in the home or in the workplace.
- Stress the importance of getting immunizations, receiving regular medical care, and doing self-examinations.** By protecting against certain viral infections, immunizations can decrease the risk of some cancers. Regular screenings and self-examinations increase the chances of early detection of cancer, allowing for a better chance of successful treatment (Mayo Clinic, 2015a).

Oxygenation Assessment			
ASSESSMENT/METHOD	NORMAL FINDINGS	ABNORMAL FINDINGS	LIFESPAN OR DEVELOPMENTAL CONSIDERATIONS
Nasal Assessment			
Inspect the nose symmetry.	The nose should be midline and symmetrical.	<ul style="list-style-type: none"> Asymmetry indicates trauma or surgery. 	<ul style="list-style-type: none"> Nasal flaring in the neonate may be indicative of respiratory compromise.
Inspect nasal cavity using a flashlight.	The septum should fall midline and be intact. The mucosa of the nares should be pink and moist without drainage. Both nares should be patent.	<ul style="list-style-type: none"> Redness and/or swelling is observed. Deviated septum narrows or occludes one naris. Foreign bodies may be found in the nares, especially of infants, toddlers, and preschoolers. Purulent or watery nasal drainage is present. Pale turbinates are seen. 	<ul style="list-style-type: none"> Nasal passages of neonates and small children are smaller than those of adults. Ensuring a clear nasal cavity may decrease the risk for respiratory compromise, as neonates and infants are nasal breathers.
Respiratory Rate Assessment			
Count respiratory rate for one full minute, counting one inspiration and one expiration as one breath.	Normal respiratory rate is eupnea (see Table 15-1 for developmental impact on rate).	<ul style="list-style-type: none"> Bradypnea Tachypnea Apnea Cheyne-Stokes respirations 	<ul style="list-style-type: none"> A child's respiratory rate is higher than that of an adult's. Rely on both sight and touch to obtain an accurate respiratory rate. Neonates are sporadic breathers so short periods of apnea (less than 15 seconds) are expected.
Assess quality of breathing: determine regularity in timing. Assess depth of inspiration. Observe effort to breathe.	The I:E ratio is normally 1:2. The cycle of inspiration and expiration should be followed by a resting period in which the sensors of the respiratory system will initiate the next cycle. Normal breathing is referred to as eupnea.	<ul style="list-style-type: none"> Shortness of breath Dyspnea Orthopnea 	<ul style="list-style-type: none"> Infants and children have softer chest walls and depend more heavily on the diaphragm to breathe. Therefore, they exhibit what is known as "seesaw" breathing, an indicator of severe distress. In older adults, lifestyle choices such as smoking can affect the quality of breathing, as can the development of respiratory diseases.
Inspection of Thoracic Cavity			
Anteroposterior diameter is half the transverse diameter.	Normal ratio is 1:2. (See Figures 15-5 and 15-6 .)	<ul style="list-style-type: none"> Anteroposterior equals transverse thoracic diameter measurements, called a barrel chest. 	<ul style="list-style-type: none"> Rapid growth early in life, the plateau in young adulthood, and decline in later life can affect normal ratios.

Nursing Assessment ... Restructured for the Third Edition, this section covers everything the new nurse needs to know about assessing patients. It includes information on.

Observation and Patient Interview

Physical Examination

Diagnostic Tests

Independent Interventions ... Emphasizes interventions that nurses can perform on their own, without an order from the healthcare provider. Examples of subsections include:

- Prevent Infection
- Promote Safety
- Sleep Hygiene

Medications		
Antimicrobial Agents		
CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION	NURSING CONSIDERATIONS
Antibiotics <ul style="list-style-type: none"> ■ Amino-glycosides ■ Macrolides ■ Tetracyclines ■ Cephalosporins ■ Penicillins ■ Sulfonamides ■ Fluoroquinolones Drug examples: Cefactor, erythromycin, penicillin, tobramycin, trimethoprim-sulfamethoxazole	Antibiotics may be used prophylactically to prevent infection or used to treat existing bacterial infection. A specific antibiotic is chosen on the basis of the pathogen causing the infection.	<ul style="list-style-type: none"> ■ Teach patients the importance of taking the entire prescribed amount. ■ Encourage adequate fluid intake. ■ Monitor for signs of allergic reaction. ■ Assess renal and hepatic function and vital signs.
Antifungal Drug examples: Amphotericin B, anidulafungin, caspofungin acetate, flucytosine, micafungin, fluconazole, nystatin	These drugs are selective for fungal plasma membranes. They inhibit ergosterol synthesis.	<ul style="list-style-type: none"> ■ Carefully monitor the patient's condition. ■ Use cautiously in patients with renal impairment and severe bone marrow suppression as well as patients who are pregnant. ■ Closely monitor kidney function (intake and output, BUN, creatinine, daily weights). ■ Monitor serum electrolytes.
Antipyretic, Analgesic Drug example: Acetaminophen	These drugs relieve pain and reduce fever.	<ul style="list-style-type: none"> ■ Monitor temperature. ■ Assess pain level. ■ Teach proper administration.
Antipyretic, Analgesic, Anti-inflammatory Drug examples: Aspirin, ibuprofen	These drugs reduce fever and inflammation, in addition to relieving pain.	<ul style="list-style-type: none"> ■ Monitor temperature. ■ Assess pain level. ■ Teach proper administration.

Collaborative Therapies ... Each Concept includes an overview of relevant therapies that require collaboration with the interprofessional team. A Medications feature covers the most common drugs used to treat alterations. Examples of subsections include.

- Surgery
- Pharmacologic Therapy
- Nonpharmacologic Therapy
- Complementary Health Approaches

REVIEW The Concept of ... As in the Second Edition, each Concept ends with a review that includes linking questions, a list of relevant skills from Volume 3, and a short case study with questions so students can apply their knowledge.

REVIEW The Concept of Elimination

RELATE Link the Concepts

Linking the concept of elimination with the concept of infection:

1. What changes in urinary elimination indicate the presence of a UTI?
2. List the effects viral gastroenteritis has on bowel elimination.

Linking the concept of elimination with the concept of communication:

3. How can therapeutic communication be beneficial when assessing patients with urinary or bowel elimination problems?
4. Describe the importance of accurate documentation when caring for a hospitalized patient with urinary or bowel elimination problems.

READY Go to Volume 3: Clinical Nursing Skills

- SKILL 1.10 Abdomen: Assessing
- SKILL 2.25 Rectal Medication: Administering
- SKILLS 4.1–4.5 Elimination: Assessment—Collecting Specimens
- SKILLS 4.6–4.16 Elimination: Bladder Interventions
- SKILLS 4.17–4.23 Elimination: Bowel Interventions
- SKILLS 4.24–4.27 Elimination: Dialysis
- SKILL 6.1 Hand Hygiene: Performing

REFLECT Apply Your Knowledge

Tony Norwinski is a 7-year-old boy in the second grade. He and his 4-year-old sister, Nyla, live at home with their mother, Diane Norwinski.

Ms. Norwinski is a single parent who works in the cafeteria at the high school. Tony has a problem with wetting the bed occasionally and is too embarrassed to discuss it with anyone. Ms. Norwinski thinks Tony wets the bed because of emotional problems caused by his father leaving them when he was so young. Ms. Norwinski does not want to try anything new to help with the bedwetting because she is afraid it will cause Tony more embarrassment and emotional upset. They try not to talk about the bedwetting because Ms. Norwinski thinks it will make matters worse for Tony and prolong the problem.

Today, both children have an appointment for an annual physical examination with the nurse practitioner prior to starting the new school year. Tony is soft spoken and reserved when questioned about his general health. Ms. Norwinski is a good historian and offers complete answers about Tony's health history. The nurse notices the odor of urine on Tony's undergarments during the initial assessment. When questioned, Tony looks at his mother and does not answer. Ms. Norwinski looks away and does not answer right away. The nurse remains silent, waiting for a response to the questions.

After a period of silence, Ms. Norwinski reassures Tony and answers the nurse's questions about the odor. Though embarrassed, Tony appears to trust the nurse because he helps his mother explain about the bedwetting.

1. What therapeutic communication techniques could the nurse use to facilitate a full disclosure of the problem?
2. What are some questions the nurse could ask Tony and his mother to obtain the most pertinent information about Tony's situation? What nursing diagnosis would best describe the priority problem?
3. List four other possible nursing diagnoses the nurse may want to incorporate in the plan of care.

Structure and Features of the Exemplars

The structure of the Exemplars is picked up from the Second Edition. Note that each Exemplar has one main learning outcome with multiple enabling objectives.

Overview ... Sets the stage for the Exemplar and often includes information on the prevalence of the disorder.

Pathophysiology and Etiology ... Describes not only the pathophysiology and etiology of the disorder, but also risk factors and prevention methods.

Pathophysiology

Etiology

Risk Factors

Prevention

Clinical Manifestations and Therapies

Chronic Obstructive Pulmonary Disease

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Bronchitis	<ul style="list-style-type: none">Chronic cough with mucus productionDyspneaTachycardiaNarrowed airway passagesWheezingAir trapping	<ul style="list-style-type: none">Smoking cessationBronchodilatorsCorticosteroidsFluids to thin secretionsElevating the head of the bedLow-flow oxygenMonitoring of ABGs and oxygenMechanical ventilation if patient cannot meet oxygen demands
Emphysema	<ul style="list-style-type: none">Air trappingPossible wheezingDyspneaBarrel chestPursed-lip breathingPosturing	<ul style="list-style-type: none">Oxygen administration as neededPursed-lip breathing techniquePatient education of posture changes to improve ventilationLow-flow oxygenMonitoring of ABGs and oxygenMechanical ventilation if patient cannot meet oxygen demandsNutritional assessment and increased calorie intake
Cardiac dysfunction	<ul style="list-style-type: none">Chest painPoor perfusionArrhythmias, particularly premature ventricular contractionsHypertensionCardiac hypertrophyCongestive heart failure	<ul style="list-style-type: none">Medications:<ul style="list-style-type: none">a. Positive inotropicsb. Calcium blockersc. Antiarrhythmic medicationsd. Diureticse. Nitratesf. AntihypertensivesMonitoring of exercise toleranceHolter monitoringAntiembolism stockings to improve venous returnFluid restrictions if cardiac dysfunction not medically managed

Clinical Manifestations

... Includes information on clinical manifestations the nurse might see in a patient with the disorder. The Clinical Manifestations and Therapies feature is an excellent tool for review.

Collaboration ... Outlines interprofessional interventions and therapies appropriate for patients with the disorder.

Diagnostic Tests

Surgery

Pharmacologic Therapy

Nonpharmacologic Therapy

Complementary Health Approaches

Lifespan Considerations ... New to the Third Edition, all specifics relevant to the lifespan are gathered in one section. Lifespan Considerations are provided as appropriate for both Concepts and Exemplars. Examples of subsections include.

Considerations for Infants

Considerations for Children and Adolescents

Considerations for Pregnant Women

Considerations for Older Adults

Nursing Process ... A detailed look at the nursing process helps students put together all of the content in the exemplar and learn the essentials of providing care to patients with the disorder.

Assessment

Diagnosis

Planning

Implementation

Evaluation

REVIEW Exemplar ... As in the Second Edition, each exemplar ends with a Review that includes linking questions and a short case study with questions to help students apply their knowledge.

REVIEW Benign Prostatic Hyperplasia

RELATE Link the Concepts and Exemplars

Linking the exemplar of BPH with the concept of sexuality:

1. What communication strategies would the nurse use to discuss the impact BPH will have on sexuality without making an older man feel uncomfortable?
2. How can you assess his concerns, fears, and knowledge regarding the impact of BPH on his sexuality?

Linking the exemplar of BPH with the concept of infection:

3. What pathophysiology of BPH could increase the risk of UTIs?
4. What nursing interventions will reduce the risk of UTIs?

READY Go to Volume 3: Clinical Nursing Skills

REFER Go to Pearson MyLab Nursing and eText

- Additional review materials

REFLECT Apply Your Knowledge

Clifford Allen is a middle manager for a small manufacturing company where he has worked for the last 20 years. Overall, Mr. Allen is in good health, although he has been undergoing treatment recently for BPH. He has a history of depression, for which he does not seek treatment because he fears the social stigma connected to the diagnosis. Mr. Allen has been considering retiring within the next few years so he and his wife can travel, but mostly to escape his stressful work environment. He enjoys bowling and is involved in activities at church. He and his wife go for a walk each evening after supper.

One evening while bowling, he notices that his bladder feels somewhat full. Mr. Allen calls to make an appointment to see his urologist for a follow-up examination. He has been taking finasteride (Proscar) for the last 6 months but does not believe it has been particularly effective. He still has trouble urinating and believes that his symptoms are worse than before he started taking the drug. When he sees the urologist 2 weeks later, he reports that he often feels his bladder is full after voiding, he has difficulty starting his stream of urine, and his stream is weak once started. He gets up frequently at night to void. His score on the AUASI is 28, which has increased from his score of 18 six months ago. The urologist confirms that the medication has not been effective and schedules further tests, including uroflowmetry, check postvoid residual, a PSA blood test, and a urinalysis. Results from the uroflowmetry and postvoid residual test show a significant obstruction of urinary flow. The serum PSA is negative, and the urinalysis is consistent with bladder inflammation. A TURP is recommended in the upcoming weeks.

1. To determine Mr. Allen's understanding of the procedure, what will the nurse want to ask him upon admission to the surgical center?
2. What teaching will the nurse prepare regarding postoperative self-care?
3. Design a nursing plan of care for this patient postoperatively.

Additional Features

Additional features found throughout the program include numbered tables, figures, and boxes that contain content presented in visual formats, and the following highlighted features: Safety Alert, Stay Current, Evidence-Based Practice, Nursing Care Plan, Focus on Diversity and Culture, and Focus on Integrative Health.

Nursing Care Plan

A Patient with Asthma

Sarah Mitchell is a 35-year-old working mother with moderate persistent asthma. Her known triggers are allergies to dust mites, cockroach feces, grass and tree pollens, and some molds. She takes immunotherapy once a week and takes maintenance medications daily. She works as a full-time preschool teacher.

Ms. Mitchell calls her allergist's office asking to be seen because she is having a bad asthma flare. She reports having to use her rescue inhaler every 3–4 hours, that her chest is very tight, and that she is having trouble breathing. She has used her home peak flow meter three times since late yesterday and has been in the yellow zone each time. She did not sleep last night because of her asthma symptoms.

ASSESSMENT	DIAGNOSES	PLANNING
<p>The nurse, Clancy O'Hara, admits Ms. Mitchell when she arrives at the allergist's office. During the health history Ms. Mitchell confirms she is compliant with her medication regimen. She takes a LABA in combination with a low-dose corticosteroid, a daily antihistamine, and montelukast. In checking Ms. Mitchell's medical record, Nurse O'Hara notes that the patient is maintaining her scheduled immunotherapy appointments. Ms. Mitchell reports that she is not aware of any unusual allergy exposure but says that several of her students have a cold this week.</p> <p>On physical examination, Nurse O'Hara notes that Ms. Mitchell's vital signs are as follows: T 37°C (98.6°F); P 96 bpm; R 36/min; BP 128/86 mmHg. Other assessment data include needing to pause frequently while speaking, use of accessory muscles for respirations, and scattered wheezes audible over both lung fields with stethoscope. ABG results are pH 7.32, PaO₂ 88 mmHg, PaCO₂ 47 mmHg, and HCO₃⁻ 38 mEq/L. Pulses are strong and equal bilaterally, and the patient expectorates a small amount of white mucus into a tissue.</p>	<ul style="list-style-type: none">■ <i>Ineffective Breathing Pattern</i> related to exacerbation of asthma■ <i>Impaired Gas Exchange</i> related to bronchoconstriction and mucus in airways■ <i>Fatigue</i> related to ineffective sleep pattern■ <i>Activity Intolerance</i> related to inadequate oxygenation <p>(NANDA-I © 2014)</p>	<p>Together Nurse O'Hare and Ms. Mitchell agree on the following outcomes:</p> <ul style="list-style-type: none">■ The patient's breathing will return to the green zone within 24 hours.■ The patient's need for her rescue inhaler will decline within 3 days and return to baseline within 1 week.■ The patient will maintain baseline respiratory rate and pattern sufficient to meet her ADLs within

IMPLEMENTATION

Ms. Mitchell's provider prescribes a higher-dose inhaled steroid to use 10–15 minutes after she uses her LABA. The provider also gives Ms. Mitchell a short, tapered course of prednisone. Ms. O'Hare initiates the following implementations:

- Teaches Ms. Mitchell how to properly self-administer medications and about possible side effects associated with steroid use, including those that should be reported immediately
- Explains the importance of taking the steroid as ordered and not stopping the medication suddenly
- Provides strategies for managing fatigue, including a handout with written instructions

- Teaches Ms. Mitchell hydration in a
- Observes Ms.
- Reviews signs and instructs
- Schedules M evaluation bu or if she sees

Many exemplars contain **Nursing Care Plans**, and additional ones can be found in the Pearson eText in MyLab Nursing. The Nursing Care Plans follow the nursing process with sections on assessment, diagnosis, planning, implementation, and evaluation. They end with a series of Critical Thinking questions.

The **Multisystem Effects** features have been redesigned for the Third Edition. Each one highlights the effects that a disorder has on various systems of the body.

Multisystem Effects of Cystic Fibrosis

Respiratory

- Viscous, sticky mucus
- Respiratory infections
- Chronic cough
- Chronic sinusitis
- Bronchiectasis
- Pneumonia
- Cysts
- Fibrosis
- Pneumothorax

Neurologic

- Depression
- Anxiety

Cardiovascular

- Clubbing of fingers and toes
- Cyanosis

Reproductive

- Delayed puberty
- Blockage or absence of vas deferens
- Decreased fertility (men and women)
- Pregnancy complications

Integumentary

- Salty skin

Metabolic Processes

- Diabetes

Musculoskeletal

- Delayed growth and development
- Osteopenia
- Osteoporosis
- Fractures

Gastrointestinal

- Chronic diarrhea
- Nutritional deficiencies
- Obstructed pancreatic ducts
- Blocked bile ducts
- Gallstones
- Abdominal pain
- Bowel obstruction/intussusception

Focus on Integrative Health Chronic Obstructive Pulmonary Disease

Complementary health approaches may be useful to help manage symptoms of COPD. Dietary measures, such as minimizing intake of dairy products and salt, may help reduce mucus production and keep mucus more liquefied. Be sure to recommend measures to replace the protein and calcium in dairy products to help maintain nutritional balance. Hot herbal teas with peppermint may act as expectorants to help relieve congestion. Patients may be interested in trying complementary health approaches to assist them in quitting smoking. While additional studies are needed to evaluate the effectiveness of complementary health approaches for use in quitting smoking, current research suggests that acupuncture and hypnotherapy may be effective in promoting smoking cessation (Tahiri et al., 2012). Likewise, Hasan et al. (2014) found that hypnotherapy may be more effective than NRT for promotion of smoking cessation.

Focus on Diversity and Culture Assessing for Cyanosis

When assessing for cyanosis, normal assessment findings vary depending on the individual's normal skin tones. For example, in a white or light-skinned individual, cyanosis due to hypoxemia most often manifests as a bluish discoloration of the lips, oral mucosa, and nail beds. Among dark-skinned individuals, cyanosis may be difficult to detect and may actually cause the skin to appear darker. Typical manifestations of cyanosis in dark-skinned individuals include pallor or an ash-gray discoloration of the skin surrounding the mouth. Conjunctivae appear gray or blue-tinged among dark-skinned individuals. Among patients whose normal skin tone is yellowish, cyanosis may manifest as a gray-green skin discoloration (Sommers, 2011).

For the most part, care of patients from different cultures is covered in the basal text. **Focus on Diversity and Culture** features are used only for unique situations of which the nurse should be aware.

Focus on Integrative Health boxes highlight the use of complementary health approaches in addition to traditional nursing practice.

SAFETY ALERT Chronic cough and sputum are not normal occurrences. An individual experiencing chronic cough and sputum beyond 3–4 days should consult with a healthcare professional. Individuals with a smoking history as well as chronic cough and sputum production should have PFTs to determine lung function.

Each **Safety Alert** provides critical information the nurse needs to know to keep patients and staff safe.

» **Stay Current:** Visit the Safe to Sleep website at <https://www.nichd.nih.gov/sts/Pages/default.aspx> to learn more about SIDS prevention.

The **Stay Current** feature provides a weblink (which is a hot link in the eText) to a website that will keep students informed on the most recent updates.

The goal of the **Evidence-Based Practice** features is to show students the necessity of evidence driving practice. Each starts with a problem, delves into the research, presents implications for the nurse, and ends with critical thinking questions for the student.

Evidence-Based Practice Compliance with Safe to Sleep Recommendations

Problem

Compared to previous recommendations for preventing SIDS, current recommendations are more complex. For example, the Safe to Sleep guidelines address not only infant positioning but also maintaining a safe sleep environment and abstaining from co-sleeping (bed sharing). The increased complexity of the recommendations may lead to decreased parental compliance with current guidelines for the prevention of SIDS (Goodstein, Bell, & Krugman, 2015).

Evidence

The Safe to Sleep recommendations include supine positioning during sleep, using a firm sleep surface, breastfeeding, room sharing without co-sleeping, routine immunizations, and the use of a pacifier. Items that should be avoided include soft bedding, toys, layered clothing, and crib bumpers (USDHHS, 2015). Research suggests that parental adherence to current recommendations for the prevention of SIDS is significantly increased when nurses model the behaviors that are reflective of all current guidelines for preventing SIDS and obtain parental signatures on a document acknowledging receipt of education related to current guidelines (Goodstein et al., 2015).

Implications

Nurses should demonstrate endorsement of all current recommendations for reducing SIDS-related deaths, including modeling and implementing all recommendations as soon as the infant is clinically stable and up to discharge. Nurses working with parents of newborns must provide additional patient teaching and follow-up, as well as ensuring that parents understand the teaching. All parents should receive documented education on safe infant sleep practices, including voluntary acknowledgement forms indicating that education has been provided with regard to the specific current guidelines (Goodstein et al., 2015).

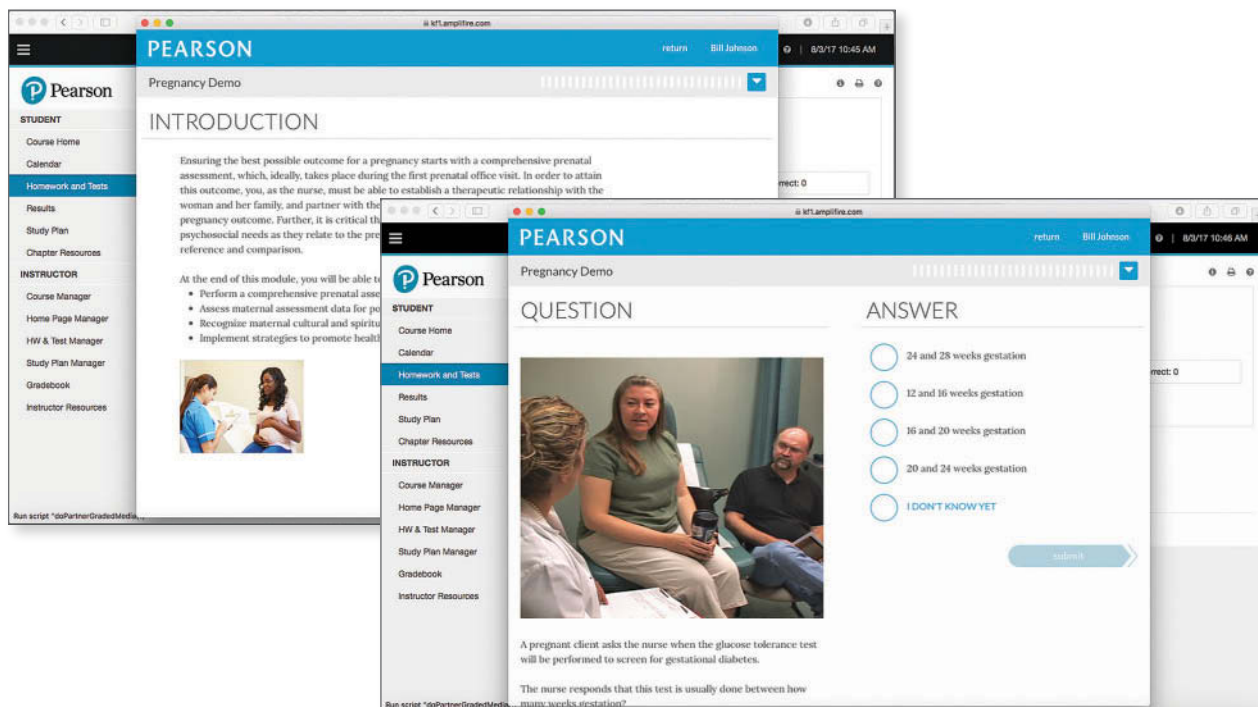

Critical Thinking Application

1. Identify barriers to educating parents and caregivers about current recommendations for preventing sleep-associated deaths.
2. Describe methods for evaluating parental understanding of the current guidelines for prevention of SIDS.

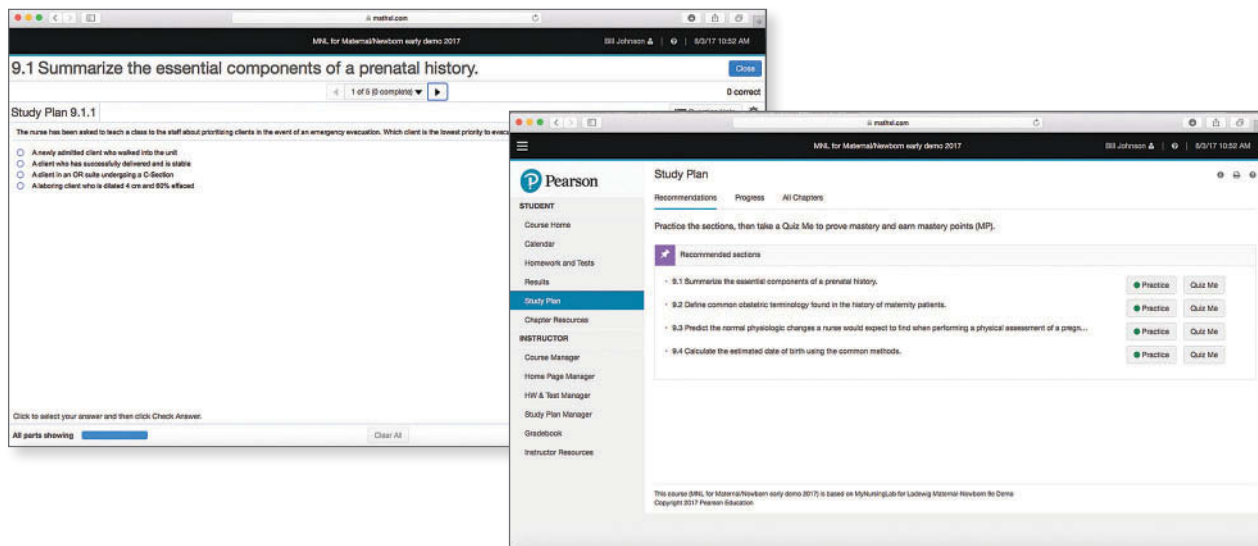

MyLab Nursing

MyLab Nursing is an online learning and practice environment that works with the text to help students master key concepts, prepare for the NCLEX-RN exam, and develop clinical reasoning skills. Through a new mobile experience, students can study *Nursing: A Concept-Based Approach to Learning* anytime, anywhere. New adaptive technology with remediation personalizes learning, moving students beyond memorization to true understanding and application of the content. MyLab Nursing contains the following features:

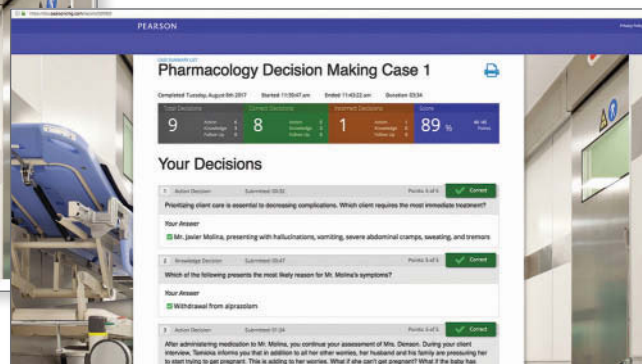

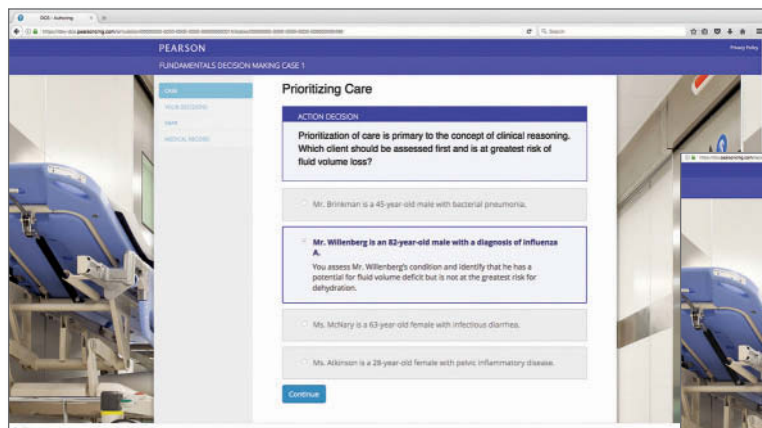

Dynamic Study Modules ... New adaptive learning modules with remediation that personalize the learning experience by allowing students to increase both their confidence and their performance while being assessed in real time.

NCLEX-Style Questions ... Practice tests with more than 3000 NCLEX-style questions of various types build student confidence and prepare them for success on the NCLEX-RN exam. Questions are organized by Concept and Exemplar.

Decision Making Cases ... Clinical case studies that provide opportunities for students to practice analyzing information and making important decisions at key moments in patient care scenarios. These case studies are designed to help prepare students for clinical practice.

Pearson eText ... Enhances student learning both in and outside the classroom. Students can take notes, highlight, and bookmark important content, or engage with interactive and rich media to achieve greater conceptual understanding of the Concepts and their Exemplars. Interactive features include audio clips, pop-up definitions, figures, questions and answers, the nursing process, hotspots, and video animations. Some examples of video animations include:

- **Fluid and Electrolyte Animations** provide students with the necessary information about the balance and imbalance of fluids and electrolytes to think, reason, and make clinical judgments.

- **Congenital Heart Defect Animations** illustrate the many congenital heart defects that may occur in newborns and provide students the opportunity to see, hear, and understand how congenital heart defects impair the correct functioning of the heart and how they may be corrected.

Concept Connections in Nursing app—available through the App store or Google Play

Comprehensive Review for NCLEX-RN app—9780134376325

RealEHRprep with iCare

The image displays two screenshots of the RealEHRprep with iCare software. The left screenshot shows a 'Homework: Case Study: Chest Pain & MI (John Lockhart)' interface. It includes a 'CASE SCENARIO' section with a detailed medical history of John Lockhart, a 45-year-old Caucasian male. Below the scenario are 'DIRECTIONS' for the user to follow, such as opening the patient's EHR, searching for the patient, and selecting the medical record. A 'WARNING: DO NOT CHART IN JOHN LOCKHART'S RECORD.' is also present. The right screenshot shows the iCare EHR interface for a patient named Allen, Clifford. It features a navigation bar with tabs like 'Procedures', 'Reports', 'Consults', 'Patient Info', 'Vitals', 'H&T Message', 'Reminders', and 'Cover Sheet'. The main area is divided into several sections: 'VITALS' (Temperature, Pulse, Respiration, Blood Pressure, Pain), 'CLINICAL REMINDERS', 'ACTIVE PROBLEMS', 'ACTIVE MEDICATIONS' (Dextrose 5% with 0.45% NaCl, Insulin), 'APPOINTMENTS/VISITS/ADMISSIONS' (General Surgery), 'ALLERGIES/ADVERSE REACTIONS', 'RECENT LAB RESULTS', and 'POSTING'.

Neighborhood 2.0

The image displays two screenshots of 'The Neighborhood 2.0' software. The left screenshot shows a character profile for Rachel, a 38-year-old Hispanic woman. It includes a photo of her, a brief biography, and a 'Neighborhood Connection' section. The right screenshot shows the main 'EXPLORE THE NEIGHBORHOOD' interface. It features a grid of character portraits organized by family or group, including the Allen family (Clifford, Pam, Gary), the Bley family (Jimmy, Cecelia, Norma), the Johnson family (Yvonne, Randall), the Martin & Ames family (Gilbert, Helen, Mary, Anthony, Kristina, Tracie), the Ocampo family (Danilo, Lydia), the Reyes family (Angelo, Rachel), the Riley family (Evelyn, Jenna, Jason), the Riley & Holmes family (Jessica, Casey, Ryan), the Ross & Jaramillo family (Greg, Benito), and the Young family. On the right side, there are icons for various community locations: 'HEALTH CONNECTIONS CLINIC', 'HOSPITAL', 'PUBLIC SCHOOL', and 'SENIOR CENTER'.

Acknowledgments

We would like to extend our heartfelt thanks to more than 80 instructors from schools of nursing across the country who have given their time generously during the past few years to help us create this concept-based learning package. The talented faculty on our Concepts Editorial Board and all of the Contributors and Reviewers helped us to develop this Third Edition through a variety of contributions and by answering myriad questions right up to the time of publication. *Nursing: A Concept-Based Approach to Learning*, Third Edition, has benefited immeasurably from their efforts, insights, suggestions, objections, encouragement, and inspiration, as well as from their vast experience as faculty and practicing nurses.

We would like to thank the editorial team, especially Julie Alexander, Publisher, for her continuous support

throughout this process; Katrin Beacom, Director of Portfolio Management for championing this project; Erin Sullivan, the editorial assistant for helping to keep all the balls in the air; Bianca Sepulveda and Melissa Bashe for keeping us organized and putting together all of the components of the concepts program; and most of all, Laura Horowitz and Addy McCulloch, development editors, for their dedication and attention to detail that promoted an excellent outcome once again. Special thanks to the design team, led by Mary Siener, and Studio Montage for the thoughtful and integrated design of our concepts solution. Many thanks to Kelly Ricci and the Aptara team for producing this book with precision.

Part II

Psychosocial Modules

Part II consists of the psychosocial modules within the individual domain. Each module presents a concept that directly relates to sociologic or psychologic domains that impact patient health and well-being—such as cognition, family, and stress and coping—and selected alterations of that concept presented as

exemplars. In the concept of cognition, for example, exemplars include Alzheimer disease, confusion, and schizophrenia. Each module addresses the impact of that concept and selected alterations on individuals across the lifespan, inclusive of cultural, gender, and developmental considerations.

Module 22	Addiction	1647
Module 23	Cognition	1705
Module 24	Culture and Diversity	1765
Module 25	Development	1785
Module 26	Family	1851
Module 27	Grief and Loss	1883

Module 28	Mood and Affect	1909
Module 29	Self	1975
Module 30	Spirituality	2023
Module 31	Stress and Coping	2047
Module 32	Trauma	2105

Module 22

Addiction

Module Outline and Learning Outcomes

The Concept of Addiction

Addiction

22.1 Summarize the processes involved in addiction.

Manifestations of Substance Use Disorders

22.2 Summarize manifestations of substance use disorders.

Concepts Related to Addiction

22.3 Outline the relationship between addiction and other concepts.

Health Promotion

22.4 Outline health promotion activities to reduce the risk for substance abuse and relapse.

Nursing Assessment

22.5 Differentiate common assessment procedures and tests used to examine individuals suspected of abusing a substance.

Independent Interventions

22.6 Analyze independent interventions nurses can implement for patients with substance use disorders.

Collaborative Therapies

22.7 Summarize collaborative therapies used by interprofessional teams for patients with substance use disorders.

Lifespan Considerations

22.8 Differentiate considerations related to the assessment and care of patients throughout the lifespan who abuse substances.

Addiction Exemplars

Exemplar 22.A Alcohol Abuse

22.A Analyze manifestations and treatment considerations for patients who abuse alcohol.

Exemplar 22.B Nicotine Use

22.B Analyze manifestations and treatment considerations for patients with an addiction to nicotine.

Exemplar 22.C Substance Abuse

22.C Analyze manifestations and treatment considerations for patients who abuse substances.

Codependence, 1651		Milieu therapy, 1661		Tolerance, 1648

Addiction is defined as a psychologic or physical need for a substance (such as alcohol) or process (such as gambling) to the extent that the individual will risk negative consequences in an attempt to meet the need. Many individuals use substances recreationally to modify mood or behavior, and there are wide sociocultural variations in the acceptability of chemical use. Prescription medications include narcotics, sedatives, and stimulants

and are dangerous when misused or abused. Illegal drugs include cocaine (including crack), heroin, hallucinogens, and inhalants. Marijuana/hashish use is illegal in many states. An individual may abuse any of these substances to the point of becoming addicted and unable to stop, despite dangerous, often life-threatening consequences. An individual who uses one or more substances to this extent may be diagnosed with a **substance use disorder**.

Substance use disorders (SUDs) are divided into one of two categories: the SUD itself and substance-induced disorders. The substance use disorder category covers the actual addictive process to a substance, such as alcohol or opiates. The substance-induced disorder grouping includes related conditions such as intoxication, withdrawal, and substance/medication-related mental disorders, such as psychosis, bipolar and related disorders, sleep disorders, sexual dysfunction, and others (American Psychiatric Association, 2013). Nursing interventions include providing acute care for patients with substance-induced disorders who are experiencing intoxication or withdrawal; educating patients and their family members about the disorder; and supporting recovery and abstinence in community-based programs.

The etiology of addiction is multifaceted. Childhood trauma, genetic variabilities, and other considerations are thought to play a role. Regardless of the reasons or etiology behind addiction, it can have grave consequences for both individuals and those who care for them.

The Surgeon General released a report in 2016 that stated:

Historically, our society has treated addiction and misuse of alcohol and drugs as symptoms of moral weakness or as a willful rejection of societal norms, and these problems have been addressed primarily through the criminal justice system. Our health care system has not given the same level of attention to substance use disorders as it has to other health concerns that affect similar numbers of people. Substance use disorder treatment in the United States remains largely segregated from the rest of health care and serves only a fraction of those in need of treatment (Surgeon General, 2016, Executive Summary).

Nurses can play a role in prevention, education, and treatment of substance abuse and addiction.

Addiction

Addictive processes create cognitive, behavioral, and physiologic symptoms. The term *addiction* needs to be differentiated from dependence. **Dependence** is a physiologic need for a substance that the patient cannot control and that results in withdrawal symptoms if the drug or substance is stopped or withheld. Dependence on a substance also causes the user to develop a physiologic **tolerance** for the substance, requiring greater quantities of the substance to achieve the same pleasurable effects. In addition to physiologic symptoms, addiction also includes a psychologic need that causes affected individuals to seek the substance to which they are addicted—at any cost. Individuals with substance use disorders (often referred to as “addicts”) may neglect their children, their work, or other responsibilities to meet their physiologic and psychologic needs.

Physiology and Psychology of Addiction

Various factors help explain why one person becomes addicted while another does not. The biopsychosocial model theorized by psychiatrist George L. Engel has been generally accepted as the most comprehensive theory for the process

of addiction. Clinicians use his model as a foundation to link biological, genetic, psychologic, emotional, and sociocultural factors contributing to the development of addiction.

Biological Factors

E. Morton Jellinek (1946) first identified biological factors in his disease model of alcoholism. He hypothesized that addiction to alcohol had a biochemical basis and identified specific phases of the disease. Expanding on Jellinek’s early work, researchers implicated low levels of dopamine and serotonin in the development of alcohol dependence (Czermak et al., 2004; Nellissery et al., 2003). More recent clinical studies have continued to confirm this finding (Kash, 2012).

Dopamine, dopamine receptor sites, and transporters, which recycle the neurotransmitter and cut off communication between neurons, are all intricately involved in the complex workings between the nervous system and substances of abuse (National Institute on Drug Abuse [NIDA], 2014a). Dopamine is a neurotransmitter present in regions of the brain that regulate movement, emotion, motivation, and feelings of pleasure. The limbic system, which links together a number of brain structures, contains the brain’s reward circuit. The limbic system controls and regulates the ability to feel pleasure and mediates perception of other emotions, which helps to explain the mood-altering properties of many substances (NIDA, 2014a). When activated at normal levels, this system rewards natural human behaviors.

Overstimulating the reward system with drugs produces euphoric effects, which strongly reinforce the behavior of drug use (NIDA, 2014a). Most drugs that impact the biochemical mechanism of the brain affect one or more receptor sites (**Figure 22-1** »). Most abused substances mimic or block the brain’s most important neurotransmitters at these respective receptor sites. For example, heroin and other opiates mimic natural opiate-like neurotransmitters, such as endorphins. Cocaine and other stimulants block the reuptake of dopamine, serotonin, and norepinephrine, which causes the neurons to release abnormally large amounts of natural neurotransmitters or interferes with the normal reuptake of these neurotransmitters. These imbalances produce greatly amplified signals in the brain, ultimately permanently altering or disrupting neurons and neural pathways (NIDA, 2014a).

Whenever the reward circuit is activated, the brain encodes a memory, which encourages the individual to perform the same pleasurable act—or take the pleasurable substance—again and again. The reward experienced by the individual using the substance can be significant: For instance, cocaine can cause the release of 2 to 10 times the amount of dopamine released by eating or sexual intercourse (NIDA, 2014a). Neurobiological research into addiction postulates that addiction is the result of an increase in focus on a particular addictive behavior with a corresponding gradual loss of interest in other activities. The mesolimbic dopaminergic system is believed to play an important role in the search for rewarding stimuli, with a resulting increase in dopamine when the stimulus is received. Particular areas in the brain define something as pleasure. When these areas are stimulated as a result of addiction, the level of need for the substance or behavior is increased.

Other biological factors involved in addiction include other medical conditions and the individual’s stage of development.

Figure 22-1 ➤ Action of abused substances at brain receptor sites.

Mental disorders such as anxiety, depression, and schizophrenia may precede addiction; in other cases, drug abuse may trigger or exacerbate those mental disorders, particularly in people with specific vulnerabilities (NIDA, 2014a).

During adolescence, the prefrontal cortex—the part of the brain that helps individuals to assess situations, make sound decisions, and moderate emotions and impulses—is still developing. Thus, adolescents are at risk for making poor decisions about trying drugs or continuing to take them. Also, introducing drugs during this period of development may cause brain changes that have profound and long-lasting consequences (NIDA, 2014a). Abusing drugs during adolescence can interfere with meeting crucial social and developmental milestones and also compromise cognitive development. For example, heavy marijuana use in the teen years may cause a loss of several IQ points that are not regained even if users later quit in adulthood (NIDA, 2014e).

Genetic Factors

Genetic factors include an apparent hereditary factor that affects alcohol use and dependence. A link has been found between addiction and impulse control, although it is not fully understood. As stated earlier, addiction is strongly linked to the dopaminergic system of the brain's reward system. The speed with which someone becomes addicted depends on the substance, the frequency of use, the means of ingestion, the intensity of the high the person obtains, and the person's genetic and psychologic susceptibility. Adequate proof exists that addiction is, at least in part, genetically moderated. Researchers estimate that genetic factors account for between 40 and 60% of an individual's

vulnerability to addiction, a statistic that also accounts for the effects of environmental factors on the function and expression of a person's genes (NIDA, 2014a). Several genes have been identified that seem to influence the risk for alcohol dependence (Foroud & Phillips, 2012).

Psychologic Factors

No addictive personality type has been identified; however, several common factors seem to exist among alcoholics and drug users. Many individuals with substance use disorders experienced sexual or physical abuse in their childhood and, as a result, experience anxiety, low self-esteem, and difficulty expressing emotions. Research indicates a high correlation among substance use and childhood and adolescent trauma (NIDA, 2014a, 2014e). Therapist Peter Bernstein (2013) states "The vast majority of people with substance abuse problems have a traumatic past" (p. 16).

A link also exists between substance abuse and psychiatric disorders such as depression, bipolar disorder, anxiety, and antisocial and dependent personalities. The habit of using a substance becomes a form of self-medication to cope with day-to-day problems and develops into an addiction over time.

The pleasure model, proposed by Nils Bejerot, views addiction as an emotional fixation acquired through learning that is aimed at obtaining pleasure and avoiding discomfort. If the pleasure (euphoria) that results is sufficiently strong, it induces repetition and overcomes the person's natural drive, resulting in addiction. This model is the basis of zero tolerance for drugs as a prevention strategy.

Sociocultural Factors

Sociocultural factors are thought to play a strong role in the development of and tolerance for an addiction. Sociocultural factors often influence individuals' decisions as to when, what, and how they use substances. The way drugs are processed, the degree of acceptance or rejection of drug use, and an individual's financial resources influence what substance is used, how much is used, and what peer pressure the individual will face in his or her culture as the abuse becomes evident.

Family environment can increase a child's risk for developing addictive behaviors as an adolescent or adult. Parents or older family members who abuse alcohol or drugs or engage in criminal behavior can increase adolescents' risks of developing drug problems. Violence, physical and emotional abuse, and mental illness in the household also increase this risk (NIDA, 2014a, 2014e). Other factors include the availability of drugs within the neighborhood, community, and school and whether the adolescent's friends are using them (NIDA, 2014e). Academic failure or poor social skills can put a child at further risk for using or becoming addicted to drugs. Other factors predicting addiction are early use of substances and smoking a drug or injecting the substance into a vein, which increases its addictive potential. Smoked or injected drugs enter the brain within seconds and produce a powerful pleasure effect (NIDA, 2014a).

Sociocultural factors such as personality and religion/spirituality appear to play a part in the risk profile for developing alcoholism in that interest in religion/spirituality

practices have been correlated with lower alcohol use (Holt et al., 2015).

Research indicates that lesbian and bisexual women are at greater risk for alcohol and drug use disorders, whereas gay and bisexual men are at greater risk for illicit drug use. Affiliation with the gay culture and HIV status are correlated with increased substance abuse (Green & Feinstein, 2012).

Many factors place an individual at risk for substance use, abuse, and dependence. No single cause can explain why one individual develops a pattern of drug use and another person does not.

Manifestations of Substance Use Disorders

Specific behavioral and physiologic manifestations of substance use vary by substance. An overview of these manifestations and treatment options is provided in the Alterations and Therapies feature; further details can be found in the

exemplars for this module. Most individuals who abuse substances for more than a few weeks begin to experience an array of health and emotional problems. They face increased risk for comorbid illness and family complications. It is helpful to nurses and practitioners working with this patient population to understand the prevalence of substance use in this country as well as the language of addiction and recovery.

Prevalence

Substance abuse in the United States is so common that very few people are unaffected by it.

- In 2015, more than 27 million Americans reported the current use of illicit drugs or misuse of prescription drugs (Surgeon General, 2016).
- In 2015, 66 million Americans reported binge drinking within the past month, which is almost one quarter of the adolescent and adult population (Surgeon General, 2016).

Alterations and Therapies

Addictions

ALTERATION	DESCRIPTION	TREATMENT
Nicotine addiction	Addiction to nicotine can result from smoking tobacco in the form of cigarettes, cigars, or pipes as well as from chewing tobacco.	<ul style="list-style-type: none"> ■ Medications (e.g., bupropion [Zyban] and varenicline tartrate [Chantix]) ■ Nicotine replacement treatments (NRTs; e.g., nicotine gum/spray and the transdermal nicotine patch) ■ Behavior therapy ■ Support groups
Alcohol addiction	Chronic use of alcohol can lead to addiction, resulting in delirium tremens (DTs) if alcohol is not consumed.	<ul style="list-style-type: none"> ■ Medications (e.g., disulfiram [Antabuse]) ■ Behavioral therapy ■ Support groups ■ 12-step program (e.g., Alcoholics Anonymous [AA]) ■ Detoxification ■ Milieu therapy ■ Family therapy
Substance addiction	Substance addiction may include abuse of heroin, cocaine, marijuana, crack, narcotics, barbiturates, inhalants, or any chemical substance that leads to addiction.	<ul style="list-style-type: none"> ■ Behavior therapy ■ Support groups ■ Detoxification ■ Pharmacologic therapy, which may be required to minimize complications from withdrawal ■ Removal of peers providing substance ■ Milieu therapy ■ 12-step programs (e.g., Narcotics Anonymous [NA]) ■ Family therapy
Process addictions (sex, gambling, shopping, work)	Process addictions are those behaviors compulsively performed to reduce anxiety; they are considered by some to be a form of obsessive-compulsive disorder.	<ul style="list-style-type: none"> ■ Psychotherapy ■ Behavior therapy ■ Milieu therapy ■ Support groups ■ 12-step programs (e.g., Gamblers Anonymous) ■ Family therapy

TABLE 22–1 Terminology Associated with Substance Abuse

Term	Definition
Abstinence	Voluntarily going without drugs or alcohol
Codependence	A cluster of maladaptive behaviors exhibited by significant others of a substance-abusing individual that serves to enable and protect the abuse at the expense of living a full and satisfying life
Co-occurring disorders	Concurrent diagnosis of a substance use disorder and a psychiatric disorder; one disorder can precede and cause the other, such as the theorized relationship between alcoholism and depression
Cross-tolerance	Tolerance to one drug conferring tolerance to another drug
Delirium tremens (DTs)	A medical emergency usually occurring 3–5 days following alcohol withdrawal and lasting 2–3 days; characterized by paranoia, disorientation, delusions, visual hallucinations, elevated vital signs, vomiting, diarrhea, and diaphoresis; also known as alcohol withdrawal delirium
Detoxification	The process of helping an addicted individual safely through withdrawal; commonly referred to as detox
Dual diagnosis	The coexistence of substance abuse/dependence and a psychiatric disorder in one individual (used interchangeably with dual disorder and co-occurring disorders)
Korsakoff psychosis	Secondary dementia caused by thiamine (B ₁) deficiency that may be associated with chronic alcoholism; characterized by progressive cognitive deterioration, confabulation, peripheral neuropathy, and myopathy
Physical dependence	A state in which withdrawal syndrome will occur if drug use is discontinued
Polysubstance abuse	The simultaneous use of many substances
Psychologic dependence	An intensive, subjective need for a particular psychoactive drug
Sobriety	The state of habitually refraining from using alcohol or drugs
Tolerance	A state in which a particular dose elicits a smaller response than it formerly did; with increased tolerance, the individual needs higher and higher doses to obtain the desired response
Wernicke encephalopathy	Neurologic symptoms caused by biochemical lesions of the central nervous system after exhaustion of B-vitamin reserves, especially thiamine (vitamin B ₁); symptoms often include ophthalmoplegia (abnormal eye movements), ataxia, and confusion
Withdrawal syndrome	A constellation of signs and symptoms that occurs in physically dependent individuals when they discontinue drug use

- Abuse of tobacco, alcohol, and illicit drugs is costly; in the United States, the costs related to crime, lost work productivity, and healthcare are estimated to be \$249 billion annually for alcohol misuse and \$193 billion annually for illicit drug use (Surgeon General, 2016).
- In 2014, 1.5 million people (0.6% of the population) age 12 or older were current users of cocaine; this figure included about 354,000 current users of crack (Center for Behavioral Health Statistics and Quality [CBHSQ], 2015).
- In 2014, an estimated 22.2 million Americans (8.4% of the population) age 12 or older were current users of marijuana. This represented an increase of 5.8% since 2007 (CBHSQ, 2015). The increase is likely due to the decriminalization and commercial sale of marijuana in several states.
- In 2014, about 435,000 people (0.2% of the population) age 12 or older were current heroin users (CBHSQ, 2015). Heroin has continued to grow as a drug of choice, and heroin-related overdose deaths increased fourfold between 2002 and 2013 (Centers for Disease Control and Prevention [CDC], 2015e).

These statistics only scratch the surface of the number of people dealing with addiction. These figures in combination with figures related to process addictions demonstrate the need for nurses to understand, recognize, and be able to screen patients for past and present addictions and behaviors.

The Language of Addiction and Recovery

The process of addiction and recovery has its own vocabulary. These terms are used by professionals from all aspects

of healthcare who work with substance-abusing patients and their families. Many of these terms are appropriate regardless of the substance or process being abused. See **Table 22–1** » for a list of some of these terms and their definitions.

Comorbidities

Substance abuse has a high rate of morbidity with both physical and mental illness (see the Concepts Related to Addiction feature). Imaging scans, chest x-rays, and blood tests show the damaging effects of drug abuse throughout the body. For example, tests show that tobacco smoke causes cancer of the mouth, throat, larynx, blood, lungs, stomach, pancreas, kidney, bladder, and cervix. Some drugs of abuse, such as inhalants, are toxic to nerve cells and may damage or destroy them either in the brain or in the peripheral nervous system.

Medical illnesses can be promoted or exacerbated by neglect of one's health and lack of preventive healthcare. Immunity is often compromised by malnutrition, poor hygiene, and risky behaviors related to addiction. Some infectious diseases, such as hepatitis A, B, and C, HIV and AIDS, and tuberculosis, are transmitted by substance abuse, either directly or indirectly. Adverse central nervous system (CNS) effects are seen in manifestations of substance dependence, tolerance, craving, and withdrawal. Addiction behaviors affect the mental health and physical health of the addicted patient as well as the patient's family.

Individuals who abuse substances have a higher incidence of mental health disorders than the general population. Among the 20.7 million adults in the United States who experienced a substance use disorder in 2014, 40.7%—8.4 million adults—had a co-occurring mental illness (CBHSQ, 2015).

The depression that may be a part of the addiction process itself must be differentiated from a diagnosable mental illness. Because substance use disorder often co-occurs with other mental illnesses, patients presenting with one condition should be assessed for the other.

Individuals who abuse substances also commonly present with numerous social problems, ranging from dysfunctional family relationships to under- or unemployment or homelessness. Because of the scope of problems associated with chronic substance abuse and the staggering impact of untreated behavioral health conditions on individuals' lives and the cost of healthcare delivery, the Substance Abuse and Mental Health Services Administration (SAMHSA), the federal agency that spearheads the nation's behavioral health public health efforts, supports *integrative* care of co-occurring mental health and substance use disorders. Integration extends beyond health (including primary, specialty, emergency, and rehabilitative care) and behavioral healthcare systems and also requires addressing patients' social needs, such as housing, employment, and transportation (SAMHSA, 2015a).

Effects of Addiction on Families

Substance abuse can have particularly devastating consequences for families, because it increases the family members' risk for social isolation and decreases their access to social supports that can be helpful to those experiencing addiction and their families. Typically, defensive coping mechanisms (particularly denial) arise as family members find themselves unable to cope with the addiction in a healthy way. Substance abuse can also interfere with normal family processes, from day-to-day activities related to parenting (such as not being able to drive for the carpool in the morning) to long-term changes such as role reversals, with older children taking on caregiving responsibilities.

Addiction within the family is often cloaked in secrecy and shame. An individual who is addicted is unable to control substance use (or, in the case of process addiction, excessive, compulsive behavior) and will use any means necessary to satisfy the overwhelming need for the substance. Family members, in an effort to protect the family and the addicted member from discovery, often close family ranks to the outside world.

Often, the term **boundaries** is used when talking about interpersonal relationships and addiction. Boundaries represent a type of relationship safety zone around a family and its members. Children and parents in healthy relationships have boundaries that are usually dictated by their role in the family. For example, the parent takes care of the children, the cohabiting adult couple has an intimate personal and physical relationship, and the child is a friend to peers and other children. Normally, boundaries around families are flexible, allowing members to interact with those outside of the family and with the community as needed and desired. Clear boundaries keep people safe within functional relationships. When addiction is present in a family, these boundaries often become rigid and inflexible. Such boundaries do not let information about the family needs or requests for needed assistance out and do not allow input or assistance from individuals or community agencies outside of the family.

Family members of addicts are often seen as enablers, inadvertently supporting the addict's behaviors. **Enabling behavior** is any action an individual takes that consciously or unconsciously facilitates substance dependence. Examples of enabling include family members making excuses to employers or teachers, or discontinuing their own social relationships with friends or neighbors in order to preserve the "healthy image" of the family in the community.

In families where addiction is present, communication is poor within and outside of the family system. Isolation results in an escalating cycle of addiction and dysfunction for the entire family. It is important for healthcare providers to recognize that shame and fear often lead to this isolation. A nonjudgmental approach to assessment and intervention, coupled with empathy and respect, is essential when working with those who are addicted to substances and their families. Substance abuse sometimes correlates with a history of abuse, economic instability, criminal behavior, and educational upheaval. Addiction is a family disease and should be viewed and treated within the context of the family. The longer the addiction continues, the more entrenched family members become in behaviors that further the addiction, such as denial and enabling. This codependency, in which the behaviors of the addict and those of the family revolve around the addiction and their shared behaviors in service of the addiction, harms the family. Children may carry these behaviors into adulthood, taking on specific characteristics beyond the family relationship. Characteristics of codependent individuals are described in **Box 22-1** ». A number of support networks and groups, including Adult Children of Alcoholics and Al-Anon, exist to help family members learn about and recover from the effects of addiction.

Children growing up in a household with a parent who is addicted to drugs or alcohol face a number of challenges. Approximately 7.5 million children younger than the age of 18 (10.5% of all children) live with a parent who had an alcohol use disorder in the past year (CBHSQ, 2012). These

Box 22-1

Characteristics of Codependent Individuals

- Have low self-esteem.
- Have an exaggerated sense of responsibility for others' actions.
- Feel guilty when they assert themselves.
- Deny that they have a problem; think the problem is someone else or the situation.
- Tend to become hurt when their efforts aren't recognized.
- Do more than their share of work all of the time; have trouble saying "no" to anyone.
- Need approval and recognition.
- Fear being abandoned or alone.
- Have difficulty identifying their feelings despite experiencing painful emotions.
- Have difficulty adjusting to change.
- Struggle with intimacy and boundaries.
- Have poor communication skills.
- Have difficulty making decisions.
- Offer advice whether it has been asked for or not.
- Feel like a victim.
- Use manipulation, shame, or guilt to control others' behavior.

children are at a greater risk for depression, anxiety disorders, problems with cognitive and verbal skills, and parental abuse or neglect. Moreover, they are four times more likely than other children to develop alcohol problems themselves (CBHSQ, 2012). Similar issues exist with parents who abuse other substances or combine other substances with alcohol.

Parents often neglect their responsibilities for drugs, alcohol, or other behaviors, up to and including diverting household funds to pay for their addiction. Parents may disappear for hours or days at a time or may be emotionally and physically unavailable to their children even when at home. Compared with families in which substance abuse is not an issue, families with parents who abuse demonstrate poorer problem-solving abilities, both among the parents and within the family as a whole. These poor communication and problem-solving skills may be mechanisms through which lack of cohesion and increased conflict develop and escalate in affected families (National Association for Children of Alcoholics [NACOA], 2015). Children whose parents abuse substances are at risk for disruptive behavioral problems and are more likely to be sensation seeking, aggressive, and impulsive. Because of the secrecy and shame associated with substance abuse, many children of addicts are hesitant to talk about their own feelings, needs, and wants.

While some children growing up in families with addiction have obvious and apparent problems, others cope quite well. The level of dysfunction or resiliency of the nonabusing spouse is a key factor in the impact of the addiction on the children (NACOA, 2015). However, longitudinal research has confirmed the adverse lifelong psychosocial, behavioral, and developmental effects of growing up in a household headed by addicted parents.

Case Study » Part 1

Paul is the 19-year-old son of Mark and Susan John. The Johns have been married for 20 years. Ms. John is a full-time stay-at-home mom. Paul's dad is a corporate attorney who has always been somewhat demanding of his wife and children. He drinks alcohol daily but has always been employed and has maintained a middle-class lifestyle for his family. Paul has two younger sisters: Mara, the younger of the two, has been treated for anorexia since the age of 12. His 15-year-old sister, Jess, is doing well in high school. Paul did well in high school, where he played varsity soccer and did fairly well academically.

Paul has just returned home from his first full year at college. His mother is concerned because he doesn't seem like his old self; he shows no interest in his old friends or in getting a summer job. On the other hand, he seems secretive and has left the house on many occasions claiming that he has new friends who "get it." He is very short tempered with his sisters, constantly irritable and discontented. He is very evasive when asked about his grades or any college activities. He has noticeable weight loss and appears unkempt. His father is intolerant of his behavior. His mother is concerned and has arranged to accompany him on a visit to his primary care provider. She is hoping to find out what his problem is so it can be treated before his father becomes angrier with him and his behavior. You are the nurse who is assessing Paul.

Clinical Reasoning Questions Level I

1. Describe the elements of the interview/assessment environment that you should consider before beginning Paul's patient assessment.

2. What questions would be appropriate in assessing Paul's physiologic, emotional, and psychologic status?
3. What elements of the family history might indicate a potential for substance use or abuse in Paul?

Clinical Reasoning Questions Level II

4. If substance abuse is suspected, how should you proceed to address any ego defense mechanisms displayed?
5. What diagnostic measures might be needed based on your assessment?
6. If depression is suspected, what further assessments would you perform?

Process Disorders

Although this chapter focuses on the care of patients with substance use disorders, it is important for nurses to also be able to recognize that individuals can become addicted to certain behaviors. Process disorders or addictions are groups of repetitive behaviors (e.g., gambling, shopping, internet gaming, exercise, sex) that activate biochemical reward systems similar to those activated by drugs of abuse. Process addictions produce behavioral symptoms comparable to those seen in substance use disorders (APA, 2013). One significant difference, however, is that the individual is not addicted to a substance, but to the behavior or the feeling brought about by the relevant action. In addition, the physical signs of drug addiction are absent in behavioral or process addiction (Alavi et al., 2012).

Gambling disorder is the only one of the repetitive processes with sufficient data to be included in the *Diagnostic and Statistical Manual of Mental Disorders* (5th ed.; DSM-5) as a diagnosable mental disorder (**Figure 22-2** »). The essential feature of gambling is the individual's willingness to risk something of value in the hope of obtaining something of greater value. The diagnostic criteria for gambling disorder highlight the similarities between a process addiction and a substance use disorder. To be diagnosed

Figure 22-2 » Gambling disorder, one of the process disorders, produces behavioral symptoms comparable to those seen in substance use disorders.

with gambling disorder, an individual must experience clinically significant impairment or distress related to the gambling; experience distress when trying to reduce or quit gambling; be preoccupied with gambling to the extent of jeopardizing income, employment, or significant relationships; and have a history of unsuccessful attempts to control or stop gambling (APA, 2013).

Other process addictions, which do not yet appear in the DSM-5 as diagnosable mental health disorders, also cause severe stress and strain to individuals and families. For example, in some individuals who initiate healthy levels of exercise, the practice later morphs into a full-blown **exercise addiction**. Research has suggested that an individual who is addicted to exercise will continue exercising regardless of physical injury, personal inconvenience, or disruption to other areas of life, including marital strain, interference with work, and lack of time for other activities (Landolfi, 2013). Individuals who become addicted to exercise are more likely than committed exercisers to exercise for intrinsic rewards and experience disturbing withdrawal sensations when unable to exercise. The characteristic personality traits in individuals with exercise addiction included high levels of excitement seeking and striving for achievement.

Excessive online shopping, often associated with overspending and aided by the internet, comprises compulsive and addictive forms of consumption and buying behavior. Review of the literature has shown that attributes associated with **online shopping addiction (OSA)** include low self-esteem, low self-regulation, negative emotional state, enjoyment, female gender, social anonymity, and cognitive overload (Rose & Dhandayudham, 2014). Increased accessibility, hyperstimulating marketing techniques, a loss of the protective delay between impulse and purchase, and overvaluing of the shopping process and objects purchased may all contribute to the potentially addictive nature of shopping (Hartston, 2012). Shopping addiction can adversely affect the individual's family, social, and occupational life. The addiction is associated with high rates of psychiatric comorbidity (Murali, Ray, & Shaffiullha, 2012). Compulsive buying has been linked with substance addiction, depression, and obsessive-compulsive disorder, as well as hoarding, but some research has found that excessive shopping is most closely related to addiction, that is, an increased sensitivity to reward (Lawrence, Ciorciari, & Kyrios, 2014).

Internet gaming disorder (IGD) is the persistent use of the internet to engage in games, often with other players, leading to clinically significant impairment or distress. Proposed criteria for diagnosis of IGD include preoccupation with gaming; withdrawal symptoms when gaming is taken away; tolerance (the need to spend increasing amounts of time in gaming or gaming-related activities); unsuccessful attempts to control use and participation; continued gaming despite distress or interference with other activities or interference with relationships; lying about time spent gaming; and using gaming to relieve a negative mood (APA, 2013).

There have been several proposed diagnostic labels for persistent, excessive sexual behaviors, often referred to as **sex addiction** or compulsive sexual behavior (CSB). Typical activities may include engaging in risky sexual practices with a number of partners; preoccupation with recurrent,

intense, sexually arousing fantasies, sexual urges, or behaviors; visiting strip clubs; and engaging in phone sex (De Guzmán et al., 2016). These behaviors cannot be diagnosable as a paraphilia. CSB is estimated to affect up to 3 to 6% of the U.S. population (De Guzmán et al., 2016).

Clinicians have been researching how CSB can be escalated by the internet. Being online seems to facilitate and stimulate addictive tendencies in relation to sexual behavior, such as accessibility, affordability, anonymity, convenience, escape, and disinhibition. The internet has enabled behaviors that an individual would never imagine engaging in offline, such as cybersexual stalking, and has increased access to pornography (Cravens & Whiting, 2014; Griffiths, 2016). Moreover, personal communication devices such as cell phones make practices such as "sexting" (communicating sexually suggestive comments or photos) or engaging in cybersex chatrooms extremely convenient. Aside from the time consumed by a compulsion, hypersexual behavior, particularly time spent pursuing online sexual addictions, causes damage to interpersonal relationships and families. Many clinicians, even those trained in sexual disorders or addiction medicine, have difficulty detecting and diagnosing compulsive sexual behaviors and difficulty treating sexual compulsivity and cybersex addiction unless significant personal and social consequences have occurred that result in the individual seeking help.

Concepts Related to Addiction

Substance use disorder is not a self-contained disorder. Substance use can affect the physical, psychological, and spiritual health of both the individual and the family. A few examples of systems and concepts that are related to substance abuse are outlined here.

Substance use impacts cognitive ability, including slowing reaction times, decreasing inhibitions, and impairing judgment and memory (SAMHSA, 2015b). Substance use also negatively impacts intellectual development in the children of abusing parents. Alcohol abuse is the primary factor contributing to the neurocognitive deficits and intellectual disabilities exhibited by children who have fetal alcohol spectrum disorders (FASD) because of in utero exposure to alcohol (Chokroborty-Hoque, Alberry, & Singh, 2014).

Gastrointestinal disorders (including the GI tract, liver, and pancreas) occur frequently with long-term substance use. For example, cocaine abuse can result in various gastrointestinal complications, including gastric ulcerations, retroperitoneal fibrosis, visceral infarction, intestinal ischemia, and gastrointestinal tract perforations (SAMHSA, 2015b). Long-term alcohol use often leads to cirrhosis of the liver, which impairs digestion of food and absorption of key nutrients.

Infectious diseases are common in individuals who abuse substances. Hepatitis C virus infection is the most common form of infectious hepatitis in patients with substance use disorders. At least 76% of patients who have used injectable drugs for less than 7 years are positive for hepatitis C, while 25% of patients who abuse alcohol and those who do not inject drugs also show serologic evidence of infection (SAMHSA, 2015b). Other infectious diseases associated with SUD are endocarditis, bacterial pneumonia, tuberculosis,

skin infections resulting from administration of intravenous drugs (e.g., *Staphylococcus aureus* and *Streptococcus pyogenes*), and the sexually transmitted infections HIV/AIDS.

Individuals with SUD are prone to accidents of all kinds, with complications ranging from head trauma to falls with fractures. Chronic pain frequently is seen in patients as a result of trauma, poor health maintenance, or an inability to deal with pain without opioid drug use (SAMHSA, 2015b). Also, clinicians should also consider traumatic brain injury (TBI) when individuals with SUD present with neurologic impairment. People who abuse substances have a high risk of falls, motor vehicle accidents, gang violence, domestic violence, and so on, all of which may result in head injury (SAMHSA, 2015b).

Many individuals who experience overwhelming stress turn to substance use as a maladaptive coping mechanism. For example, researchers found that individuals of both genders who reported higher levels of stress tended to drink more. However, men turned to alcohol as a means for dealing with stress more often than women. For those who reported at least six stressful incidents, the percentage of

men who engaged in binge drinking was about 1.5 times that of women, and alcohol abuse among men was 2.5 times higher than among women (National Institute on Alcohol Abuse and Alcoholism [NIAAA], 2012).

Veterans who have been in active combat are especially likely to turn to alcohol as a means of relieving stress. Post-traumatic stress disorder (PTSD) has been found in 14 to 22% of veterans returning from recent wars in Afghanistan and Iraq and has been linked to increased risk for alcohol abuse and dependence (NIAAA, 2012). Individuals who abuse substances and have experienced trauma have worse treatment outcomes for substance abuse than those without histories of trauma (SAMHSA, 2014a). Because traumatic experiences and their sequelae are closely tied to behavioral health problems, many clinicians have integrated trauma-informed care into addiction recovery programs (SAMHSA, 2014a). See the Evidence-Based Practice feature on trauma-informed care.

The Concepts Related to Addiction feature links some, but not all, of the concepts integral to addiction. They are presented in alphabetical order.

Concepts Related to Addiction

CONCEPT	RELATIONSHIP TO ADDICTION	NURSING IMPLICATIONS
Cognition	<ul style="list-style-type: none"> ↓ B₁ (thiamine) in the brain can cause changes in cognition, specifically confusion ↓ Memory, judgment, reaction times, cognitive ability 	<ul style="list-style-type: none"> ■ Assess for Wernicke encephalopathy, Korsakoff psychosis, and dementia. ■ Provide for patient safety. ■ Anticipate provision of thiamine therapy.
Family	<ul style="list-style-type: none"> ↑ Substance use and abuse of family member → ↑ Family secrecy → ↑ Family isolation → ↓ Supportive resources available 	<ul style="list-style-type: none"> ■ Determine family understanding of substance abuse and addiction. ■ Communicate clearly, honestly, openly, and without judgment. ■ Anticipate involving the entire family in all aspects of the treatment process.
Infection	<ul style="list-style-type: none"> ↑ Spread of infection through intravenous use of drugs, e.g., needle sharing ↑ Risk of sexually transmitted infections 	<ul style="list-style-type: none"> ■ Assess for hepatitis C, endocarditis, bacterial pneumonia, tuberculosis, skin infections resulting from administration of intravenous drugs. ■ Assess for sexually transmitted infections such as HIV/AIDS.
Nutrition	<ul style="list-style-type: none"> ↓ Nutritional status → ↓ Body's ability to synthesize antibodies 	<ul style="list-style-type: none"> ■ Be alert to signs/symptoms of malnutrition and opportunistic infections. ■ Anticipate the need for a nutritional assessment, balanced diet, vitamin and mineral supplements. ■ Provide discharge planning that promotes patient's ability to meet nutritional needs.
Safety	<ul style="list-style-type: none"> ↑ Risk-taking behaviors leads to ↑ risk for injury, violence, and HIV 	<ul style="list-style-type: none"> ■ Assess for risk behaviors, including driving under the influence, unprotected sex, or sharing needles. ■ Provide education related to safety. ■ Anticipate denial, family interference, or enabling.
Trauma	<ul style="list-style-type: none"> Substance abuse as coping mechanism → poorer outcomes Combat, TBI ↑ risk for PTSD → ↑ risk for substance abuse 	<ul style="list-style-type: none"> ■ Assess for patient and family safety. ■ Identify and refer to recovery programs that provide integrative, trauma-informed care. ■ Support family during recovery process.

Health Promotion

Prevention efforts related to substance abuse generally revolve around education. Federal initiatives include prevention efforts by SAMHSA and other federal organizations. Community and local initiatives, often sponsored as collaborations among law enforcement and local health and mental health professionals, may be developed to target needs in a specific community. At the individual level, nurses and other healthcare professionals assess patients' risk for substance abuse and provide education related to prevention, especially related to using healthy coping mechanisms and obtaining appropriate treatment for existing mental health disorders, such as depression.

Health promotion activities can be particularly important for patients who are in recovery from an addiction. Generally speaking, health promotion activities to help prevent patients from experiencing relapse include reviewing with patients the situations or feelings that triggered use in the past and helping patients recall and maintain healthy coping strategies that have been successful in helping them maintain sobriety. Nurses working with sober patients may need to help identify additional resources for patients during challenging times. For example, consider a mother with a history of substance use who gives birth to a premature newborn. Prior to discharge from the hospital, the nurse or case worker sets up early childhood intervention services. A nurse or early childhood intervention specialist will make weekly home visits to see how mother and baby are doing and provide supportive interventions that may include teaching feeding and parenting strategies. By reducing the stress level of the mother and promoting mother-child bonding, the mother will be at less risk for resuming addictive behaviors.

Nursing Assessment

A trusting nurse-patient relationship, along with the nurse's ethical obligation to maintain confidentiality, may help the patient share information more freely. By including family members in the assessment process, nurses may uncover addictions or behaviors the patient is hiding. Nurses must help patients understand the importance of full disclosure of any addictions to protect them from potential treatment complications. All too often patients fail to admit addiction until permanent damage has already occurred. The nurse's responsibility is to recognize clues while complications are still preventable.

SAMHSA recommends that clinicians at all levels of treatment use SBIRT (screening, brief intervention, and referral to treatment) to identify patients with substance abuse issues (SAMHSA, 2015c). The goal is early intervention and treatment services for persons with substance use disorders, as well as those who are at risk of developing these disorders. *Screening* quickly assesses the severity of substance use and identifies the appropriate level of treatment. *Brief intervention* focuses on increasing insight and awareness regarding substance use and motivation toward

Box 22-2

Gender Differences Associated with Substance Use Disorder Treatment

During the past decade, SAMHSA has devoted research to discovering what features of substance treatment engage patients and promote recovery for different segments of the population. SAMHSA has issued treatment improvement protocols looking at gender differences between women and men seeking treatment for substance use issues.

For women, being responsible for the care of dependent children is one of the deterrents to treatment (SAMHSA, 2009). Women who do not have access to a treatment program that provides child care or who cannot arrange alternative child care may have to choose between caring for their children and entering treatment. Unfortunately, few programs allow mothers to bring their children or assist with services for children or child care (SAMHSA, 2009). Women who have children often fear that admitting a substance use problem will cause them to lose custody of their children. Clinicians need to be sensitive to this barrier, explore resources in the community, and help female patients deal with this issue.

For men, employment-related issues can strongly affect men's substance use/abuse, and men with substance use disorders are at greater risk for unemployment (SAMHSA, 2013). For men who are employed, their type of profession may affect the pattern and extent of their substance use. For example, research has shown a relationship between drinking and having positions that are typically male dominated. Men who work in production and craft jobs and jobs that require working with machinery or hazardous materials are more likely to use substances than those in positions that carry less risk (SAMHSA, 2013).

Men in particular have a fear of risking their employment to enter treatment. SAMHSA research has shown that men who needed substance abuse treatment were more than 16 times as likely as women who needed treatment to express concern that entering treatment would affect their jobs. Clinicians need to explore this fear with men and help them find treatment that will help safeguard existing employment.

behavioral change. *Referral to treatment* helps direct those who need more extensive treatment toward access to specialty care (SAMHSA, 2015c). In addition, SAMHSA has researched and recommended some gender-based treatment considerations (**Box 22-2** »).

Most clinicians use multidimensional assessment criteria developed by the American Society of Addiction Medicine (ASAM) when determining the most appropriate facility and level of care for initial placement, continued stay, and transfer/discharge of patients who abuse substances (ASAM, 2015). Assessment criteria include acute intoxication or withdrawal potential; biomedical conditions and complications; emotional, behavioral, or cognitive conditions and complications; readiness to change; relapse, continued use, or continued problem potential; and recovery/living environment (ASAM, 2015). The levels of care typically used in the United States range from ambulatory detoxification without extended onsite monitoring to medically managed intensive inpatient detoxification (SAMHSA, 2015b).

For individuals withdrawing from alcohol, sedative-hypnotics, or opioids, hospitalization (or some form of 24-hour medical care) is the preferred setting for detoxification, based on safety and symptom-relief concerns (SAMHSA, 2015b). Concurrent mental health issues, such as exacerbation of schizophrenia or bipolar disorder, may also require hospitalization for stabilization. Distressing physiologic symptoms also indicate the need for immediate hospitalization. These symptoms include, among others, a change in mental status, increasing anxiety and panic, hallucinations, seizures, temperature greater than 100.4°F (suggesting potential infection), significant increases and/or decreases in vital signs, abdominal pain, gastrointestinal bleeding, heightened deep tendon reflexes, and central nervous system irritability (SAMHSA, 2015b). Young individuals in good health, with no history of previous withdrawal reactions, may be able to manage withdrawal without medication. Nonmedical detoxification is a current trend because of cost effectiveness and inexpensive access to treatment for certain individuals seeking treatment (SAMHSA, 2015b).

SAFETY ALERT Clinicians need to assess for suicidality in individuals with substance use issues. Individuals with substance use disorders are about six times more likely to commit suicide than the general population (Ross, 2014). Roughly one in three individuals who commit suicide are under the influence of drugs, typically opiates such as oxycodone or heroin, or alcohol (Ross, 2014).

Observation and Patient Interview

Nurses who work with individuals with addiction issues often note observable manifestations at the first patient encounter. Familiar manifestations include unsteady gait and poor balance, lack of coordination, slurred speech, tremors, and unusual smells on the breath, body, or clothes. Other common manifestations include:

- Loss of interest in personal hygiene and grooming
- Watering or bloodshot eyes; large or small pupils
- Rhinorrhea (runny nose)
- Obvious weight loss or gain
- Inability to concentrate; hyperactivity, agitation, or giddiness
- Anger, frustration, or mood swings
- Appearing fearful, anxious, or paranoid with no reason
- Appearing lethargic or “spaced out.”

These are only a few observable manifestations of substance use. Symptoms specific to certain substance addictions are described in more detail in following sections.

The nursing history plays an important role in determining potential addictive behavior. Patients may feel shame, contempt, or embarrassment about revealing their addiction. In addition, fear of legal reprisal may cause the patient to be reluctant to share information if the addiction is to an illegal substance.

Patients also may need to be assessed regarding the extent of crisis they are facing in their lives as the result of their substance use disorder, particularly if a crisis event or behavior

motivates them to seek healthcare. The following list of questions provides a general crisis assessment that can be used in any problem-solving situation. It is of particular use for the patient whose crisis is the result of addiction behavior.

Individual Assessment

1. What is the most significant stress/problem occurring in your life right now?
2. Has this problem increased the frequency of substance use? (Quantify change in frequency or amount of substance used.)
3. Is your addiction behavior causing or contributing to the problem?
4. Who is the problem impacting? You? Your family? Your employer?
5. How long has this been a problem?
6. What does this problem mean to you?
7. What are the factors that cause this problem to continue?
8. Would the problem resolve if you stopped abusing the substance?
9. Have you had similar stresses/problems in the past?
10. What other stresses do you have in your life?
11. How are you managing your usual life roles (partner, parent, homemaker, worker, student, and so on)?
12. In what way has your life changed as a result of this problem?
13. Are you feeling as though you want to harm yourself or anyone else?
14. Describe how you have managed problems in the past.
15. What have you done to try to solve the problem so far? What happened when you tried this?
16. Describe possible resources (e.g., family, friends, employer, teacher; financial, spiritual).
17. Are you interested in abstaining from substance abuse? Are you considering a rehabilitation program?
18. What part of the overall problem is most important to deal with first?

Family Assessment

1. How do you perceive the current problem and the patient's addiction behavior?
2. In what way has the problem and the patient's addiction behavior affected your roles in the family?
3. How has your lifestyle changed since this problem began?
4. Describe communication within the family before and since this current problem began.
5. How does the family typically manage problems?
6. What has the family done to try to solve the problem so far?
7. What happened when you tried this?
8. How well do you believe the family is coping at this time?
9. Describe possible resources (e.g., extended family, friends; financial).
10. What are your expectations and hopes concerning this problem and the patient's addiction behavior?
11. Which part of the overall problem is most important to deal with first?
12. Can the problem be resolved without resolution of the addiction behavior?

Community Assessment

1. What are the living conditions of the neighborhood?
2. Are affordable child care services available?
3. Is there a community mental health center or rehabilitation center?
4. What support groups are available in the community?
5. Are there any possible funding resources?

Physical Examination

Physical assessment findings depend on the nature of the addiction and the substance being used. When performing a physical assessment, nurses must be alert for symptoms that are abnormal or not within expected boundaries and assess patient explanations for inconsistencies. Unless the patient comes to the provider under the influence or is referred by an employer, the physical examination may provide the first indications that an addiction is involved.

Diagnostic Tests

Diagnostic tests required for patients with addiction will be ordered based on the type of addiction they display. Specific diagnostic tests will be ordered for each type of addiction and may include serum drug levels; toxicology; chest x-rays for inhaled substances; organ biopsies related to damage caused by a substance; and urine, saliva, and serum testing for substance metabolites. Hair testing may be done to determine substance use within a period of 90 days.

Case Study » Part 2

Paul is admitted to the emergency department (ED) at 2 a.m. on a Sunday morning in August as the result of a motor vehicle crash. His speech is slurred and his gait is ataxic. He is bleeding from a laceration on his left forehead, and he is complaining that his left arm is extremely painful and “falling off.” A decision is made to admit Paul to the trauma unit. His father, as next of kin, is notified of the admission. His father states, “I knew this would happen. Let him rot.” Paul becomes combative as you attempt to assess his state of consciousness and physical injuries.

Clinical Reasoning Questions Level I

1. You suspect substance use. What are your immediate concerns?
2. How will you promote Paul's cooperation with your assessment and eventual treatment?
3. What specific diagnostic tests will be appropriate related to both his suspected substance use and his physical injuries?

Clinical Reasoning Questions Level II

4. *Refer to the module on Legal Issues:* Are you able to begin assessment and treatment of Paul without consent from next of kin? What are the legal implications in this situation?
5. Paul's mother arrives in the ED. She is very upset and demanding to see him. Will you involve Paul's mother in his care? Why or why not?

Independent Interventions

Nurses may use a number of independent and collaborative caring interventions with patients who are addicted or who exhibit addiction behaviors. **Recovery** is generally defined as a state of voluntary sobriety in which the individual maintains personal health and functions normally within

society without the use of the addictive substance or behavior. The goal of all interventions is to move the patient toward treatment and into recovery. Recovery is a lifelong process. Nurses must remember that no single intervention is sufficient to ensure permanent recovery, which requires substantial and continual work on the part of the individual.

Independent nursing interventions for patients with substance use disorders primarily focus around nursing care for any specific presenting symptoms, developing and maintaining the therapeutic nurse–patient relationship (including establishing and maintaining appropriate boundaries), and promoting healthy patient communication and coping skills. See the module on Stress and Coping for a discussion about defense mechanisms and nursing interventions to help patients develop healthy coping skills. As always, providing culturally competent care is critical to reducing barriers and improving outcomes (see the Focus on Diversity and Culture feature).

Promote Communication

Respect, empathy, and caring are essential components of caring for those with substance use disorders. Establishing a therapeutic nurse–patient relationship that places the patient at the center of all communication is essential for two reasons: (a) Many patients with substance use disorders have poor communication skills and rely on their addictive behaviors to avoid communicating with others, and (b) these patients are experienced at hiding their addictions and avoiding their addiction as the topic of discussion.

Because many individuals who abuse substances come from families with impaired communication, it is important that communication be simple, direct, and powerful (LaPierre, 2015). Many student and new clinicians will use euphemisms or talk too much when communicating with a substance

Focus on Diversity and Culture Improving Cultural Competence Among Mental Health Clinicians

In 2014, the Substance Abuse and Mental Health Services Administration (SAMHSA) published a *Treatment Improvement Protocol: Improving Cultural Competence* to improve patient engagement in services, patient–provider therapeutic relationships, treatment retention, and outcomes. The protocol cites cultural competence as an essential ingredient in decreasing disparities in behavioral health. According to SAMHSA (2014b), culturally competent mental health and substance abuse clinicians:

- Frame issues in culturally relevant ways
- Allow for complexity of issues based on cultural context
- Make allowances for variations in the use of personal space
- Are respectful of culturally specific meanings of touch (e.g., hugging)
- Explore culturally based experiences of power and powerlessness
- Adjust communication styles to the patient's culture
- Interpret emotional expressions in light of the patient's culture.

abuser. Subtlety is counterproductive with many of these patients because they may not want to hear the message being conveyed and are often skilled in manipulating words and phrases as well as people (LaPierre, 2015). Recommended strategies for communicating with individuals who abuse substances include:

- Express concerns or pass along information without judgment. Correct any false ideas and fill in information gaps.
- Use “I” statements to describe concerns without singling out the substance-abusing individual.
- Remain calm without arguing or getting angry.
- Listen for contingency words such as “probably,” “possibly,” or “maybe” in conversations with individuals who abuse substances. These adverbs usually mean that the individual is not going to follow through on the topics being discussed.
- Hold patients accountable. If they agree to follow through on a task or plan, make a specific plan with them to encourage completion.
- Practice active listening skills. Notice when patients with substance use disorders are using defense mechanisms such as *deflecting* (turning the topic back on the speaker, changing the subject, or using humor to lighten the mood); *rationalizing* (explaining why a behavior or action that is clearly not acceptable is acceptable); *minimizing* (downplaying the extent of the addiction and its consequences); and *avoiding* (pretending not to hear or refusing to engage in discussion).
- Notice body language. Eye contact may indicate interest, while staring at the floor or other spots may indicate shame, exasperation, or refusal to engage. Other non-verbal indicators are muscle tension, indicating stress and fear; hand wringing, indicating anxiety and worry; and turning away, indicating termination of the conversation (British Columbia Schizophrenia Society, 2015; LaPierre, 2015).

Limit Setting and Boundary Violations

Limit setting refers to establishing parameters of desirable and acceptable patient behavior. Limit setting helps patients feel safe, advances therapeutic goals by eliminating nonproductive behaviors, promotes positive behavior change, and protects significant others and children of individuals who abuse substances from unacceptable behaviors (British Columbia Schizophrenia Society, 2015). Limit setting teaches the individual that there are choices, but there are also consequences for making poor decisions. The goal of setting limits is to teach patients how to consistently make good decisions. Unfortunately, setting limits can be challenging for both clinicians and family members, as substance users often respond with anger and resentment, with some even threatening to terminate the therapeutic or personal relationship. Clinicians and family members may feel defeated, angry, and frustrated when limits are breached (British Columbia Schizophrenia Society, 2015).

Often substance users have an unhealthy sense of personal boundaries and frequently cross them, by engaging in activities such as appropriating and selling or pawning a family member’s property to pursue an addiction. Clinicians

should encourage family members to set and enforce clear boundaries with defined consequences. Reluctance by family members to enforce personal boundaries is often related to poor communication and enmeshed, codependent behavior (Lander, Howsare, & Byrne, 2013; Mental Health America, 2015a).

Likewise, clinicians need to be aware of professional boundaries, which the patient can violate or exploit. Boundary crossing can involve inappropriate physical contact, giving and receiving gifts, contact outside of the normal therapy session, and use of provocative language, clothing, and proximity of the therapist and patient during sessions (Lander et al., 2013; Mental Health America, 2015b). The clinician also needs to guard against ambiguous relationships where multiple roles exist between a therapist and a patient, such as if the patient is also a student, friend, family member, employee, or business associate of the clinician.

Promote Adequate Nutrition

Patients who engage in any type of substance abuse are at risk for deficiencies in key nutrients. In the case of alcoholism, for example, thiamine deficiency can cause complications such as Wernicke syndrome. Nurses administer vitamins and dietary substances as ordered and monitor lab work (e.g., total albumin, complete blood count, urinalysis, electrolytes, and liver enzymes) and report significant changes to the provider. Nurses also collaborate with dietitians to determine the number of calories necessary for patients to maintain adequate nutrition and appropriate weight. In inpatient settings, nurses document intake, output, and calorie count and weigh patients daily if necessary. Nurses also teach patients with substance abuse about the importance of adequate nutrition and the physical effects of alcohol or substance abuse and related malnutrition on body systems. Nurses provide information about adequate nutrition using USDA recommendations.

Promote Participation in Treatment

Patients are more likely to participate in treatment when nurses and other clinicians are genuine, honest, and respectful of patients. Keep all promises and convey an attitude of acceptance. Do not accept the use of defense mechanisms such as rationalization or projection as the patient attempts to blame others or make excuses for his or her behavior. Encourage patients to examine how unhealthy coping mechanisms and maladaptive behaviors are impacting their lives and those they care about, and help them learn more healthy ways of coping and responding to stressful situations. Encourage patient participation in therapeutic group activities such as 12-step and support-group meetings with other people who are experiencing or have experienced similar problems. Patients often are more accepting of peer feedback than feedback from authority figures.

Collaborative Therapies

Treatment for addiction may be determined by level of severity and how the individual comes to seek treatment. Some patients are adjudicated to treatment by the judicial system. Patients with severe impairment of function may be involuntarily admitted or may be admitted for medical care

associated with an injury. These are some of the many factors that influence individual patient plans of care.

Many clinicians routinely use the **5 A's** to help identify users and appropriate interventions based on the patient's willingness to quit (Agency for Healthcare Research and Quality [AHRQ], 2012). The steps are described below.

1. **Ask:** Identify and document substance use status for every patient at every visit.
2. **Advise:** In a clear, strong, and personalized manner, urge every substance user to quit.
3. **Assess:** Is the substance user willing to make a quit attempt at this time?
4. **Assist:** For the patient willing to make a quit attempt, use counseling and pharmacotherapy to help him or her quit. For those who need a higher level of care, for example, inpatient detoxification, make arrangements for admission.
5. **Arrange:** Schedule follow-up contact, in person or by telephone, preferably within the first week after the quit date (AHRQ, 2012).

In some cases, individuals seek care after being persuaded they need care through a process of confrontation called **intervention**. The goal of intervention is to prevent the addict from denying the problem and force him or her to face the negative aspects of behavior and enroll in treatment, typically in a residential treatment facility. In *family intervention*, the family enlists the help of a professional clinician to conduct the intervention with the participation of the family. The clinician and family meet with the individual together, with family members stating how the individual's addiction affects the family. Although the detoxification team can leverage the relationship the patient has with significant others, it is not recommended that clinicians use direct confrontation solely to force a person with a substance use disorder into treatment, because research has shown that treatment programs that rely on confrontational clinician techniques have yielded poor outcomes (SAMHSA, 2015b).

Frequently, individuals enter treatment because their inability to manage life skills and events results in a crisis. Often, these crises result in legal issues, such as impaired driving citations and vehicle crashes, child custody disputes, separation and divorce, and violent encounters. Other challenges such as job loss, financial difficulties, ruptured relationships, and distressing medical symptoms can also lead a patient with SUD to seek treatment. It is during crisis situations that patients with SUDs are most likely to be motivated to seek help. The inability to maintain emotional equilibrium is an important but short-lived feature of a crisis. Typically, the high level of anxiety created by a crisis forces the individual to return to the previous level of addiction; develop more constructive coping skills and seek help; or decompensate to a lower level of functioning.

While the process of detoxification, stabilization, and recovery frequently contains significant medical and pharmaceutical components, the motivation for long-term change often comes from psychosocial interventions. Psychosocial interventions for substance use disorders can be defined as interpersonal or informational activities, techniques, or strategies that target biological, behavioral, cognitive, emotional, interpersonal, social, or environmental

factors with the aim of improving health functioning and well-being (Institute of Medicine [IOM], 2015).

The efficacy of psychosocial interventions, by themselves or combined with medication, has been well documented. Psychosocial interventions can address psychosocial problems that negatively impact adherence to medical treatments or can help the patient deal with the interpersonal and social challenges present during recovery. Not only are psychosocial interventions effective, but patients often prefer them to medications for SUD: 75% of patients, especially younger patients and women, preferred psychotherapy (McHugh et al., 2013). Psychosocial interventions also can be important to provide an alternative for those for whom medication is inadvisable (e.g., pregnant women, children, those with complex medical conditions); to enhance medication adherence; or to deal with the social and interpersonal issues that complicate recovery from mental health and substance use disorders (IOM, 2015). One such intervention is the incorporation of trauma-informed care into the overall treatment plan for individuals with alcohol or substance use disorders who have a history of trauma. See the Evidence-Based Practice feature for more information.

Behavior-Related Therapies

In **behavioral therapy**, patients learn techniques to modify or change their addictive behaviors. Classic *behavioral modification* therapy is based on the principle that all behavior has specific consequences. Thus, behavior can be changed by conditioning—a process of reinforcement, punishment, and extinction. Consequences that increase the likelihood of a particular behavior are referred to as **reinforcement**. *Positive reinforcement* provides a reward for the desired behavior, such as a token or treats for treatment compliance. *Negative reinforcement* removes a negative stimulus to increase the chances that the desired behavior will occur, such as when someone with a substance use disorder enters treatment and is able to separate from friends who are also abusing drugs.

Negative consequences that lead to a decrease in undesirable behavior are referred to as **punishment**. **Extinction** refers to the progressive weakening of an undesirable behavior through repeated nonreinforcement of the behavior. Most behavioral therapists believe that behavior changed through reinforcement is a more desirable clinical outcome than behavior changed through punishment. **Contingency contracts** may be an effective reinforcement process through which the patient is rewarded contingent upon meeting desired outcomes. Incentives found to be effective include both vouchers or cash equivalents (guaranteed payment) and “prize-based” approaches that feature the chance to earn a large prize (IOM, 2015). **Token economies** are formalized programs of contingency contracts common in behavior modification programs in which patients can accrue a number of token rewards to exchange for privileges or activities.

A more common approach is **cognitive-behavioral therapy (CBT)**, which is used for a wide array of mental health and substance use disorders. It combines behavioral techniques with cognitive psychology—the scientific study of mental processes, such as perception, memory, reasoning, decision making, and problem solving (IOM, 2015). The goal is to replace maladaptive behavior and faulty cognitions

Evidence-Based Practice

Substance Use Disorders and Trauma-Informed Care

Problem

Trauma results from an event, series of events, or set of circumstances that an individual experiences as physically or emotionally harmful or threatening. Trauma can occur as a result of violence, abuse, neglect, loss, disaster, war and other negative events. Traumatic experiences affect all segments of society, regardless of age, gender, socioeconomic status, race, ethnicity, geography, or sexual orientation. Trauma has lasting adverse effects on the individual's functioning and physical, social, emotional, or spiritual well-being and often causes the individual to seek alcohol or drugs to deal with psychic pain (SAMHSA, 2014b). People who abuse substances and have experienced trauma have worse treatment outcomes than those without histories of trauma.

Evidence

Many individuals with substance use disorders have experienced trauma as children or adults; conversely, substance abuse is known to predispose individuals to higher rates of traumas, such as dangerous situations and accidents, while under the influence and as a result of the lifestyle associated with substance abuse (SAMHSA, 2014a). During the past decade, which has featured natural disasters, overseas wars, and mass violence, clinicians have been focusing on how trauma, psychologic distress, quality of life, health, mental illness, and substance abuse are linked.

Research from two influential studies—the *Adverse Childhood Experiences Study* (CDC, 2013a) and the *Women, Co-occurring Disorders and Violence Study* (SAMHSA, 2007)—documented the relationships among exposure to traumatic events, impaired neurodevelopmental and immune systems responses, and subsequent health risk behaviors resulting in chronic physical or behavioral health disorders (SAMHSA, 2014a).

Implications

Patients with trauma histories were not responding to traditional therapies that focused solely on co-occurring mental health disorders and substance use. To address this treatment gap, trauma-informed therapies—known collectively as trauma-informed care (TIC)—have been created. Implementing trauma-informed services can improve screening and assessment, treatment planning, and placement while also decreasing the risk for retraumatization (SAMHSA, 2014a). TIC implementation may enhance patient-provider communication, thus decreasing risks associated with misunderstanding the patient's reactions and presenting problems or underestimating the need for appropriate referrals for evaluation or trauma-specific treatment (SAMHSA, 2014a).

The introduction of TIC has required re-education of mental health clinicians and increased sensitivity to patients' trauma histories. Personnel at public institutions and service systems such as schools and the court system are also being introduced to the concept of TIC and are being trained to identify patients with trauma histories and make appropriate referrals for mental health services.

Critical Thinking Application

1. Why were traditional therapies for substance use disorder unsuccessful with patients who abused alcohol and/or drugs and had trauma histories?
2. How does trauma relate to alcohol and substance use? Would it be better for patients with SUD to focus on trauma therapy or SUD therapy? Or should therapies be combined?
3. Which symptoms of trauma should school and court personnel be trained to recognize in children, adolescents, and adults?
4. Could mental health practices such as restraints and seclusion contribute to retraumatization? If yes, how?

with thoughts and self-statements that promote adaptive behavior. Variants of CBT include **rational-emotive behavior therapy (REBT)**, an active, solution-oriented therapy that focuses on resolving emotional, cognitive, and behavioral problems resulting from faulty evaluation of negative life events (Ellis, 2015), and **dialectical behavior therapy (DBT)**, during which patients are taught how to regulate destructive emotions, practice mindfulness, and better tolerate distress (Linehan, 2015).

Behavior-oriented therapies are well suited to treating individuals with addictions because patients must alter familiar maladaptive coping mechanisms and find more successful methods of reducing anxiety. Because they spend a great deal of time with patients, nurses are in an ideal position to evaluate patient response to treatment and encourage developing patterns of positive behavioral change.

Milieu Therapy

A successful recovery environment supports behavior changes, teaches new coping measures, and helps the patient move from addiction to a sober life. This supportive environment is often referred to as **milieu therapy**. The milieu is a supportive environment in which clinicians and staff work with patients to provide safety and structure while assessing the patient's relationships and behavior (Menninger Clinic,

2015). Patients benefit because a consistent routine is maintained, which fosters predictability and trust. A milieu is considered therapeutic when the program's community provides a sense of civility, membership, belonging, care, and accountability (Menninger Clinic, 2015).

The structure of milieu therapy helps patients contain negative behavior and provides an opportunity to learn how to respond to challenging situations through staff and peer feedback and modeling constructive behavior. Other goals of milieu therapy include treating patients as responsible people, encouraging group and social interaction, emphasizing patients' rights to choose and participate in a variety of treatments, and accentuating informal relationships with healthcare professionals. Milieu therapy also supports clear communication and often features a tightly structured activity schedule with clear therapeutic goals. Patients are also taught how to use and access a support network. The overall goal behind all of these components is to support constructive, permanent behavioral change in the patient with SUD. The therapeutic milieu can be created in residential and inpatient programs as well as outpatient programs, such as group homes, community centers, or day programs.

Within the therapeutic milieu, the nurse plays a pivotal role by modeling and teaching desirable behaviors. Often, the nurse is the member of the patient's psychiatric team

who spends the most time with, and around, the patient. The nurse's observations of, and interactions with, the patient provide information and opportunities critical to understanding the patient's addiction behavior and to helping the patient determine a successful path to recovery.

Group Therapy

Therapeutic groups provide support to individual members as they work through problems. During **group therapy**, which is facilitated by a professional group therapist, the group navigates psychologic, cognitive, behavioral, and spiritual dysfunctions. Irving Yalom is widely considered to be the father of modern group therapy. Through his work as a psychiatrist, Yalom defined many of the characteristics of successful groups, such as goal setting, group size, duration of therapy, and leader and member characteristics. Yalom recognized that the intensive group experience is a "powerful agent of change" (1974, p. 85), where members feel stimulated by the group, develop close bonds, and experience affective adjustments. Functional groups generate heightened emotional reflection, creating an atmosphere of group trust and support. Through interactions with others in the group, members practice valuable self-reflection (Yalom, 1974). Today, interactive group therapy is a mainstay in addiction recovery.

Groups can be held in the inpatient-unit or outpatient setting, community mental health centers, or other locations. Ballinger and Yalom (1995) identified mechanisms of change within a group and called them *curative factors* of group therapy. These factors provide a rationale for a variety of group interventions. **Table 22-2** describes the curative factors.

Nurses can function as group therapists in many different settings, leading groups to achieve desired outcomes. Certified advanced practice nurses can run interactive therapy groups and conduct psychotherapy with individuals, families, and groups. A single nurse may lead groups or share leadership responsibilities with a cotherapist. As the group leader, the nurse can unify the group members and help them relate to each other. Some important duties of the

group leader include encouraging members to remain in the group, helping the group develop a sense of cohesiveness, and establishing a code of behavior and norms within the group (Ballinger & Yalom, 1995).

Adolescents can participate in group therapy and other peer support programs during and following treatment to help them achieve abstinence from substances (NIDA, 2014e). When led by trained clinicians following well-validated cognitive-behavioral therapy protocols, groups can provide positive social reinforcement through peer discussion. They can also help enforce incentives to avoid substance use and live a substance-free lifestyle. However, group treatment for adolescents carries a risk of unintended adverse effects: Group members may steer conversation toward talk that glorifies or extols substance use, thereby undermining recovery goals. Trained counselors need to be aware of that possibility and direct group activities and discussions in a more positive direction (NIDA, 2014e).

Support Groups

Because individuals with addictions typically have inadequate social networks, often restricted to fellow substance users, it is important for them to develop more functional support networks that can contribute to increased self-esteem and dignity, a sense of identity, and improved self-responsibility. Nurses frequently refer patients and their families to support groups that allow peers to share their thoughts and feelings and help one another examine issues and concerns. In support groups, members define their own needs, have equal power, and usually participate voluntarily. They may or may not be assisted by a mental health professional. For individuals with substance use issues, group recovery support generally consists of peer-based mentoring, education, and support services provided by individuals in recovery to individuals with substance use disorders or co-occurring substance use and mental disorders (Reif et al., 2014).

The support group SMART Recovery (Self-Management and Recovery Training) is based on the "scientifically

TABLE 22-2 Curative Factors of Group Therapy

Factor	Description
Instillation of hope	As patients observe other members further along in the therapeutic process, they begin to feel a sense of hope for themselves.
Universality	Through interaction with other group members, patients realize they are not alone in their problems or pain.
Imparting of information	Teaching and suggestions usually come from the group leader but may also be generated by the group members.
Altruism	Through the group process, patients recognize that they have something to give to the other group members.
Corrective recapitulation of the primary family group	Many patients have a history of dysfunctional family relationships. The therapy group is often like a family, and patients can learn more functional patterns of communication, interaction, and behavior.
Development of socializing techniques	Development of social skills takes place in groups. Group members give feedback about maladaptive social behavior. Patients learn more appropriate ways of socializing with others.
Imitative behavior	Patients often model their behavior after the leader or other group members. This trial process enables them to discover what behaviors work well for them as individuals.
Interpersonal learning	Through the group process, patients learn the positive benefits of good interpersonal relationships. Emotional healing takes place through this process.
Existential factors	The group provides opportunities for patients to explore the meaning of their life and their place in the world.
Catharsis	Patients learn how to express their own feelings in a goal-directed way, speak openly about what is bothering them, and express strong feelings about other members in a responsible way.
Group cohesiveness	Cohesiveness occurs when members feel a sense of belonging.

informed” use of psychologic treatments and legally prescribed psychiatric and addiction medication. The SMART program considers substance abuse and addiction to be complex maladaptive behaviors with possible physiologic factors and emphasizes teaching increasing self-reliance, rather than powerlessness (SMART Recovery, 2015). SMART features both face-to-face and online support. SMART’s recovery program focuses on the following points: building and maintaining motivation; coping with urges; managing thoughts, feelings and behaviors; and living a balanced life (SMART Recovery, 2015).

Twelve-Step Programs

Twelve-step programs are support groups that offer a spiritual plan for recovery. These include Al-Anon, Narcotics Anonymous, Cocaine Anonymous, Adult Children of Alcoholics, Emotions Anonymous, Gamblers Anonymous, Overeaters Anonymous, and Sex Addicts Anonymous. Clinicians often employ 12-step facilitation therapy, an active engagement strategy designed to increase the likelihood that a substance user will join and participate in a 12-step group (NIDA, 2012b).

The 12-step program consists of prescribed beliefs, values, and behaviors. The sequential plan for recovery is stated in 12 steps. It begins with the individual admitting powerlessness over the substance and continues through steps that help individuals take responsibility for addictive behaviors and seek spiritual awakening in community with others. Step work is considered to be a lifelong process, usually facilitated by a peer sponsor. Twelve-step fellowship includes activities such as helping others, building relationships among members, and sharing joys and hardships. The only requirement for membership in 12-step programs is the sincere desire to change the target behavior.

» **Stay Current:** The 12 Steps of Alcoholics Anonymous can be found at http://www.aa.org/assets/en_US/smf-121_en.pdf.

While many clinicians consider 12-step programs to be effective in treating individuals with substance use disorders (NIDA, 2012b), some researchers have found that 12-step groups may yield more modest outcomes (Reif et al., 2014). Studies do support findings that individuals who participate in 12-step programs have reduced relapse rates, increased treatment retention, improved relationships with treatment providers and social supports, and increased participant satisfaction with the overall treatment experience. However, research has uncovered concerns as to whether the benefits of 12-step peer recovery support can be distinguished from those of other concurrent recovery support activities (Reif et al., 2014).

Family Therapy

Family behavior therapy (FBT), which has demonstrated positive results in both adults and adolescents, addresses not only substance use problems but other co-occurring problems as well, including conduct disorders, mistreatment of children, depression, family conflict, and unemployment (NIDA, 2012b). In FBT, the patient and at least one significant other, such as a cohabiting partner or a parent (in the case of adolescents), try to apply the behavioral strategies taught in sessions and acquire new skills to improve the home environment.

In the treatment of adolescents, family involvement can be particularly important, since the adolescent will often be living with at least one parent and be subject to the parent’s controls, rules, and/or supports (NIDA, 2012b, 2014e). Family-based approaches generally address a wide array of problems in addition to the substance problems, including family communication and conflict; co-occurring behavioral, mental health, and learning disorders; problems with school or work attendance; and peer networks. Research shows that family-based treatments are highly efficacious; some studies even suggest they are superior to other individual and group treatment approaches (NIDA, 2014e).

Family-based treatments can be adapted to various settings (e.g., mental health clinics, drug abuse treatment programs, social service settings, families’ homes) and treatment modalities. **Brief strategic family therapy (BSFT)** is based on a family systems approach to treatment, in which one member’s problem behaviors appear to stem from unhealthy family interactions. Over the course of 12 to 16 sessions, the BSFT counselor establishes a relationship with each family member, observes how the members behave with one another, and assists the family in changing negative interaction patterns (NIDA, 2014e). **Functional family therapy (FFT)** combines a family systems view of family functioning (e.g., unhealthy family interactions underlie an individual’s problem behaviors) with behavioral techniques to improve communication, problem-solving, conflict resolution, and parenting skills. Principal treatment strategies include engaging families in the treatment process and enhancing their motivation for change, as well as modifying family members’ behavior using CM techniques, communication and problem solving, behavioral contracts, and other methods (NIDA, 2014e).

Two other types of family therapy have been shown to be effective with adolescents and their families. Both are comprehensive, family-oriented, community-based therapies. **Multidimensional family therapy (MDFT)** has been shown to be effective even with more severe substance use disorders and can facilitate the reintegration of substance abusing juvenile detainees into the community (NIDA, 2014e). **Multisystemic therapy (MST)** has been shown to be effective even with adolescents whose substance abuse problems are severe and with those who engage in delinquent and/or violent behavior. The therapist may work with the family as a whole but will also conduct sessions with just the caregivers or the adolescent alone (NIDA, 2014e).

Pharmacologic Therapy

Pharmacologic therapies are available to treat and prevent symptoms of withdrawal and to treat overdose. Treating symptoms of withdrawal may involve reducing physiologic cravings for the drug of choice, but it may also involve reducing anxiety that serves as a stimulus for using a substance or to prevent dangerous symptoms associated with sudden withdrawal from powerful substances such as sedatives and hypnotics. A number of pharmacologic therapies are available. Many of these, however, have multiple drug interactions and should be used with caution. For example, disulfiram (Antabuse) should never be used during pregnancy and should be used with caution in patients taking phenytoin. See the Medications feature.

Medications

Used to Treat Addiction and Withdrawal Manifestations

CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION	NURSING CONSIDERATIONS
Opioid Antagonists <i>Drug example:</i> Naloxone	Used to treat a narcotic overdose, these drugs block narcotic receptor sites and quickly reverse the effect of the narcotic if administered via IV therapy.	<ul style="list-style-type: none"> Monitor patient condition, including respiratory rate, and anticipate the need for pain management as narcotic effects are reversed.
Benzodiazepines <i>Drug examples:</i> Chlordiazepoxide Diazepam Oxazepam Lorazepam	Diminishes anxiety; anticonvulsant qualities help provide safe withdrawal. May be ordered q4h or prn to manage effects from withdrawal; then dose is tapered to zero.	<ul style="list-style-type: none"> Monitor for oversedation Caution patients not to mix with alcohol; can cause respiratory depression High potential for addiction; should be used for short term only Taper dosage; stopping abruptly may trigger seizures
Abstinence Medications <i>Drug examples:</i> Disulfiram Naltrexone Acamprosate Methadone	Diminishes cravings for alcohol and opioids; blocks cravings for heroin.	<ul style="list-style-type: none"> Disulfiram can cause flushing of the face, headache, vomiting, and other unpleasant sensations if alcohol is consumed. Naltrexone will cause opioid withdrawal if given to an individual who has not detoxed. Methadone is addictive and can be abused. Monitor for cardiac arrhythmias. Overdose can cause respiratory depression, especially if mixed with alcohol.
Antiseizure Drugs <i>Drug examples:</i> Phenytoin Carbamazepine Valproic acid Phenobarbital Magnesium sulfate	Reduces and controls seizure activity resulting from withdrawal syndrome.	<ul style="list-style-type: none"> Implement seizure precautions to maintain patient safety. If a seizure occurs, place a pillow under the patient's head and time the seizure, noting patient behavior during and after the event. Phenobarbital can cause a serious allergic reaction; monitor for hypersensitivity response. Phenobarbital is a teratogen and should not be taken by pregnant women. Magnesium sulfate can cause dizziness; flushing; irregular heartbeat; muscle paralysis or weakness. Patients should be assisted when standing or transferring.
Nicotine Replacement Therapy <i>Drug examples:</i> Nicotine patch Nicotine gum Nicotine lozenge Nicotine nasal spray Nicotine inhaler	Supplies the body with nicotine to support smoking cessation therapy.	<ul style="list-style-type: none"> Patient support is an important element of smoking cessation, and patients benefit from behavior modification teaching in addition to pharmacotherapy.
Antidepressants <i>Drug examples:</i> Bupropion hydrochloride Fluoxetine Sertraline	Some antidepressants have been shown to reduce the craving for nicotine and support smoking cessation programs. Can also be administered to reduce depression occurring as the result of substance withdrawal.	<ul style="list-style-type: none"> Monitor and assess for suicidal ideation. Assess for drug side effects, including drowsiness, insomnia, and blurred vision. Teach patient about self-administration of medications and symptoms to report. Teach patient not to mix drug with alcohol because of increased risk of seizures. Teach patient that antidepressants can take 3–4 weeks to become effective and not to discontinue abruptly; medication should be tapered off.

Medications (continued)

CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION	NURSING CONSIDERATIONS
Nicotine Acetylcholine Receptor Agonists Drug example: Varenicline	Stimulates nicotine receptors more weakly than nicotine itself does, reducing cravings for and decreasing the pleasurable effects of tobacco.	<ul style="list-style-type: none"> Assess for nicotine withdrawal symptoms such as depression, agitation, and exacerbation of preexisting mental health disorders. Suicide and suicidal ideation have been associated with use of varenicline. Assess patients for thoughts of suicide or changes in mood and affect.
Vitamins Drug examples: Thiamine (vitamin B ₁) Folic acid Multivitamins	Prevents alcohol-related Wernicke encephalopathy. Corrects vitamin deficiency caused by heavy, long-term alcohol abuse.	<ul style="list-style-type: none"> May not be absorbed properly in patients with impaired liver function. High-dose folic acid may increase risk of heart attack in some patients. Water-soluble vitamin overdoses can cause nausea and diarrhea.

SAFETY ALERT Drugs of abuse alter the brain's structure and function, resulting in changes that persist long after drug use has ceased. This may explain why individuals with substance use disorders are at risk for relapse even after long periods of abstinence and despite the potentially devastating consequences (NIDA, 2014a).

Lifespan Considerations

Addiction in Children and Adolescents

Research shows that many adolescents start to drink at very young ages. According to data from the 2012 *Monitoring the Future* study (Johnston et al., 2013), over half (54%) of 12th graders and more than one seventh (13%) of 8th graders report having been drunk at least once in their life. In 2012, 24% of 12th graders reported **binge drinking** (having five or more drinks in a row at least once in the prior 2 weeks). The survey also discovered that 1 in 15 (6.5%) high school seniors is a daily, or near-daily, marijuana user. As far as legal cigarettes, 1 in 6 (16%) 8th graders has tried smoking, and nearly 1 in 20 (5%) currently smoke. By 12th grade, more than a third (40%) have tried smoking, and nearly 1 in 6 (17%) is currently smoking.

The brain continues to develop well into the 20s, during which time it continues to establish important communication connections and further refines its function. Brain circuitry involving reward and memory and the prefrontal cortex, which governs emotional regulation and decision making, are still developing. This lengthy developmental period may help explain some of the risk-taking behavior that is characteristic of adolescence. Teenagers are highly motivated to pursue pleasure, but their judgment may be impaired, increasing the adolescent's risk for developing substance abuse. For some adolescents, thrill-seeking may include experimenting with alcohol and drugs. Developmental changes also offer a possible physiologic explanation for why teens act impulsively, often not recognizing that their risky behaviors have consequences.

Addiction in Pregnant Women

Among pregnant women age 15 to 44, 5.4% were current illicit drug users based on data averaged across 2012 and 2013, compared with 11.4% of women in this age group who were not pregnant (CBHSQ, 2015). Current illicit drug use was lower among pregnant women during the third trimester than during the first and second trimesters, with younger pregnant women age 15 to 17 reporting the highest use (CBHSQ, 2015). During 2011–2013, 10.2% of pregnant women reported using alcohol, and 3.2% had engaged in binge drinking in the past 30 days (Tan et al., 2015). By contrast, the prevalences of alcohol use and binge drinking among women who were not pregnant were 53.6% and 18.2%, respectively. Of significance, pregnant women who engaged in binge drinking reported a significantly higher frequency of binge drinking with a larger amount of alcohol consumed than women who were not pregnant (Tan et al., 2015).

Alcohol, nicotine, illicit drugs, and some prescription drugs are considered **teratogens**—agents that interrupt development or cause malformation in an embryo or fetus. Alcohol use during pregnancy can lead to fetal alcohol spectrum disorders (FASDs) and other adverse birth outcomes, while SUD can cause neonates to experience substance dependence and withdrawal symptoms, low birth weight, neurologic issues, developmental delays, and other issues (NIDA, 2015a; Tan et al., 2015). It is generally assumed that pregnant women who use alcohol or illicit drugs during pregnancy are continuing habits formed prior to their pregnancies. For this reason, health promotion related to substance use and abuse is important for all women seeking to become pregnant and at each healthcare interaction with the pregnant woman.

Addiction in Older Adults

Substance abuse in older adults is believed to be underestimated, underidentified, underdiagnosed, and undertreated. Until relatively recently, alcohol and prescription drug misuse, which affects a growing number of older adults, was

not discussed in either the substance abuse or the gerontologic literature. For example, alcohol use disorders affect 1 to 3% of older adults. But researchers believe that might still be an underestimate (Caputo et al., 2012).

Insufficient knowledge, limited research data, and hurried office visits are cited as causes for why healthcare providers often overlook substance abuse and misuse in this population. Diagnosis is often difficult because symptoms of substance abuse in older individuals sometimes mimic symptoms of other medical and behavioral disorders common among older adults, such as diabetes, dementia, and depression. In addition, many older adults do not seek treatment for substance abuse because they do not feel they need it (Hazelden Betty Ford Foundation, 2015).

Impaired Nurses

In 1982, the American Nurses Association (ANA) passed a resolution addressing alcohol and drug misuse and psychologic problems among nurses, with the intention of shifting the focus from punishment to rehabilitation. In 2002, the ANA adopted an updated resolution that called attention again to impaired nursing practice, stressing the need for peer assistance programs (Heise, 2003). The ANA currently joins with the International Nurses Society on Addictions to emphasize its commitment to the peer assistance programs offered by most—but not all—of the state boards of nursing. These programs offer comprehensive monitoring and support services to reasonably ensure the safe rehabilitation and return of the nurse to her or his professional community (ANA, 2015).

Healthcare providers are as susceptible as anyone else to developing substance abuse. By the very nature of their roles, dentists, pharmacists, physicians, and nurses are in frequent contact with drugs and are at high risk for substance abuse

problems. As a rule, nurses experience many pressures in the workplace and have easy access to drugs. The American Nurses Association estimates that 10% of all nurses may be impaired or in recovery from alcohol or drug addiction; other researchers suggest that as many as 20% may have substance abuse issues (Starr, 2015). They also reported that the two best predictors of successful recovery from addiction are the length of treatment and the willingness of the nurse. Nurses who remained in treatment for at least a year are twice as likely to be drug free.

Substance abuse and dependence can lead to impaired professional practice; therefore, nurses must act responsibly when coworkers display signs of substance abuse. The American Nurses Association Code of Ethics for Nurses provides a framework for patient safety. Four suggestions for implementing its philosophy are:

1. Do not ignore poor performance.
2. Do not lighten or change the nurse's patient assignment.
3. Do not accept excuses.
4. Do not allow yourself to be manipulated or fear confronting a nurse if patient safety is in jeopardy (Thomas & Siela, 2011).

If nurses are showing signs of a substance abuse problem, their colleagues can find information about impaired nurse programs through state boards of nursing. Warning signs of impaired nurses in the workplace are listed in **Table 22-3** ».

The ANA (2015) has stated that nurses with substance abuse problems not only pose a potential threat to those for whom they care, but they also tend to neglect their own health and well-being. Nurses with addiction issues may be reluctant to report themselves because of shame, guilt, or fear of job loss. The ANA encourages nurses to self-report

TABLE 22-3 Warning Signs of Impaired Nurses in the Workplace

At-Risk Situations	Observable Warning Signs
Easy access to prescription drugs	Inaccurate narcotic counts or drugs frequently missing Patient complaints of ineffective pain control, denial of having received pain meds Excessive "wasting" of drugs Likelihood of volunteering to give medications to patients Frequent trips to the bathroom
Role strain	Frequent tardiness or absenteeism, especially before and after scheduled days off Haphazard, shoddy charting Judgment errors in patient care Unorganized, erratic behavior; unkempt appearance
Depression	Irritability, unable to focus or concentrate Abrupt mood swings Isolating self, taking long breaks Apathetic, depressed, lethargic Unexplained absences from assigned unit
Signs of alcohol or drug use	Smell of alcohol on breath Excessive use of perfumes, mouthwash, or mints Slurred speech, flushed face, reddened eyes, unsteady gait Long sleeves worn in hot weather to cover up arms
Signs of withdrawal	Tremors, restlessness, sweating Watery eyes, runny nose, stomachaches

and contact peer assistance programs offered by their state nursing organization or state board of nursing. Most state nurses' associations have peer assistance programs. Resources vary by state, but generally are accessible through each state association's website. Many state boards of nursing offer programs designed to guide nurses to sobriety, rather than instituting immediate disciplinary consequences. In addition, larger agencies may offer programs for employees, including employee assistance programs and support groups. Regardless, nurses who feel they are developing a substance abuse problem are ethically required to seek help in order to prevent mistakes in the workplace.

Case Study » Part 3

It is 36 hours post-ED admission, and Paul is being transferred from the trauma unit to a semiprivate room on a general medical-surgical unit. The scalp laceration is healing; there is no evidence of head injury. Paul's right humerus was fractured in the crash and a cast applied following a closed reduction. Laboratory studies revealed a blood alcohol level of 0.28 on admission. Paul now appears mildly anxious and has a mild visible tremor of his hands. He is being prepared for discharge

tomorrow. Admission to a substance abuse treatment program is being considered.

Clinical Reasoning Questions Level I

1. List at least three nursing diagnoses that would apply to Paul.
2. What members of the interprofessional (IP) healthcare team should be involved in Paul's care and discharge planning? Delineate the role of each team member.
3. Consider the impact of Paul's addiction on him and on his entire family.
4. Can Paul be treated independently of his family?
5. Give some specific examples of how family involvement could be planned by members of the IP team.

Clinical Reasoning Questions Level II

6. Identify comprehensive, measurable long-term treatment goals for Paul and his family.
7. Discuss inpatient, outpatient, and community treatment options for Paul and his family. Consider the advantages and disadvantages of each.
8. Consider the impact of cognition (both Paul's and his family's) in Paul's long-term treatment plan.
9. What lifestyle changes may be necessary for Paul and his family?

REVIEW The Concept of Addiction

RELATE Link the Concepts

Linking the concept of addiction with the concept of family:

1. In a family with rigid boundaries—those in which rules and roles remain fixed under all circumstances—what approach(s) might be optimal for gaining trust in and building a therapeutic relationship?
2. Considering the many treatment options for those with addictions, design a comprehensive treatment plan to meet the needs of a family such as the one that we have been exploring through our case study, the John family.

Linking the concept of addiction with the concept of immunity:

3. Dietary support is an essential component of recovery. Describe the diagnostic assessment for deficiencies in the B-complex vitamins, particularly thiamin, folate, and B₁₂, and the fat-soluble vitamins, A, D, and E.
4. Why are individuals with addictions prone to opportunistic infection?

REFLECT Apply Your Knowledge

George Brown is a 68-year-old man, in apparent good health with unremarkable lab work, who came to the ambulatory surgery center for elective gallbladder surgery. During the laparoscopic surgery, which started at 1 p.m., the surgeon noted some inflammation that made visualization of the gallbladder difficult. There was also more bleeding than expected. The surgeon converted the surgery into an open cholecystectomy, and the procedure was finished without any further issues.

After recovery in the perianesthesia unit, Mr. Brown is sent to the medical-surgical floor and arrives on the floor at 7:30 p.m. His wife joins him and remains at the bedside until 11 p.m. Aside from some occasional pain at the incision site, which is treated successfully with oral oxycodone/acetaminophen, Mr. Brown spends most of the night resting. On postoperative day 1, he is to ambulate. He receives two remaining doses of intravenous antibiotics because of the open surgery. If Mr. Brown progresses as anticipated, the surgeon expects to discharge him in the early evening.

When the day-shift nurse makes her initial morning assessment, Mr. Brown is restless but alert and oriented × 4. At 12 p.m., he is extremely restless, but knows he is in the hospital and reports some pain at the incision site. At 4 p.m., Mr. Brown is trying to get out of bed and leave the hospital; he knows who he is but thinks he is in the men's room at a local sports arena. By the time Ms. Brown arrives at 6:30 p.m., Mr. Brown is agitated and aggressive, trying to hit anyone approaching his bed. The attending physician is notified, and her adult nurse practitioner (ANP), who is rounding in the hospital, comes to Mr. Brown's room. After looking at recent vital signs of T 99.9°F, HR 110, and BP 165/98, the ANP orders a dose of intramuscular ziprasidone for agitation. After vigorously objecting to the shot, Mr. Brown eventually calms somewhat, but his eyes dart around the room and he hisses and startles occasionally, throwing his hands over his head. When asked, he reports seeing buzzards in the room. The ANP asks the night-shift nurse (who requests the CNA to stay with Mr. Brown while she left the room) and Ms. Brown to join her in a small family meeting room.

During the conference, the ANP states that she suspects Mr. Brown was going into alcohol withdrawal delirium. She asks

Ms. Brown about his social history. Ms. Brown reports that she and her husband moved to a nearby upscale retirement community 6 or 7 years ago. Mr. Brown had been suddenly retired from the investment firm he worked at in Chicago, when the company collapsed during the recession and was acquired by a competitor. Ms. Brown shares that they lost about a third of their retirement savings, but the move to a southern state stabilized their living expenses and they are now “comfortable.” Mr. Brown had worked at his job for 35 years, was devoted to the company, and enjoyed his job. He was “devastated” when his job ended and was “anguished” when executives of his former company were vilified in the financial press for bad business decisions. Since his move, Mr. Brown has been a “little down,” but he has thrown himself into charitable endeavors, serving on a number of boards and committees. Ms. Brown says that her husband is a

“moderate” social drinker, who drinks four large vodka tonics every night and never appears to be drunk. She seems surprised that the ANP thinks her husband is withdrawing from alcohol.

1. Why do you think the ANP immediately suspected alcohol withdrawal? What were the clues that led her in that direction?
2. Do you think Mr. Brown has some unresolved psychosocial issues from his forced retirement? Are there any underlying mental health issues that may need treatment?
3. What will likely happen to Mr. Brown now? How will his hospital plan of care change? What orders are commonly on a detox protocol?
4. What will be Mr. Brown's discharge plan after he has been stabilized in the hospital? What will be Ms. Brown's role?

Exemplar 22.A Alcohol Abuse

Exemplar Learning Outcomes

22.A Analyze the manifestations and treatment considerations for patients who abuse alcohol.

- Describe the pathophysiology of alcohol abuse.
- Describe the etiology of alcohol abuse.
- Compare the risk factors and prevention of alcohol abuse.
- Identify the clinical manifestations of alcohol abuse.
- Identify the clinical manifestations of alcohol withdrawal.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with an alcohol use disorder.
- Differentiate the care of patients across the lifespan who abuse alcohol.
- Apply the nursing process to promote patient safety during withdrawal and detoxification.
- Apply the nursing process in providing culturally competent care to an individual with alcohol use disorder.

Overview

Alcohol includes liquor, beer, and wine. While much of society sees the use of nicotine and drugs as inappropriate, use of alcohol is still socially acceptable and often encouraged. Alcohol is frequently offered at weddings and other family events, beer is the favorite drink at sports venues across the country, and many grocery stores and restaurants now offer weekly or monthly wine tastings. Alcohol's availability may be the primary reason it is the most commonly used and abused substance in the United States. The most recent estimate of the economic costs of alcohol abuse in the United States is \$235 billion (CDC, 2015c). These costs result from losses in workplace productivity, healthcare expenses for problems caused by excessive drinking, law enforcement and other criminal justice expenses related to excessive alcohol consumption, and motor vehicle crash costs from impaired driving (CDC, 2015c).

In 1992, the Joint Committee of the National Council on Alcoholism and Drug Dependence and the American Society of Addiction Medicine defined **alcoholism** as a “primary, chronic disease with genetic, psychosocial, and environmental

factors influencing its development and manifestations” (Morse & Flavin, 1992). It is characterized by the behaviors discussed in the Concepts section of this module: inability to control the primary addictive behavior (drinking), fixation with the drug and continued use of it regardless of consequences, and impaired thought processes. The terms *alcoholism*, *alcohol abuse*, and *alcohol use disorder* are often used interchangeably. However, it should be noted that an individual can abuse alcohol to the extent that it impairs function and results in life-threatening symptoms without developing addiction behaviors or dependency. Alcoholism and **alcohol use disorder** more specifically refer to a chronic disease process with specific, identifiable manifestations and patterns. Clinicians following the guidelines of the American Society of Addiction Medicine may be more likely to use the term *alcoholism*, whereas those adhering to the DSM-5 may be more likely to use the term *alcohol use disorder*. Nurses working in all settings should be able to identify acute manifestations of both abuse and withdrawal, as well as patterns of dependence.

The pattern of **alcohol dependence** varies from person to person. Seven in 10 adults in the United States always drink

Figure 22-3 » One standard drink = $\frac{1}{2}$ oz of ethyl alcohol.

at low-risk levels or do not drink at all (NIAAA, 2015a). Low-risk drinking is defined as no more than 4 drinks on any one day/no more than 14 drinks per week for men, and no more than 3 drinks on any one day/no more than 7 drinks per week for women (NIAAA, 2015a). The measurement of a standard drink is shown in **Figure 22-3** ». Some people regularly drink large amounts of alcohol daily. Others restrict their use to heavy drinking on weekends or days off from work, often drinking copious amounts in a single session, a pattern of consumption known as **binge drinking**. Binge alcohol use is defined as drinking five or more drinks on the same occasion on at least 1 day in the past 30 days. Heavy alcohol use is defined as drinking five or more drinks on the same occasion on 5 or more days in the past 30 days (CBHSQ, 2014). Many individuals who engage in binge drinking begin doing so in college: College alcohol consumption has been linked with harmful consequences such as alcohol poisoning, drug overdoses, sexual assaults, and alcohol-impaired driving, which accounts for the majority of alcohol-related deaths among college students nationwide (NIAAA, 2015b).

Some people are able to abstain for long periods of time and then begin dysfunctional drinking patterns again. At times, individuals with alcohol dependence can drink with control; at other times, they cannot control their drinking behavior. As the course of alcoholism continues, addiction behaviors appear with increasing frequency. These may include starting the day off with a drink, sneaking drinks throughout the day, shifting from one alcoholic beverage to another, and hiding bottles at work and at home. An individual with alcoholism may find that drinking—or being sick from drinking—has often interfered with home or family duties, caused trouble at school or work, and created legal difficulties resulting from impaired driving (NIAAA, 2015a).

» **Stay Current:** Visit the website of the National Institute on Alcohol Abuse and Alcoholism to see current research on alcohol dependence: <http://www.niaaa.nih.gov/research>.

Pathophysiology and Etiology

In 2014, a total of 139.7 million Americans age 12 or older reported current use of alcohol, 60.9 million reported binge

alcohol use in the past month, and 16.3 million reported heavy alcohol use in the past month (CBHSQ, 2015). Long-term alcohol use contributes to more than 200 diseases and injury-related health conditions, including alcohol dependence, liver cirrhosis, cancers, and injuries. In 2012, 5.1% of the burden of disease and injury worldwide (139 million disability-adjusted life years) was attributable to alcohol consumption (NIAAA, 2015a).

Approximately 8.7 million people age 12 to 20 reported drinking alcohol, with some 5.3 million reporting binge drinking and 1.3 million reporting heavy alcohol use (CBHSQ, 2015). It is critical to understand the extent of alcohol use among those who are not of drinking age, because the negative consequences can be serious. In younger users, negative outcomes from alcohol use include interference with normal adolescent brain development, increased risk of developing an alcohol use disorder (AUD), sexual assaults, and injuries (NIAAA, 2015c). Among college-age alcohol users, negative consequences related to alcohol use include motor-vehicle crashes, assault by another student who has been drinking, alcohol-related sexual assault or date rape, and potential for developing an AUD (roughly 20% of college students do meet the criteria for an AUD). About 1 in 4 college students report academic consequences from drinking (NIAAA, 2015c).

Pathophysiology

Alcohol is a CNS depressant; as such, it acts on neurotransmitters in the brain, such as gamma-aminobutyric acid (GABA). GABA, the most prevalent inhibitory neurotransmitter in the brain, has a major role in decreasing neuronal excitability. Alcohol creates an additive effect with GABA, further inhibiting arousal and depressing the autonomic nervous system. Alcohol decreases glutamate activity, a major excitatory neurotransmitter. This may explain why cross-tolerance effects occur when alcohol and other CNS depressants are used in combination. When taken together, alcohol and other CNS depressants (e.g., benzodiazepines and barbiturates) can lead to respiratory depression and death.

Alcohol is absorbed in the mouth, stomach, and digestive tract. The liver metabolizes approximately 95% of the

ingested alcohol; the rest is excreted via the skin, kidneys, and lungs. Generally, an individual can break down approximately 1 ounce of whiskey every 90 minutes. Factors such as body mass, food intake, and liver function can affect the rate of alcohol absorption.

Etiology and Epidemiology

Alcoholism is a complex disorder with many pathways leading to its development. Research has long suggested that certain people develop a different, more powerful relationship with alcohol than others. Researchers believe that genetic and other biological factors significantly influence the development of alcohol dependence, along with cognitive, behavioral, temperament, psychologic, and sociocultural factors. Alcohol use patterns, including alcohol abuse and alcohol dependence, are familial in nature, with genetics making up 50% of the risk for alcohol and drug dependence (NIAAA, 2015b). Similar styles of alcohol use and the presence of alcoholism are often found within the same family, running from parent to child and across multiple generations of biologically related individuals (NIAAA, 2015b).

Culturally, there are ethnic differences in alcohol use. In 2013, Whites were more likely than other racial/ethnic groups to report current use of alcohol (57.7%). The rates were 47.4% for persons reporting two or more races, 43.6% for Blacks, 43.0% for Hispanics, 38.4% for Native Hawaiians or other Pacific Islanders, 37.3% for American Indians or Alaska Natives, and 34.5% for Asians (CBHSQ, 2015). Researchers have examined biological differences among ethnic groups, including the effect of alcohol-metabolizing genes on drinking behaviors and the health effects of alcohol consumption in populations with health disparities, with no findings that have translated into treatment interventions (NIAAA, 2015c). Cultural factors such as poverty, geographic isolation, unemployment, difficulty in acculturation, social disadvantage, and alcohol availability also are significant factors that account for ethnic variability in alcohol abuse.

Mood and substance use disorders commonly co-occur with alcoholism (Pettinati, O'Brien, & Dundon, 2013). *Dual diagnosis* and *dual disorder* are older terms used to describe an individual who has both a diagnosis of substance abuse and a mental illness. For example, an individual with a depressive disorder may self-medicate with alcohol to treat the depression, or someone with alcoholism may become depressed. Research has found that medications for managing mood symptoms can be effective in individuals with substance abuse; however, these medications have not been found to impact the substance use disorder. One clinical study did find that combining one medication for depression with another for alcohol dependence reduced both the depression and the drinking simultaneously (Pettinati et al., 2013).

Risk Factors and Prevention

Native Americans experience alcoholism at higher rates than other populations. Genetics is a major contributing factor to Native American risk for alcohol abuse. Researchers found an overlap in the gene location for addiction and for the body mass index (BMI). This suggests that the combination could produce a "disorder of consumption." Native Americans also do not have the genes that alter alcohol-metabolizing enzymes, and they lack protective variants

found in other groups. Native Americans' genes are associated with risk factors for drug sensitivity or tolerance. Specific environmental factors also contribute to an elevated risk for addiction among Native Americans. These include trauma exposure, early onset of use of substances, and environmental hardship (Ehlers & Gizer, 2013).

Sociocultural factors influence risk for alcohol abuse. Demographic characteristics that have been associated with higher rates of substance misuse include lower educational levels and not marrying by age 30. Becoming parents is associated with lower rates of substance misuse for both men and women. For successful prevention efforts, attention should be directed to the finding that the patterns of substance misuse were consistent and already observed by age 18 (Oesterle, Hawkins, & Hill, 2011). There is some evidence that stigma or discrimination may contribute to increased risk for alcohol abuse. Research has indicated that, when compared with the general population, LGBT (lesbian, gay, bisexual, and transgender) individuals are more likely to use alcohol and drugs, have higher rates of substance abuse, are less likely to abstain from use, and are more likely to continue heavy drinking into later life (SAMHSA, 2012a). Despite the fact that homosexuality is now considered a normal variation of human sexual and emotional expression, LGBT individuals experience discrimination and trauma at higher rates than other populations. Nurses should be careful to take a nonpathologic and nonprejudicial view of the LGBT community and, during assessment, sensitively explore for histories of trauma and alcohol and other substance abuse.

Another area that has received much research attention is that of the children of alcoholics (COAs). A study that contrasted the lifestyles of COAs with those who did not have that history found that COAs' families had higher unemployment rates. Even after controlling for their lower socioeconomic status, the COAs had significantly more mental health difficulties and a higher rate of substance use compared to the controls. Unhealthy lifestyle habits (e.g., lack of exercise, eating fast food, other poor food choices) were significantly more prevalent for COAs than for the controls. Female COAs reported more emotional and somatic symptoms than male COAs (Serec et al., 2012).

Clinical Manifestations of Alcohol Abuse

When used in moderation, certain types of alcohol can have positive physiologic effects by decreasing coronary artery disease and protecting against stroke. However, when consumed in excess, alcohol can lead to **craving** (a strong desire or urge to use alcohol), can severely diminish one's ability to function, and can ultimately lead to life-threatening conditions (APA, 2013).

Behavioral signs of alcohol abuse include (Mayo Clinic, 2015a):

- Being unable to limit the amount of alcohol consumed
- Trying to decrease the amount consumed with variable success
- Spending a lot of time drinking, getting alcohol, or recovering from alcohol use

- Feeling a strong craving or urge to drink alcohol
- Failing to fulfill major obligations at work, school, or home due to repeated alcohol use
- Continuing to drink alcohol even when it causes physical, social, or interpersonal problems
- Giving up or reducing social and work activities and hobbies
- Using alcohol in situations in which it is not safe, such as when driving or swimming

Some physiologic symptoms are developing a tolerance to alcohol so that the individual needs more alcohol to feel its effect or having a reduced effect from the same amount and experiencing withdrawal symptoms—such as nausea, sweating and shaking—when not consuming alcohol or drinking to avoid these symptoms (Mayo Clinic, 2015a).

Alcohol Intoxication and Overdose

Alcohol intoxication is the presence of clinically significant behavioral or psychologic changes due to alcohol use. Changes may include any combination of inappropriate sexual or aggressive behavior, mood lability, impaired judgment, and impaired social or occupational functioning (APA, 2013). Signs of alcohol intoxication include nausea, vomiting, lack of coordination, slurred speech, staggering, disorientation, irritability, short attention span, loud and frequent talking, poor judgment, lack of inhibition, and (for some) violent behavior. Alcohol intoxication may result in accidents or falls that cause contusions, sprains, fractures, and facial or head trauma. Evidence of mild intoxication can be seen after two drinks, with signs and symptoms of intoxication becoming more intense as the blood alcohol level (BAL or EtOH) increases (APA, 2013). High BALs may result in unconsciousness, coma, respiratory depression, and death.

Alcohol poisoning is a toxic condition that results from excessive consumption of large amounts of alcohol in a very short period of time. At BALs greater than 300 mg/dL, the symptoms of intoxication become greatly intensified. Signs and symptoms of alcohol poisoning include excessive sleepiness; amnesia; difficulty waking the patient; coma; serious decreases in pulse, temperature, blood pressure, and rate of breathing; urinary and bowel incontinence; and, eventually, death (APA, 2013). Advanced states of intoxication and alcohol poisoning are critical situations in the ED and necessitate careful triage and monitoring to prevent death or permanent disability.

BALs are highly predictive of CNS effects. At 0.10%, ataxia and dysarthria occur. From 0.20 to 0.25%, the person is unable to sit or stand upright without support. Between 0.3 and 0.4%, slipping into a coma is possible. Toxic levels in excess of 0.5% can cause death. Note that individuals with chronic alcoholism might have BALs in these ranges, but not have the same consequences, because of their developed tolerance to the effect of drinking (McNeece & DiNitto, 2012). In the United States, the legal level of intoxication is 0.08%.

Consequences of Chronic Use

Chronic use of alcohol can cause severe neurologic and psychiatric disorders. Severe damage to the liver occurs with

chronic alcohol abuse, and that damage can progress from fatty liver to other liver diseases such as hepatitis and cirrhosis. Chronic alcoholism is the major cause of fatal cirrhosis. Chronic abuse of alcohol also can cause damaging effects to many other systems. These effects include myocardial disease, erosive gastritis, acute and chronic pancreatitis, sexual dysfunction, and an increased risk of breast cancer.

Malnutrition is another serious complication of chronic alcoholism. Thiamine (B_1) deficiency in particular can result in neurologic impairments, such as Wernicke-Korsakoff syndrome (WKS). WKS typically consists of two components, a short-lived and severe condition called Wernicke encephalopathy (WE), and a long-lasting and debilitating condition known as Korsakoff psychosis (Martin, Singleton, & Hiller-Sturmhöfel, 2015). WE is an acute life-threatening neurocognitive disorder with symptoms that include mental confusion, paralysis of the nerves that move the eyes, and impaired coordination (e.g., ataxia). Approximately 80 to 90% of individuals with WE develop Korsakoff psychosis, a chronic neuropsychiatric syndrome characterized by behavioral abnormalities and memory impairments. Patients with Korsakoff psychosis have difficulties remembering old information; they are also unable to acquire new information (Martin et al., 2015). They also frequently use **confabulation**, making up information to fill in memory blanks.

Another common consequence of thiamine deficiency and long-term alcohol consumption is cerebellar degeneration, caused by atrophy of certain regions of the cerebellum, the brain area involved in muscle coordination. Cerebellar degeneration is associated with difficulties in movement coordination and involuntary eye movements, such as nystagmus. Cerebellar degeneration is found both in alcoholics with WKS and in those without it (Martin et al., 2015).

Chronic consumption of alcohol not only produces tolerance, but it creates cross-tolerance to general anesthetics, barbiturates, benzodiazepines, and other CNS depressants. If alcohol is withdrawn abruptly, the brain becomes overly excited because previously inhibited receptors are no longer inhibited. This hyperexcitability manifests clinically as anxiety, tachycardia, hypertension, diaphoresis, nausea, vomiting, tremors, sleeplessness, and irritability. Severe manifestations of alcohol withdrawal include seizures, convulsions, and DTs. Complications of DTs include respiratory failure, aspiration pneumonitis, and cardiac arrhythmias.

Multisystem Effects

Alcohol is a chemical irritant that has a direct toxic effect on many organ systems. For example, toxic effects of alcohol on the liver may include alcoholic hepatitis, cirrhosis, cancer, hepatomegaly, and fatty liver. Alcohol dependence increases the individual's risk for pneumonia, bronchitis, and tuberculosis. In addition to the CNS effects already described, alcohol abuse can result in seizures, neuropathies, sleep disturbances, and alcoholic dementia. Alcohol abuse can also cause erectile problems, decreased testosterone, decreased sex drive, and menstrual irregularities.

Alcohol Abuse and Memory

Alcohol primarily interferes with the ability to form new long-term memories. Large amounts of alcohol, particularly

Clinical Manifestations and Therapies

Alcohol Abuse

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
DTs as a result of sudden withdrawal of alcohol	<ul style="list-style-type: none"> Confusion Disorientation Agitation Severe autonomic instability Perceptual disturbances Hallucinations (primarily visual but may be tactile) Tremors of extremities Anxiety, panic, and paranoia 	<ul style="list-style-type: none"> Prescribe benzodiazepines. Reduce stimuli, but keep well lit to minimize visual misinterpretations. If present, treat with antiseizure medications.

Perform emergency surgery to stop bleeding, involving removal of part of the esophagus or cauterization of varicosities. Perform therapeutic endoscopy. Monitor intake and output. Take vital signs frequently during bleeding episodes to monitor for shock. Administer fluids via IV therapy. Administer beta-blockers if necessary to reduce incidence of bleeding.
Gastritis	<ul style="list-style-type: none"> Esophageal reflux Decreased appetite Recurrent diarrhea 	<ul style="list-style-type: none"> Provide foods that will not exacerbate GI symptoms while meeting nutritional requirements. Teach patient to remain upright for 3–4 hours following meals, eat small frequent meals, and avoid gas-producing foods. Antidiarrheals, antacids, and H₂ blockers may be appropriate medications to reduce symptoms.
Wernicke encephalopathy	<ul style="list-style-type: none"> Ataxia Abnormal eye movements Mental confusion Short-term memory loss 	<ul style="list-style-type: none"> Provide for patient safety. Place clocks and calendars to reduce mental confusion. Assess cognition and document findings. Administer IV or IM thiamine. Avoid glucose administration until after thiamine administration. Hydrate patient.

if consumed rapidly, can produce partial or complete **blackouts**, periods of memory loss for events that occurred while a person was drinking. Blackouts are much more common among social drinkers—including college drinkers—than was previously assumed, and blackouts have been found to encompass events ranging from conversations to sexual intercourse (White, 2015). Mechanisms underlying alcohol-induced memory impairments include disruption of activity in the hippocampus, a brain region that plays a central role in the formation of new memories (White, 2015). A more advanced CNS problem is Wernicke-Korsakoff syndrome, described previously.

Dementia occurs five times more often in older adults with alcoholism than in nondrinkers. On the plus side, prevention of drinking relapse in older adults with alcoholism is often better than that of younger patients. More than 20% of treated older alcohol-dependent individuals remain abstinent after 4 years (Caputo et al., 2012).

Alcohol Withdrawal

Mild alcohol withdrawal generally consists of anxiety, irritability, difficulty sleeping, and decreased appetite. The signs and symptoms of acute alcohol withdrawal generally start 6 to 24 hours after the individual takes the last drink. Alcohol withdrawal may begin when the patient still has significant blood alcohol concentrations. The signs and symptoms of acute alcohol withdrawal (**alcohol withdrawal syndrome**) may include the following: agitation; anorexia (lack of appetite), nausea, vomiting; tremor (shakiness), elevated heart rate, increased blood pressure; insomnia, intense dreaming, nightmares; poor concentration, impaired memory and judgment; increased sensitivity to sound, light, and tactile sensations; hallucinations (auditory, visual, or tactile); delusions, usually paranoid or persecutory; grand mal seizures, resulting in loss of consciousness, brief cessation of breathing, and muscle rigidity; hyperthermia; delirium with disorientation; and fluctuation in level of consciousness (SAMHSA, 2015b).

Alcohol withdrawal delirium, sometimes referred to as delirium tremens (DTs), usually occurs on days 2 and 3 but may appear as late as 14 days after the last drink consumed. The major goal of medical management is to avoid seizures and DTs, typically with aggressive use of higher doses of benzodiazepines coupled with antiseizure medications (SAMHSA, 2015b). DTs do not develop suddenly, but instead progress from earlier withdrawal symptoms. Properly administered medication and adherence to detoxification protocols will prevent DTs and limit possible overmedication (SAMHSA, 2015b). During acute withdrawal, the individual experiences confusion, disorientation, hallucinations, tachycardia, hypertension or hypotension, extreme tremors, agitation, diaphoresis, and fever. Death may result from cardiovascular collapse or hyperthermia. With intensive care and advanced pharmacology, the mortality rate related to alcohol withdrawal syndrome has dropped from 35% to 5% (Burns, 2013).

Collaboration

When caring for a patient who abuses alcohol, the nurse must work as a collaborative member of a team that may include physicians, psychologists, counselors, nutritionists,

and assistive personnel who share the collaborative goal of helping the patient achieve sobriety. Many individuals seeking recovery work with a sponsor, a recovering alcoholic with several years of sobriety. Sponsors provide peer support and often attend AA or 12-step meetings with the individuals whom they sponsor.

Diagnostic Tests

The simplest method of detecting blood alcohol content is by using a Breathalyzer. BALs are the main biologic measures for assessment purposes. Knowledge of the symptoms associated with a range of BALs is helpful in ascertaining level of intoxication, level of tolerance, and whether the individual accurately reported recent drinking. At 0.10% (after 5–6 drinks in 1–2 hours), voluntary motor action becomes clumsy, resulting in ataxia and dysarthria. The degree of impairment varies with gender, weight, and food ingestion. Small women who drink alcohol on an empty stomach achieve intoxication more quickly than large men who have eaten a full meal. At 0.20 to 0.25% (after 10–12 drinks in 2–4 hours), function of the motor area in the brain is depressed, causing an inability to remain upright (McNeece & DiNitto, 2012). A level above 0.10% without associated behavioral symptoms indicates the presence of tolerance. High tolerance is a sign of physical dependence.

Assessing for withdrawal symptoms is important when the BAL is high. Medications given for treatment of withdrawal from alcohol are usually not started until the BAL is below a set norm (usually below 0.10%) unless withdrawal symptoms become severe. Measurement of BAL may be repeated several times, several hours apart, to determine the body's metabolism of alcohol and at what time it is safe to give the patient medication to minimize the withdrawal symptoms.

Biomarkers are lab tests that suggest heavy alcohol consumption by detecting the toxic effects that alcohol may have had on organ systems or body chemistry. Included in this class are the serum measures of gamma glutamyl transferase (GGT), aspartate amino transferase (AST), alanine amino transferase (ALT), and mean corpuscular volume (MCV) (SAMHSA, 2012b). The first three are serum enzymes produced by the liver. GGT elevation is often caused by liver enzyme induction by alcohol, liver damage, or many drugs, including prescription medications. Another indirect alcohol biomarker is carbohydrate-deficient transferrin (CDT); an elevation in CDT can indicate heavy alcohol consumption. Other biomarker laboratory tests include ethyl glucuronide (EtG) and ethyl sulfate (EtS), usually measured in urine. EtG and EtS are frequently used to monitor abstinence in clinical and justice system settings (SAMHSA, 2012b).

Treatment of Withdrawal

All CNS depressants, including alcohol, benzodiazepines, and barbiturates, have a potentially dangerous progression of withdrawal. Alcohol and the entire class of CNS depressants share the same withdrawal syndrome. Treatment of severe withdrawal during detoxification is mostly symptomatic through acetaminophen, vitamins, and medications to minimize discomfort.

In managing alcohol withdrawal, the goal is to minimize adverse outcomes such as patient discomfort, seizures, delirium tremens, and mortality and to avoid the adverse effects of withdrawal medications, such as excess sedation. Close monitoring is essential to ensure protection of the patient. Critical care monitoring may be indicated to manage alcohol withdrawal delirium, particularly when very high doses of benzodiazepines are needed or when significant concurrent medical conditions are present. Medications such as benzodiazepines are a first-line therapy, used to minimize the discomfort associated with alcohol withdrawal and to prevent serious adverse effects, particularly seizures (Manasco et al., 2012).

Clinicians may order one of several treatment approaches, including fixed-schedule dosing, symptom-triggered dosing, or a combination of the two. The Clinical Institute Withdrawal Assessment for Alcohol—Revised (CIWA-Ar) scale is currently recommended as the best scale for assessing the severity of symptoms of acute alcohol withdrawal (Manasco et al., 2012). Triage nurses can use that scale to determine the need for inpatient hospital admission, such as when the CIWA-Ar score is 10 points or higher. However, recent research indicates that the CIWA-Ar scale may underestimate the severity of alcohol withdrawal syndrome in certain ethnic groups, such as Native Americans (Rappaport et al., 2013).

SAFETY ALERT Close attention to vital signs and presence of withdrawal symptoms is essential when a patient is withdrawing from alcohol. Trending the vital signs and CIWA-Ar scores over time can often show when an individual may be heading into *delirium tremens* (DTs). Preventive steps, such as aggressive use of prn medications and application of protocols, should be used to prevent DTs from occurring.

Two unique medications used to treat alcoholism are disulfiram (Antabuse) and naltrexone (ReVia, Depade). Disulfiram is a form of aversion therapy that prevents the breakdown of alcohol, causing physical illness (intense vomiting) if taken while drinking alcohol. All forms of alcohol, including over-the-counter cough and cold preparations, must be avoided. Naltrexone can help reduce the craving for alcohol by blocking the pathways to the brain that trigger a feeling of pleasure when alcohol and other narcotics are used. Because naltrexone blocks opiate receptors, patients should avoid taking any narcotics, such as codeine, morphine, or heroin, while on naltrexone. Patients also should discontinue all narcotics 7 to 10 days before starting on naltrexone; naltrexone taken while the individual is still on opioids will trigger withdrawal. It also is recommended that patients wear a medical alert bracelet stating that they are on naltrexone, in case of emergency medical treatment. Patients taking disulfiram or naltrexone must also participate in psychosocial treatments such as AA meetings, individual counseling, or group therapy because the desire to “take a break” from treatment can overcome the patient’s motivation to continue taking the medication. AA meetings and therapy provide support and reinforce patients’ efforts to continue treatment. Peer connections made through AA can be especially motivating.

Complementary Health Approaches

Alternative and complementary therapies are not usually employed as stand-alone methods for alcohol withdrawal. They are, however, generally used in a comprehensive, integrated substance abuse treatment system that promotes health and well-being, provides palliative symptom relief, and improves treatment retention (SAMHSA, 2015b). Acupuncture has been used to reduce the craving for a variety of substances, including alcohol, and appears to contribute to improved treatment retention rates. While electroencephalograph (EEG) biofeedback, also called *neurotherapy*, and herbal administration have been found to provide some benefit in the treatment of alcoholism, their use has not been supported by controlled studies (SAMHSA, 2015b). Many individuals addicted to alcohol also have found yoga to be helpful in the recovery process. Both neurotherapy and yoga may provide calming effects on the centers of the brain involved in anxiety and impulse control.

Lifespan Considerations

In recent years, alcohol researchers have focused their efforts on discovering the differences in how alcohol affects individuals at different ages, using subsequent findings to determine appropriate interventions and treatment protocols. Some of the characteristics of various ages and gender differences throughout the lifespan are detailed in this section.

Alcohol Abuse Among Adolescents

More youth in the United States drink alcohol than smoke tobacco or marijuana, making it the drug most used by American young people. The percentage of adolescents age 12 to 17 who were current alcohol users was 11.5% in 2014, which translated to 1 in 9 adolescents who were current alcohol users during that year. Nationally, 1 in 16 adolescents (1.5 million) engaged in binge drinking during the past month (CBHSQ, 2014).

Many adolescents start to drink at very young ages. In the United States, the average age at which young people age 12 to 17 begin to drink is 13 years old. Individuals who reported starting to drink before the age of 15 were four times more likely also to report meeting the criteria for alcohol dependence at some point in their lives (NIAAA, 2015d). The younger children and adolescents are when they start to drink, the more likely they will be to engage in risky behaviors. For example, frequent binge drinkers are more likely to use illicit substances, have sex with six or more partners, and earn poor grades in school (NIAAA, 2015d).

Physical, emotional, and lifestyle changes and developmental transitions, such as puberty and increasing independence, are strongly associated with the initiation of alcohol use and subsequent abuse of alcohol. These factors are discussed below.

- **Expectations.** Expectations influence drinking behaviors, including whether adolescents begin to drink and how much. An adolescent who expects drinking to be a pleasurable experience is more likely to drink than one who does not. Adolescents who drink the most also place the greatest emphasis on the positive effects of alcohol consumption (NIAAA, 2015d).

- **Sensitivity and tolerance to alcohol.** Differences between the adult brain and the brain of the maturing adolescent also may help to explain why many young drinkers are able to consume much larger amounts of alcohol than adults before experiencing the negative consequences of drinking, such as drowsiness, lack of coordination, and withdrawal/hangover effects. This unusual tolerance may help to explain the high rates of binge drinking among young adults. At the same time, adolescents appear to be particularly sensitive to the positive effects of drinking, such as feeling more at ease in social situations, and they may drink more than adults because of these positive social experiences (NIAAA, 2015d).
- **Personality characteristics and psychiatric comorbidity.** Children who begin to drink at a very early age (before age 12) often share similar personality characteristics, such as hyperactivity and aggression. These young people, as well as those who are depressive or anxious, may be at greatest risk for alcohol problems. Other behavior problems associated with alcohol use include rebelliousness, difficulty avoiding harmful situations, and acting out without regard for rules or the feelings of others (NIAAA, 2015d).
- **Environmental aspects.** Environmental factors, such as the influence of parents and peers, also play a role in alcohol use. For example, parents who drink more and who view drinking favorably may have children who drink more, and an adolescent girl with an older or adult boyfriend is more likely to use alcohol and other drugs and to engage in delinquent behaviors. The impact of the media is believed to be a significant influence. Greater exposure to alcohol advertising contributes to an increase in drinking among underage youth (NIAAA, 2015d).

Alcohol Abuse Among Women

Research has supported the concept that women are more vulnerable to the adverse consequences of alcohol abuse than men. No gender difference has been noted for age at onset of regular use, but women use alcohol for fewer years than men before entering treatment. The severity of drug and alcohol dependence has not been shown to differ by gender, but women have reported more severe psychiatric, medical, and employment complications than men (SAMHSA, 2009).

Compared with men, women experience greater cognitive impairment by alcohol and are more susceptible to alcohol-related organ damage. Women develop alcohol abuse and dependence in less time than do men, a phenomenon known as *telescoping*; women also develop damage at lower levels of consumption over a shorter period of time (SAMHSA, 2009). Women who drink the same amount as men will have higher blood alcohol concentrations because women have proportionately more body fat and a lower volume of body water to dilute the alcohol. In comparison with men, women have a lower first-pass metabolism of alcohol in the stomach and upper small intestine before it enters the bloodstream and reaches other body organs, including the liver (SAMHSA, 2009).

Women develop alcohol-induced liver disease over a shorter period of time and after consuming less alcohol, and

they are more likely than men to develop alcoholic hepatitis and to die from cirrhosis. Women who are dependent on alcohol or consume heavier amounts are more likely to die prematurely from cardiac-related conditions and have an increased risk of hypertension (SAMHSA, 2009). Numerous studies have documented associations and suggested causal relationships between alcohol consumption and breast cancer risk, especially among postmenopausal women who are moderate alcohol drinkers and who are using menopausal hormone therapy. Alcohol significantly increases the risks for many other cancers. Other negative side effects of alcohol abuse for women include osteoporosis, increased cognitive decline and brain atrophy, memory deficits, and an increased risk for Alzheimer disease (SAMHSA, 2009).

Alcohol Abuse Among Pregnant Women

Alcohol use can result in obstetric complications, miscarriage, or significant problems for the fetus. It is difficult to isolate the effects related solely to alcohol on fetal and infant development because women who abuse alcohol may be abusing other substances. Alcohol use is often accompanied by psychologic distress, victimization, and poverty. Moreover, these issues create additional demands and stressors for women, as well as guilt and shame about the use of alcohol and other substances during pregnancy (SAMHSA, 2009).

Above all other drugs, alcohol is the most common teratogen in pregnancy. Alcohol use is associated with an increased risk of spontaneous abortion, as well as increased rates of prematurity and *abruptio placentae* (premature separation of the placenta from the uterus). A study found that women who consumed five or more drinks per week were three times more likely to deliver a stillborn baby compared with those who had fewer than one drink per week (SAMHSA, 2009).

Alcohol contributes to a wide range of effects on exposed offspring, known as fetal alcohol spectrum disorders (FASDs). The most serious consequence is fetal alcohol syndrome (FAS), characterized by abnormal facial features, growth deficiencies, and central nervous system problems (see the module on Cognition for more information on FAS). Women who drink during breastfeeding pass alcohol on to the baby, which can create a variety of adverse outcomes.

Alcohol Abuse Among Older Adults

Some 41.7% of adults age 65 or older used alcohol in 2013, with 9.1% reporting binge drinking and 2.1% reporting heavy alcohol use (CBHSQ, 2014). Older adults who abuse alcohol have a greater risk for numerous physical problems and premature death. Public health clinicians have suggested that people over age 65 should have no more than 7 drinks a week and no more than 3 drinks on any one day (National Institute on Aging [NIA], 2012).

Chronic alcohol abuse is associated with irreversible tissue and organ damage. Alcohol interacts negatively with the natural aging process to increase risks for hypertension, certain cancers, liver damage and cirrhosis, immune system disorders, and brain damage (Caputo et al., 2012). Alcohol can worsen some health conditions such as osteoporosis, diabetes, hypertension, and ulcers. It can also cause changes

in the heart and blood vessels, which can dull cardiac pain, leading to delayed diagnosis of impending heart attacks (NIA, 2012). Alcohol can cause older adults to be forgetful and confused, symptoms that could be mistaken for signs of Alzheimer disease, dementia, and depression (NIA, 2012).

Mixing prescription and over-the-counter medicines or herbal remedies with alcohol can be dangerous or even deadly for older adults, who routinely take medications for chronic health issues. Medications that cause problems when mixed with alcohol include aspirin, which increases the risk of stomach or intestinal bleeding; cold and allergy medicines containing antihistamines, which can cause drowsiness or sleepiness; and acetaminophen, which can cause liver damage (NIA, 2012). Cough syrups and laxatives that have a high alcohol content will create an additive effect with alcohol, causing the blood alcohol level to increase, and may cause intoxication. Alcohol combined with some sleeping pills, opioid pain pills, or anxiety/anti-depression medicine can cause respiratory difficulties leading to death (NIA, 2012).

Because depression and alcohol abuse are the most frequently found disorders in completed suicides, nurses should routinely screen older adults for concurrent substance abuse and mental disorders. Prevention of drinking relapse in older alcoholics can be more successful than in younger patients. One study found that more than 20% of treated older adults with alcohol dependency remained abstinent after 4 years (Caputo et al., 2012).

NURSING PROCESS

Nurses may interact with patients experiencing alcohol abuse or dependence in a variety of settings. The most common setting is an alcohol abuse treatment program where patients are hospitalized for an average of 10 to 15 days for detoxification and inpatient therapy. These patients may be voluntarily admitted or court ordered to undergo treatment after charges of driving under the influence or alcohol-related child abuse or neglect.

Patients with alcohol abuse or dependence have impaired senses and increased risk-taking behaviors, which can lead to injuries from falls and accidents requiring medical attention. Therefore, nurses will also encounter these patients in hospital EDs and medical-surgical units. Occupational nurses and community health nurses also interact with patients who abuse alcohol through employee assistance programs and community health departments. School nurses may encounter adolescents who abuse alcohol. Urgent care centers, pain clinics, and ambulatory care centers are other settings in which patients with alcohol abuse disorders frequently appear for minor health problems associated with chronic disorders related to alcohol abuse or dependence.

Assessment

A thorough history of the patient's past alcohol use is important to ascertain the possibility of tolerance, physical dependence, or withdrawal syndrome. The following questions are helpful in eliciting a pattern of substance use behavior:

- How many substances has the patient used simultaneously in the past?

- How often, how much, and when did the patient first use alcohol?
- Is there a history of blackouts, delirium, or seizures?
- Is there a history of withdrawal syndrome, overdoses, and complications from previous alcohol use?
- Has the patient ever been treated in an alcohol abuse clinic?
- Has the patient ever been arrested for DUI or charged with any criminal offense while using alcohol?
- Is there a family history of alcohol use?

The patient's medical history is another important area for assessment and should include the existence of any comorbid condition such as HIV, hepatitis, cirrhosis, Wernicke-Korsakoff syndrome, or a co-occurring mental illness. Information about prescribed and over-the-counter medications as well as any allergies or sensitivity to drugs is vital. Assess for history of abuse, family violence, or other trauma as well as history of suicide attempts. Ask if the patient is having any current thoughts of self-harm, suicide, or other violence.

Information about the patient's level of stress and other psychosocial concerns can help in assessing problems with alcohol use. Assess how the patient's alcohol use is affecting relationships at home and work; the patient's usual methods of coping with stress; and the patient's current support systems.

Several screening tools such as the Michigan Alcohol Screening Test (MAST) (Pokorny, Miller, & Kaplan, 1972) and the Brief Drug Abuse Screening Test (B-DAST) (Skinner, 1982) may help the nurse determine the degree of severity of alcohol abuse or dependence. The MAST Brief version is a 10-question self-administered questionnaire that takes 10 to 15 minutes to complete. An answer of yes to three or more questions indicates a potentially dangerous pattern of alcohol abuse. The CAGE questionnaire (Ewing, 1984) is useful when the patient may not recognize that he or she has an alcohol problem or is uncomfortable acknowledging it. This questionnaire is designed to be a self-report of drinking behavior, or it may be administered by a professional. One affirmative response raises concern and indicates the need for further discussion and follow-up. Two or more yes answers signify a problem with alcohol that may require treatment.

A nonthreatening question such as "How much alcohol do you drink?" is preferable to a more judgmental question, such as "You don't drink too much alcohol, do you?" Open-ended questions that elicit more than a simple yes or no answer help to determine the direction of future counseling. The professional should use therapeutic communication techniques to establish trust prior to the assessment process.

Nurses working in medical-surgical units, psychiatric units, and special alcohol abuse units routinely care for patients experiencing acute alcohol withdrawal. Several assessment tools are available to determine the severity of withdrawal symptoms and indicate the need for pharmacologic treatment to manage withdrawal symptoms. An example of a withdrawal assessment tool is the Clinical Institute Withdrawal Assessment for Alcohol—Revised (CIWA-Ar) scale discussed earlier (Sullivan et al., 1989) (**Figure 22-4** >>). This assessment is used widely in clinical and research settings for initial assessment and ongoing monitoring of alcohol withdrawal signs and symptoms.

Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-Ar)

Patient: _____ Date: _____ Time: _____ (24 hour clock, midnight = 00:00)

Pulse or heart rate, taken for one minute: _____ Blood pressure: _____

NAUSEA AND VOMITING -- Ask "Do you feel sick to your stomach? Have you vomited?" Observation.

- 0 no nausea and no vomiting
- 1 mild nausea with no vomiting
- 2
- 3
- 4 intermittent nausea with dry heaves
- 5
- 6
- 7 constant nausea, frequent dry heaves and vomiting

TACTILE DISTURBANCES -- Ask "Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?" Observation.

- 0 none
- 1 very mild itching, pins and needles, burning or numbness
- 2 mild itching, pins and needles, burning or numbness
- 3 moderate itching, pins and needles, burning or numbness
- 4 moderately severe hallucinations
- 5 severe hallucinations
- 6 extremely severe hallucinations
- 7 continuous hallucinations

TREMOR -- Arms extended and fingers spread apart. Observation.

- 0 no tremor
- 1 not visible, but can be felt fingertip to fingertip
- 2
- 3
- 4 moderate, with patient's arms extended
- 5
- 6
- 7 severe, even with arms not extended

AUDITORY DISTURBANCES -- Ask "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?" Observation.

- 0 not present
- 1 very mild harshness or ability to frighten
- 2 mild harshness or ability to frighten
- 3 moderate harshness or ability to frighten
- 4 moderately severe hallucinations
- 5 severe hallucinations
- 6 extremely severe hallucinations
- 7 continuous hallucinations

PAROXYSMAL SWEATS -- Observation.

- 0 no sweat visible
- 1 barely perceptible sweating, palms moist
- 2
- 3
- 4 beads of sweat obvious on forehead
- 5
- 6
- 7 drenching sweats

VISUAL DISTURBANCES -- Ask "Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?" Observation.

- 0 not present
- 1 very mild sensitivity
- 2 mild sensitivity
- 3 moderate sensitivity
- 4 moderately severe hallucinations
- 5 severe hallucinations
- 6 extremely severe hallucinations
- 7 continuous hallucinations

ANXIETY -- Ask "Do you feel nervous?" Observation.

- 0 no anxiety, at ease
- 1 mild anxious
- 2
- 3
- 4 moderately anxious, or guarded, so anxiety is inferred
- 5
- 6
- 7 equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions

HEADACHE, FULLNESS IN HEAD -- Ask "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity.

- 0 not present
- 1 very mild
- 2 mild
- 3 moderate
- 4 moderately severe
- 5 severe
- 6 very severe
- 7 extremely severe

AGITATION -- Observation.

- 0 normal activity
- 1 somewhat more than normal activity
- 2
- 3
- 4 moderately fidgety and restless
- 5
- 6
- 7 paces back and forth during most of the interview, or constantly thrashes about

ORIENTATION AND CLOUDING OF SENSORIUM -- Ask "What day is this? Where are you? Who am I?"

- 0 oriented and can do serial additions
- 1 cannot do serial additions or is uncertain about date
- 2 disoriented for date by no more than 2 calendar days
- 3 disoriented for date by more than 2 calendar days
- 4 disoriented for place/or person

Total **CIWA-Ar** Score _____
 Rater's Initials _____
 Maximum Possible Score 67

The **CIWA-Ar** is not copyrighted and may be reproduced freely. This assessment for monitoring withdrawal symptoms requires approximately 5 minutes to administer. The maximum score is 67 (see instrument). Patients scoring less than 10 do not usually need additional medication for withdrawal.

Source: From Sullivan, J.T., Sykora, K., Schneiderman, J., Naranjo, C.A., and Sellers, E.M. Assessment of alcohol withdrawal: The revised Clinical Institute Withdrawal Assessment for Alcohol scale (**CIWA-Ar**). *British Journal of Addiction* 84:1353–1357, 1989.

Figure 22–4 » Assessment tool for alcohol withdrawal.

The CIWA-Ar scale is a validated 10-item assessment tool that can be used to monitor and medicate patients going through alcohol withdrawal. The CIWA-Ar assesses for several alcohol withdrawal symptoms (e.g., high blood pressure, rapid pulse and respirations, tremors, insomnia, irritability, sweating, convulsions) and results in a score that is used to direct the administration of benzodiazepines or other drugs to relieve associated symptoms of withdrawal and to prevent seizures. A score of 8 points or fewer corresponds to mild withdrawal symptoms. Scores of 9 to 15 points indicate moderate withdrawal, whereas a score of 15 or greater denotes severe withdrawal and an increased risk of DTs and seizures.

SAFETY ALERT Alcohol withdrawal symptoms present within 8 hours after the last drink and usually peak within 24 to 72 hours. Patients with severe liver impairment and other physical complications may exhibit withdrawal symptoms for as long as a week after the last drink.

Diagnosis

Nursing diagnoses are individualized to specific patient needs. Primary diagnoses may include:

- *Injury, Risk for*
- *Violence, Risk for Other-Directed*
- *Denial, Ineffective*
- *Coping, Ineffective*
- *Imbalanced Nutrition: Less Than Body Requirements*
- *Knowledge, Deficient*
- *Liver Function, Risk for Impaired*
- *Family Processes, Dysfunctional*
- *Confusion, Acute*
- *Confusion, Chronic.*

(NANDA-I © 2014)

Planning

Goals for patient care depend on patient needs. The patient who denies a problem with alcohol will have far different needs than the patient experiencing withdrawal, participating in an alcohol abuse program, or facing serious complications from years of abuse. Possible goals may include the following:

- The patient will admit alcohol is controlling his or her life.
- The patient will agree to enter an alcohol treatment facility or outpatient program.
- The patient will experience no complications (or no further complications) as a result of alcohol abuse or alcohol withdrawal.
- The patient will achieve optimal nutritional status.
- The patient will remain sober.
- The patient will participate in support groups such as AA after discharge from treatment facility.

Implementation

During recent years, addiction specialists have sought to develop an efficient system of care that matches patients'

clinical needs with an appropriate care setting in the least confining and most cost-effective manner, a practice known as *least restrictive care* (SAMHSA, 2015c).

Unlike in the past, when patients in active withdrawal were always monitored in acute care settings, today's patients are more likely to withdraw from alcohol in community-based *social detoxification* programs with limited medical oversight (SAMHSA, 2015b). Sites of care include residential rehabilitation programs, halfway houses, and partial hospitalization programs. Community and faith groups often operate social detoxification programs that may or may not have clear procedures for pursuing appropriate medical referral and emergency care. An advantage of these outpatient programs is that they provide structured environments while allowing the patient to maintain a viable presence in the community.

Another trend is *home detoxification*. ED and family physicians are now implementing outpatient alcohol detoxification guidelines with pharmacotherapy for individuals with mild to moderate alcohol withdrawal symptoms and no serious psychiatric or medical comorbidities (Muncie, Yasinian, & Oge, 2013). Many of these protocols advocate daily office visits or home visits. Because of the increasing array of treatment options, it is likely that nurses will perform more home or community visits or use telehealth to monitor patients withdrawing from alcohol in the future.

Withdrawal is often accompanied by poor physiologic and psychologic outcomes. As described earlier, withdrawal is a particularly high-risk event, when potentially dangerous withdrawal symptoms—confusion; seizures accompanied by rapid heartbeat, high blood pressure, and hyperthermia; delirium tremens; and coma leading to death—occur. Safety is a paramount concern. Equally important after detoxification are promoting physical recovery from alcohol addiction, enhancing coping skills, and providing referrals to services that prepare the patient for long-term abstinence from alcohol use. Among these necessary referrals are vocational counseling, self-help groups such as AA, and individual, group, and family therapy.

Patients who have histories of trauma may be ambivalent about treatment and feel “stuck,” perceiving themselves as having fewer options (SAMHSA, 2014a). In addition, patients may avoid engaging in treatment because it is one step closer to addressing their trauma. These patients may exhibit challenging behaviors and need a longer course of treatment.

Caring interventions are based on the patient's need, diagnoses chosen, and goals set for care throughout the course of treatment. For all patients, nurses will work to promote healthy coping skills (see the module on Stress and Coping) to help patients reduce the need to use alcohol as a coping mechanism. In addition, patients who abuse alcohol require health promotion related to maintaining adequate nutrition, and in particular should take thiamine supplements as necessary to prevent complications from chronic alcoholism. Specific interventions to help patients begin the path to recovery from alcohol abuse follow.

Promote Patient Safety During Acute Withdrawal

- Observe the patient for withdrawal symptoms. Monitor vital signs frequently per protocol until the patient has stabilized. Provide adequate nutrition and hydration.

Take seizure precautions. These actions provide supportive physical care during detoxification.

- Assess blood alcohol level routinely and look for escalating signs of withdrawal, using an instrument such as the CIWA-Ar. Reliable information about withdrawal symptoms comes from BAL and vital signs; these measurements provide information about the need for prn medication to prevent DTs and other severe complications.
- Administer scheduled medications according to the detoxification protocol. Benzodiazepines help minimize the discomfort of withdrawal symptoms, anticonvulsants help prevent seizures, and vitamins and nutritional supplements support neurologic health.
- Assess the patient's level of orientation frequently. Orient and reassure the patient of safety in the presence of hallucinations, delusions, or illusions.
- Explain all interventions before approaching the patient. Use simple step-by-step instructions and face-to-face interaction. Minimize environmental distractions and talk softly to the patient. Excessive stimuli increase agitation.
- Provide positive reinforcement when thinking and behavior are appropriate or when the patient recognizes that delusions are not based in reality. Alcohol can interfere with the patient's perception of reality.
- Express reasonable doubt if the patient relays suspicious or paranoid beliefs. Reinforce accurate perception of people or situations. It is important to communicate that you do not share the false belief as reality.
- Do not argue with the patient who is experiencing delusions or hallucinations. Convey acceptance that the patient believes a situation to be true, but that you do not see or hear what is not there. Arguing with the patient or denying the belief serves no useful purpose because it does not eliminate the delusions.
- Talk to the patient about real events and real people. Respond to feelings and reassure the patient about being safe from harm. Discussions that focus on the delusions may aggravate the condition. Verbalization of feelings in a nonthreatening environment may help the patient develop insight.

Promote Safety in Outpatient and Home Settings

When an individual initiates outpatient or home care, obtain a drug history as well as urine and blood samples for laboratory analysis of substance content. Subjective history often is not accurate, and knowledge regarding substance use is important for accurate assessment and determining the appropriate care setting.

- Assess orientation and cognition. If the patient's level of cognitive functioning is not sufficient to implement the outpatient or home plan of care, contact a clinician who can evaluate the patient and assist in transfer to a higher level of care if needed.
- Have the patient (if able) or others in the home or community setting monitor vital signs frequently during the first day of detox using reliable home equipment, and several times per day subsequently. Teach the patient and

lay personnel about the signs and symptoms of severe withdrawal and make sure they understand when they should notify the clinician.

- Administer or teach the patient/others to administer scheduled medications according to the detoxification protocol. Monitor vital signs and symptoms such as increasing agitation and a change in level of consciousness to determine whether the patient should remain in outpatient or home care. Use vital signs to determine whether prn medications are indicated.
- Monitor for signs of alcohol intoxication. Some patients will start drinking again when withdrawal symptoms become too distressing.
- Suggest that the patient remain in a quiet room to decrease excessive stimuli. Monitor for excessive hyperactivity or agitation, which may indicate severe withdrawal symptoms, and suicidal ideation. These symptoms indicate that the patient may need emergency care.
- Determine specific risks to patient safety. Make sure that the patient is oriented to reality and the environment. Ensure that potentially harmful objects are stored outside the patient's immediate area, so that the patient cannot harm self or others if disoriented and confused.

Promote Healthy Self-Esteem

- Spend time with the patient and convey an attitude of acceptance. Encourage the patient to accept responsibility for his or her behaviors and feelings. An attitude of acceptance enhances self-worth.
- Encourage the patient to focus on strengths and accomplishments rather than weaknesses and failures. Minimize attention to negative ruminations.
- Encourage participation in therapeutic group activities. Offer recognition and positive feedback for actual achievements. Success and recognition increase self-esteem.
- Teach assertiveness techniques and effective communication techniques such as the use of "I feel" rather than "You make me feel" statements. Previous patterns of communication may have been aggressive and accusatory, causing barriers to interpersonal relationships.

Provide Patient Education

- Assess the patient's level of knowledge and readiness to learn the effects of alcohol on the body. Baseline assessment is required to develop appropriate teaching material.
- Develop a teaching plan that includes measurable objectives. Include significant others if possible. Lifestyle changes often affect all family members.
- Begin teaching with simple concepts and progress to more complex issues. Use interactive teaching strategies and written materials appropriate to the patient's educational level. Include information on the physiologic effects of alcohol, the propensity for physical and psychologic dependence, and risks to the fetus if the patient is pregnant. Active participation and handouts enhance retention of important concepts.

Patients are at highest risk for relapse within the first few months of stopping use of alcohol. An acronym that many

therapists use to assist the patient in recognizing some behaviors that lead to relapse is **HALT**:

Hungry

Angry

Lonely

Tired.

Nurses should also emphasize the importance of a balanced diet, adequate sleep, healthy recreational activities, and a caring support system to prevent relapse.

Evaluation

The patient is evaluated on the ability to meet goals set during the planning stage of the nursing process. Potential expected outcomes include the following:

- The patient in the acute, community, or home setting undergoes withdrawal without physiologic complications.
- The patient controls anxiety to the extent the patient refrains from drinking when anxiety levels rise.
- The patient displays new coping mechanisms.
- The patient does not start using alcohol again.
- The patient does not experience any new physiologic or psychologic complications as a result of sobriety.
- The patient accepts responsibility for how his or her behavior impacts the family unit.

Over time, patients will maintain whatever coping supports they learned to continue abstinence and sobriety. Patients who do not address underlying psychologic issues will find sobriety challenging. Thus, the patient and clinician will need to evaluate progress at periodic intervals for an extended period of time.

New nurses may be surprised to see how often patients with an alcohol-use disorder return to drinking. An 8-year longitudinal study of 1162 people who entered treatment showed that extended abstinence does predict long-term recovery. This research showed that only about a third of people who are abstinent less than a year will remain abstinent, *while more than two thirds will relapse* (Dennis, Foss, & Scott, 2007). For those who achieve a year of sobriety, less than half will relapse. Patients who maintain 5 years of sobriety have a less than 15% chance of relapse.

When reevaluating the plan of care, nurses should consider factors such as the patient's physiologic health, mental health, coping responses, legal involvement, vocational involvement, housing, peers, and social and spiritual support. Other factors hindering sobriety include the success of the transition from rehab to home, engagement with after-care, motivation and ambivalence toward recovery, unrealistic expectations, and continued use of other substances. After considering all of these factors, the clinician should work with the patient to modify the plan of care to accommodate these new circumstances.

Nursing Care Plan

A Patient Experiencing Withdrawal from Alcohol

George Russell, age 58, fell at home and broke his arm. His wife took him to the emergency department where an open reduction and internal fixation of his right wrist was performed under general anesthesia in the operating room. He was admitted to the postoperative unit for observation following surgery because he required large amounts of anesthesia during the procedure.

Mr. Russell has a ruddy complexion and looks older than his stated age. He discloses that he was laid off from his factory job 2

years ago and has been working odd jobs until last week, when he was hired by a local assembly plant. His father was a recovering alcoholic, and his 30-year-old son has been treated for alcohol abuse in the past. Mr. Russell states that he knows alcoholism runs in the family, but he believes that he has his drinking under control. However, he cannot remember the events that led up to his fall and how he might have broken his arm.

ASSESSMENT

During the nursing assessment, Mr. Russell is hesitant to provide information and refuses to make eye contact. Prior to his operation, a BAL was drawn because the ED nurse detected alcohol on his breath. His BAL was 0.40%, which is five times the legal limit for intoxication. His vital signs are within the upper limits of normal, but he is confused and disoriented with slurred speech and a slight tremor of the hands. He is 6 feet tall and weighs 140 pounds. His total albumin is 2.9 mg, and he has elevated liver enzymes. His wife states that he rarely eats the meals she prepares because he is usually drinking and has no appetite for food.

DIAGNOSES

- *Ineffective Coping* related to possible hereditary factor and personal vulnerability
- *Risk for Injury* related to aggressive behavior, unsteady gait, and impaired motor responses
- *Ineffective Denial* related to inability to recognize maladaptive behaviors caused by substance use
- *Imbalanced Nutrition: Less Than Body Requirements* related to anorexia manifested by decreased weight and low serum protein levels

(NANDA-I © 2014)

PLANNING

- The patient will express his true feelings associated with using alcohol as a method of coping with stressful situations.
- The patient will identify three adaptive coping mechanisms he can use as alternatives to alcohol in response to stress.
- The patient will verbalize the negative effects of alcohol and agree to seek professional help with his drinking.
- The patient will be free of injury as evidenced by steady gait and absence of subsequent falls.
- The patient will gain 1 pound (0.45 kilogram) per week without evidence of increased fluid retention. Serum albumin levels will return to normal range.

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Establish a trusting relationship with the patient and spend time with him discussing his feelings, fears, and anxieties.
- Consult with a physician regarding a schedule for medications during detoxification, and observe the patient for signs of withdrawal syndrome.
- Explain the effects of alcohol abuse on the body, and emphasize that prognosis is closely associated with abstinence.
- Teach a relaxation technique that the patient believes is useful.
- Provide community resource information about self-help groups and, if the patient is receptive, a list of meeting times and phone numbers.
- Consult with a dietitian to determine the number of calories needed to provide adequate nutrition and a realistic weight. Document intake, output, and calorie count.
- Consult with a physician to begin vitamin B₁ (thiamine) and dietary supplements.

EVALUATION

Mr. Russell is discharged from the postoperative unit without complications. He successfully undergoes detoxification and contacts the employee assistance program at his new place of employment. He is on medical leave while his arm completely heals and now

attends AA meetings 5 days a week. He reports that he enjoys taking long walks with his wife in the warm weather and that his appetite has returned. He has gained 10 pounds in the past 6 weeks and feels better physically than he has in many years.

CRITICAL THINKING

1. Explain why, during the initial nursing assessment, it would be important to ask questions about Mr. Russell's medication history and his use of other medications.
2. Mr. Russell asks you to explain the risks of taking disulfiram (Antabuse). What should you tell him?
3. Develop a care plan for Mr. Russell for the nursing diagnosis of *Imbalanced Nutrition: Less Than Body Requirements*. Why is this care plan necessary?

REVIEW Alcohol Abuse

RELATE Link the Concepts and Exemplars

Linking the exemplar of alcohol abuse with the concept of comfort:

1. Why might the patient who has detoxified from alcohol have trouble sleeping?
2. What nursing care might you provide to improve the patient's ability to sleep?

Linking the exemplar of alcohol abuse with the concept of infection:

3. What pathophysiology would increase the risk for infection in the patient who chronically abuses alcohol?
4. What nursing care would you provide this patient to reduce the risk of infection?

Linking the exemplar of alcohol abuse with the concept of legal issues:

5. The nurse, working in an ED, admits a patient accompanied by a police officer who requests that a serum BAL be drawn and tested for use in a court case related to the patient's driving while intoxicated. What are the patient's legal rights, and what legal obligations does the nurse have regarding this patient's rights of privacy?

Linking the exemplar of alcohol abuse with the concept of safety:

6. The nurse is caring for a patient who was brought to the ED with a BAL of 0.32%. The patient is somnolent, is speaking in incomplete sentences that are garbled and difficult to understand,

and has a laceration on his forehead. He is admitted to the acute care facility for observation. How will you assess this patient's neurologic status to determine whether there is an alteration in level of consciousness reflecting a brain injury or alcohol intoxication?

REFLECT Apply Your Knowledge

Candy Collins, a 46-year-old wife and mother of two, comes to her physician's office seeking help for alcohol abuse. She says her husband has threatened to leave her and take her children with him if she doesn't stop. The nurse determines that Mrs. Collins drinks at least five or six alcoholic beverages daily, usually starting after dinner, although sometimes she begins drinking after the children leave for school. The nurse learns that Mrs. Collins's behavior began 5 years ago, shortly after her youngest child began preschool. She denies having blackouts, although she reports occasionally waking in the morning with no memory of the night before.

1. What other data would you want to collect from Mrs. Collins related to her abuse of alcohol?
2. What treatment would you anticipate as appropriate for this patient?
3. What teaching would you provide both Mrs. Collins and her husband?

Exemplar 22.B Nicotine Use

Exemplar Learning Outcomes

22.B Analyze manifestations and treatment considerations for patients who use nicotine.

- Describe the pathophysiology of nicotine use.
- Describe the etiology of nicotine use.
- Compare the risk factors and prevention of nicotine use.
- Identify the clinical manifestations of nicotine use.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual who uses nicotine.

Overview

Cigarette smoking is the single most preventable cause of disease and death in the United States. The CDC (2013d) estimates that 443,000 deaths each year are attributable to cigarette smoking. This estimate does not include patients exposed to secondhand smoke or patients who consume nicotine by using chewing tobacco.

Nicotine, a highly addictive chemical found in tobacco, is used worldwide and results in many complications (see the Focus on Diversity and Culture feature). Nicotine enters the body via the lungs (cigarettes, pipes, and cigars) and oral mucous membranes (chewing tobacco as well as smoking). Although smoking is legal, it has become increasingly socially unacceptable, as evidence of the danger of both smoking and breathing in others' secondhand smoke has been demonstrated. Burning of tobacco releases the active substances in the plant, making it available for absorption via the lungs into the bloodstream.

Commercial tobacco contains more than 4000 chemicals. Among these are nicotine (one of the most addictive substances known to humans); arsenic and hydrogen cyanide (poisons); acetone (a simple ketone that can irritate tissues and is a CNS depressant); and tar (which deposits on the lungs via cigarette smoke and reduces the elasticity of the alveoli, slowing air exchange). Cancer-causing agents in commercial tobacco include nitrosamines, cadmium, benzo(a)pyrene, polonium-210, nickel, urethane, and toluidine. As a result of the combination of chemicals entering the bloodstream, smoking has profound effects on virtually every organ system, ranging from hypertension due to vasoconstriction to suppression of the immune system.

A new public health concern is *vaping*, which uses battery-powered electronic cigarettes with an atomizer of liquid consisting of propylene glycol, glycerol, distilled water, flavorings (which may or may not be approved for food use), preservatives, and nicotine. The atomizer aerosolizes the liquid for inhalation (Farsalinos & Polosa, 2014). Consumers, known as *vapers*, may choose from several nicotine strengths, as well as non-nicotine liquids and flavorings. It remains to be proven whether e-cigarettes are actually safe or simply less harmful than tobacco, and debate rages about whether or how the devices should be regulated (Arnold, 2014). In many parts of the United States and the world, vaping is unregulated.

- Differentiate care of patients who use nicotine across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual who uses nicotine.

Exemplar Key Terms

Nicotine, 1682

Nicotine replacement therapy (NRT), 1684

Of particular concern is the exploding popularity of e-cigarettes among teens and young adults (**Figure 22-5**). According to the CDC (2015b), e-cigarette use among middle and high school students tripled from 2013 to 2014, increasing from 4.5% in 2013 to 13.4% in 2014, rising from approximately 660,000 to 2 million students. Among middle school students, current e-cigarette use more than tripled from 1.1% in 2013 to 3.9% in 2014—an increase from approximately 120,000 to 450,000 students. In 2014, e-cigarette use surpassed current use of every other tobacco product overall, including conventional cigarettes. E-cigarettes were the most used tobacco product for non-Hispanic Whites, Hispanics, and non-Hispanic other race, while cigars were the most commonly used product among non-Hispanic Blacks (CDC, 2015b).

Pathophysiology and Epidemiology Pathophysiology

In low doses, nicotine stimulates nicotinic receptors in the brain to release dopamine (a precursor to norepinephrine) and epinephrine, causing vasoconstriction. This increases the

Source: Nicolas McComber/E+/Getty Images.

Figure 22-5 At least 2 million teens and young adults are using e-cigarettes. Researchers have yet to determine whether e-cigarettes are actually safe or are simply less harmful than tobacco.

Focus on Diversity and Culture

Nicotine Use: Still a Global Epidemic

In 2012, 21% of the global population age 15 and above smoked tobacco. Men smoked at five times the rate of women; the average rates were 36 and 7%, respectively (World Health Organization [WHO], 2015a). Smoking among men was highest in the WHO Western Pacific Region, with 48% of men smoking some form of tobacco. Smoking among women was highest (19%) in the WHO European Region.

The rates at which adolescent girls age 13 to 15 use tobacco averaged around 8% globally. Among other regions, the highest prevalence among girls was seen in the WHO Region of the Americas, where almost 14% of young adolescent girls were already tobacco users. Boys age 13 to 15 in WHO South-East Asia Region and WHO Eastern Mediterranean Region used tobacco at higher rates than their counterparts in other regions, at over 20% in both regions (WHO, 2015a).

heart rate, blood pressure, and peripheral vascular resistance, increasing the heart's workload. Gastrointestinal effects include an increase in gastric acid secretion, an increase in the tone and motility of GI smooth muscle, nausea, and increased risk of vomiting.

In the CNS, nicotine occupies the receptors for acetylcholine in both dopamine and serotonin neural pathways. This causes the release of dopamine and norepinephrine. Initially, nicotine increases mental alertness and cognitive ability, but eventually it depresses those responses (Kneisl & Trigoboff, 2013).

Smokers can develop tolerance to nausea and dizziness, which may be experienced with initial use of nicotine, but not to the cardiovascular effects. Furthermore, because of the vasoconstriction, tissue oxygenation can be impaired in areas where vessels are already narrowed by atherosclerosis. Researchers have also found an association between ingredients in vaping liquids and lung disease. Diacetyl, a flavoring chemical linked to cases of severe respiratory disease, was found in more than 75% of flavored electronic cigarettes and refill liquids (Roeder, 2015). Inhaled diacetyl can cause the debilitating respiratory disease *bronchiolitis obliterans*, known as "popcorn lung" because it first appeared in workers who inhaled artificial butter flavor in microwave popcorn processing facilities.

Smokers often have more difficulty falling asleep than nonsmokers because nicotine acts as a stimulant. Smokers are usually easily aroused and often describe themselves as light sleepers. By refraining from smoking after the evening meal, the person usually sleeps better; moreover, many former smokers report that their sleeping patterns improve once they stop smoking.

Nicotine dependence results from chronic use. Research suggests that dopaminergic processes have a role in regulating the reinforcing effects of nicotine, making cessation difficult (Kneisl & Trigoboff, 2013). Withdrawal symptoms include craving, nervousness, restlessness, irritability, impatience, increased hostility, insomnia, impaired concentration, increased appetite, and weight gain. Gradual reduction in nicotine use seems to prolong suffering. Chronic health problems from smoking have been well established in the form of cancer, heart disease, emphysema, hypertension, and death.

Etiology and Epidemiology

Some of the most common factors that influence people to smoke are emotions, social pressure, alcohol use, lack of education, and age. Young people are more likely to use tobacco if they have access to smoking areas and tobacco products, especially to low-cost or free tobacco. They are also more likely to use tobacco if they have friends, brothers, or sisters who use tobacco; watch movies that have smoking in them; are not doing well in school or have friends who are not doing well in school; are not engaged in school or religious activities; and use other substances, such as alcohol or marijuana (CDC, 2012). People of lower socioeconomic status are more likely to smoke than those of higher socioeconomic status, partially because smoking is more socially acceptable in groups with fewer resources. Furthermore, these individuals are less successful in quitting smoking because they lack high-quality health education, lack support for quitting, and are exposed to smoking more often.

Approximately one in five U.S. adults smokes cigarettes, and smoking-related diseases claim more than 393,000 American lives each year (American Lung Association, 2013). Smoking is the most common form of recreational drug use, practiced by more than 1 billion people in the majority of human societies. According to a 2012 Surgeon General's report, *Preventing Tobacco Use Among Youth and Young Adults* (2012), more than 80% of adult smokers began smoking by 18 years of age, with 99% of them lighting up by age 26.

Risk Factors

As stated above, age, socioeconomic status and lack of engagement in activities are among the risk factors for smoking. Smoking itself is a risk factor for a number of diseases. It harms nearly every organ in the body and is a main cause of lung cancer and chronic obstructive pulmonary disease (COPD). Smoking is also a cause of coronary heart disease, stroke, and a host of other cancers and diseases (American Lung Association, 2013). Graves disease, infertility, early menopause, dysmenorrhea, impotence, osteoporosis, and degenerative disc disease have also been associated with smoking. Other less serious consequences include discolored teeth and fingernails, premature aging and wrinkling, bad breath, reduced sense of smell and taste, strong smell of smoke clinging to hair and clothing, and gum disease (Zhang & Wang, 2013). Smoking during pregnancy has been associated with preterm labor, spontaneous abortion, low-birth-weight infants, sudden infant death syndrome (SIDS), and learning disorders (Knopik et al., 2012).

Nonsmokers who are exposed to secondhand smoke at home or work increase their lung cancer risk by 20 to 30%. Concentrations of many cancer-causing and toxic chemicals are higher in secondhand smoke than in the smoke inhaled by smokers (CDC, 2013c). Secondhand smoke presents a number of dangers, particularly to children of smokers. According to the CDC (2013d), secondhand smoking increases children's risks for SIDS, otitis media, and asthma and other respiratory conditions. In addition, mothers who smoke and mothers who are exposed to secondhand smoke are more likely to have lower-birth-weight babies.

Prevention

Smoking and smokeless tobacco use are initiated and established primarily during adolescence. Adolescents and young adults are uniquely susceptible to social and environmental influences to use tobacco, and tobacco companies spend billions of dollars on cigarette and smokeless tobacco marketing. The Surgeon General's 2012 report provides evidence that coordinated, high-impact interventions, including mass media campaigns, price increases, and community-level changes protecting people from secondhand smoke, are effective in reducing the initiation and prevalence of smoking among youth.

National, state, and local program activities that have reduced and prevented youth tobacco use in the past have included combinations of the following: counteradvertising mass media campaigns (such as TV and radio commercials); comprehensive school-based tobacco-use prevention policies and programs; and higher costs of tobacco products through increased excise taxes.

Clinical Manifestations

Clinical manifestations of nicotine use are usually nonexistent in the early stages of use and are seen only when a complication such as COPD, cancer, or heart disease occurs. People who smoke for many years often have deep voices secondary to trauma to the vocal cords caused by the heat of the smoke and the chronic cough they often develop. See the exemplar on Lung Cancer in the module on Cellular

Regulation for manifestations of cancers associated with nicotine use; the exemplar on Chronic Obstructive Pulmonary Disease in the module on Oxygenation for the impact of smoking on lung function; and the exemplars on Coronary Artery Disease and Peripheral Vascular Disease in the module on Perfusion for information related to heart disease and peripheral vascular disease.

Collaboration

As with any addiction, the treatment process is a collaborative one. Individuals who are addicted to nicotine benefit from the support of family and friends, especially during times when they would usually be smoking or using tobacco. Although pharmacologic therapies are available over the counter, it is important for the patient to discuss treatment with healthcare providers to minimize symptoms of withdrawal and prevent interactions with prescribed medications. Some patients may seek complementary health approaches and support groups to help them quit smoking.

Nicotine Replacement Therapy

Nicotine replacement therapy (NRT) helps relieve some of the physiologic effects of withdrawal, including cravings, for patients trying to quit smoking or using tobacco. NRT transdermal patches and gums are available over the counter; nicotine inhalers and nasal sprays are available by prescription only. Use of these nicotine substitution products is not without complications. They do not treat underlying

Patient Teaching

What Is Too Much Nicotine?

A potential issue with nicotine patches and gum in nicotine replacement therapy is that some of the transdermal patches and gum are designed for heavy smokers and may contain too large of a dose of nicotine. Depending on weight and customary nicotine usage, patients may experience unpleasant side effects from ingesting too much nicotine. Some of these signs include abdominal cramps, nausea, or vomiting; chest pain or difficulty breathing; rapid heart rate; panic attacks; dizziness; ringing in the ears; anxiety or agitation; headache; and muscle twitching.

Keep in mind that there is the possibility of nicotine poisoning with children who chew on patches or gum. This may present a medical emergency. Because of this risk, teach consumers to store NRT products out of the reach of children.

psychologic needs or address addictive behaviors associated with tobacco use. They also come with contraindications and warnings. Nurses should provide information about these contraindications and warnings to patients considering NRT. Nurses also should encourage patients to use nicotine therapy in combination with a smoking cessation program that will help them address the psychologic issues related to nicotine abuse.

Smoking Cessation Programs

Smoking cessation programs provide peer support, group therapy, and behavior therapy modifications that can help patients who smoke to quit smoking. The websites of the U.S. Surgeon General, the CDC, the American Heart Association, and the American Lung Association all provide information about smoking cessation programs and other means of quitting smoking.

>> Stay Current: The U.S. Department of Health and Human Services provides information and resources to help individuals quit smoking at the website <http://betobaccofree.hhs.gov>.

Complementary Health Approaches

A number of complementary therapies have been advocated as tools for quitting smoking, hypnotherapy and acupuncture among them. Generally speaking, any therapy that helps reduce patient anxiety levels, such as yoga and massage, will lower the likelihood that the patient will want to use nicotine to alleviate anxiety.

There is conflicting evidence about the success of hypnotherapy as a smoking cessation tool. As with any type of therapy, the qualifications and experience of the therapist have an effect on the success of the therapy. To increase the likelihood of success, nurses should encourage patients who are considering hypnotherapy also to participate in more traditional cessation programs.

Lifespan Considerations

Nicotine Addiction in Adolescents

In 2014, 1.7 million adolescents age 12 to 17 used tobacco products during the past month, and 1.2 million reported

smoking cigarettes (CBHSQ, 2015). From 2002 to 2014, the percentage of adolescents who used tobacco in the past month declined roughly by half, from 15.2 to 7.0%. Similarly, the percentage of adolescents who were current cigarette smokers in 2014 was lower than the percentages in 2002 to 2013. In 2002, for example, about 1 in 8 adolescents were current cigarette smokers, while about 1 in 20 adolescents age 12 to 17 in 2014 were current cigarette smokers (CBHSQ, 2014). However, as mentioned previously, nicotine use reports have not yet included vaping use, which has exploded.

As seen with other substances, the teen years seem to be the gateway for nicotine use. Early research studies of the psychosocial risk factors for smoking indicated that stress, peer and family influences, ethnicity, and depression all served as risk factors for the development and maintenance of smoking in adolescents (Schepis & Rao, 2005). Protective factors include parental expectations and monitoring, religious activity, and sociopolitical factors such as tobacco-related marketing bans and higher cigarette taxes (CDC, 2012, 2013b). Neurobiological research has examined the concept of disinhibition as a risk factor for smoking in adolescents (Schepis & Rao, 2005).

Among young people, the short-term health consequences of smoking include respiratory and nonrespiratory effects, addiction to nicotine, and the associated risk of other drug use (World Health Organization [WHO], 2015b). Significantly, most young people who smoke regularly continue to smoke throughout adulthood. Smoking harms both performance and endurance in teen sports. Smoking reduces the rate of lung growth and reduces lung function: Teenage smokers experience shortness of breath almost three times more often than teens who do not smoke and produce phlegm more than twice as often as teens who do not smoke. Young adult smokers also show early vascular signs of heart disease and stroke and are at increased risk of lung cancer. The resting heart rates of young adult smokers are two to three beats per minute faster than those of nonsmokers. On average, someone who smokes a pack or more of cigarettes each day lives 7 years less than someone who never smoked (WHO, 2015b).

Smoking among adolescents is associated with increased risk for use of other substances. Teens who smoke are 3 times more likely than nonsmokers to use alcohol, 8 times more likely to use marijuana, and 22 times more likely to use cocaine. Smoking is associated with a host of other risky behaviors, such as fighting and engaging in unprotected sex (WHO, 2015b).

Nicotine Addiction in Pregnant Women

Generally speaking, pregnant women smoke at lower rates than women who are not pregnant, and this seems to hold true across all age groups. While there is some evidence of decline in smoking as pregnancy progresses, it is perhaps not enough: in 2012–2013, smoking rates of pregnant women age 15 to 44 were 19.9% in the first trimester, 13.4% in the second trimester, and 12.8% in the third trimester (CBHSQ, 2014).

There is a substantial body of literature documenting the dangers of maternal nicotine use for the fetus. First, there are the more than 4000 chemicals in cigarette smoke, more than

40 of which are known carcinogens. Nicotine crosses the placenta, and fetal concentrations of nicotine can be 15% higher than maternal concentrations (Knopik et al., 2012). Maternal cigarette smoking during pregnancy is associated with increased risk for spontaneous abortion, preterm delivery, respiratory disease, immune system difficulties such as asthma and allergies, and cancer later in life. Various studies link placental complications linked to prenatal exposure to cigarette smoke, including alterations to the development and function of the placenta. A body of research has suggested that prenatal tobacco exposure has been associated with serious neurodevelopmental and behavioral consequences in infants, children, and adolescents, including delayed psychomotor and mental development, increased physical aggression during early childhood, attention deficits, issues with learning and memory, increased impulsivity, and speech and language impairments (Knopik et al., 2012).

Nicotine Addiction in Older Adults

A 2012 survey of Medicare recipients found that 8.8% were current smokers; 44.7% and 46.5% of the sample, respectively, were former and never smokers (Choi & DiNitto, 2015). Current smokers had lower socioeconomic status, were more socially isolated, and had higher depressive symptoms than older adults who never smoked. Among the admitted smokers, 88.9% of them continued to smoke. The odds of successful smoking cessation increased if the individual received a new diagnosis of chronic illness (Choi & DiNitto, 2015). However, the odds decrease in those who are heavy smokers; these patients may require extended pharmacotherapy and counseling to be successful in smoking cessation.

Among people 50 and older, smokers are more likely to report health problems such as coughing, trouble breathing, and getting tired more easily than nonsmokers. Smoking often worsens existing medical conditions. Smoking increases the risk of many types of cancer, especially cancers along the respiratory and GI tracts (National Institutes of Health [NIH], 2015). Smoking has also been linked to diseases other than cancer in seniors, including pulmonary and cardiovascular diseases, diabetes complications, bone disease, bone density loss, cataracts, and stomach ulcers. Smokers are up to 10 times more likely to get cancer than a person who has never smoked (NIH, 2015).

NURSING PROCESS

Nurses may interact with patients addicted to nicotine in a variety of settings ranging from acute care to outpatient centers. Nurses often note the smell of smoke on a nicotine user and can implement a plan of care aimed at helping the patient make healthier lifestyle choices. Because of the high rate of smoking among patients with mental health disorders, psychiatric facilities are a common place to meet patients with nicotine addictions. It is not uncommon for patients to have addictions to multiple substances, and nurses should assess for other substance abuse problems. A nonjudgmental approach is important when caring for patients addicted to nicotine. Health promotion efforts are directed toward education about making healthy life choices and strategies to support the patient in abstaining from nicotine. Through

school programs, nurses can provide adolescents with ways to avoid peer pressure, thereby preventing nicotine use.

Assessment

When assessing patients who use nicotine, it is important to assess for amount and frequency of use, length of time nicotine has been used, and the presence of any symptoms indicating possible complications such as a chronic cough, shortness of breath, hypertension, chest pain, or unexpected symptoms. A comprehensive approach to the assessment of substance use is essential to ensure adequate and appropriate intervention. Three important areas to assess are a history of the patient's past substance use, medical and psychiatric history, and the presence of psychosocial concerns. Part of every assessment of individuals who abuse nicotine should be to determine their willingness and motivation to consider abstinence. Ask questions in a nonthreatening, matter-of-fact manner, phrased so as not to imply wrongdoing. Open-ended questions, such as the following, that elicit more than a simple yes or no answer help to determine the direction of future counseling:

- On average, how long have you used nicotine-containing products?
- On a typical day, how many cigarettes (cigars or pipes) do you smoke (or how much tobacco do you chew)?
- When did you last smoke or use tobacco?
- What kinds of problems has nicotine use caused for you and your family, friends, finances, and health? How much money do you think you spend on smoking or tobacco use?
- Tell me about any attempts you've made to quit using nicotine. How long did you quit? What made you return to nicotine use?
- How do you feel about the idea of being nicotine-free? Do you want help to quit now?

The patient's medical history is another important area for assessment and should include the existence of any concomitant physical or mental condition. Ask about prescribed and over-the-counter medications as well as any allergies or sensitivity to drugs. A brief overview of the patient's current mental status also is significant. Ask questions to assess patients for feelings of depression and thoughts of self-harm or harming others. Inquire about the use of nicotine by family members.

Information about the patient's level of stress and other psychosocial concerns can help in the assessment of substance use problems. Assess for the degree to which the patient's nicotine use is affecting relationships at home and work. Assess the patient's current coping mechanisms and support system.

Diagnosis

Every patient is unique, and the choice of the nursing diagnosis will depend on the type of complications the patient may be experiencing as a result of nicotine use. The needs of a patient being treated for lung cancer or heart disease after years of smoking will differ from the needs of the adolescent patient who may not yet be experiencing adverse effects

from the newly begun habit. Possible nursing diagnoses include the following:

- *Injury, Risk for*
- *Denial, Ineffective*
- *Coping, Ineffective*
- *Airway Clearance, Ineffective*
- *Anxiety.*

(NANDA-I © 2014)

Planning

When designing the plan of care, the nurse must put the patient's needs, and no other expectations, at the forefront of the plan. If the patient has no motivation to make healthier life choices, the nurse must respect the choices the patient makes. Goals for patient care may include the following:

- The patient will verbalize the negative effects, both short term and cumulative, associated with smoking.
- The patient will voice strategies for support with quitting if/when the patient is ready to stop smoking.
- The patient will identify three activities that can aid in avoiding nicotine use.
- The patient will not experience complications as a result of nicotine use.

Implementation

The nurse's role regarding smoking is to (a) serve as a role model by not smoking, (b) provide educational information regarding the dangers of smoking, (c) help make smoking socially unacceptable (e.g., by posting no-smoking signs in patient lounges and offices), and (d) suggest resources such as hypnosis, lifestyle training, and behavior modification to patients who want to stop smoking. Nurses also can promote health related to tobacco by being aware of marketing efforts that target young adults. The tobacco industry has developed very effective campaigns to encourage smoking among young adults by advertising and sponsoring entertainment events.

Federal and state public policies have been some of the most effective tools at combating smoking. Some of these included making tobacco products less affordable; restricting tobacco marketing; banning smoking in public places, for example, workplaces, schools, day care centers, hospitals, restaurants, hotels, and parks; and requiring tobacco companies to label tobacco packages with information

regarding health risks (CDC, 2012). Mass media campaigns against tobacco use, such as TV ads, have proven effective at helping prevent tobacco use by young people. Studies show that teens respond most to ads that trigger strong negative feelings, such as ads about the dangerous health effects of smoking and secondhand smoke and ads that expose the tobacco industry's marketing strategies that target young people (CDC, 2012). Even ads targeted for adult audiences help reduce tobacco use among young people. Finally, major league sports organizations have launched anti-tobacco media campaigns aimed at children and young adults. The focus of the campaigns has been athletes who use smokeless tobacco, implicated in oral, pancreatic, and esophageal cancers; mouth lesions; and tooth decay (Campaign for Tobacco-Free Kids, 2015). See the module on Oxygenation for additional interventions related to smoking cessation.

Evaluation

Patients are evaluated on the basis of the goals created during the planning stage. Expected outcomes may include the following:

- The patient describes feelings regarding nicotine use, abstinence, and methods of coping without the use of nicotine.
- The patient verbalizes negative effects on his or her own life and the lives of loved ones as a result of nicotine use.
- The patient is free of injury or complications resulting from nicotine use.
- The patient describes strategies that will be or can be useful when beginning a program to quit smoking.

Nurses should not be surprised when patients have difficulty quitting. The American Cancer Society (ACS) (2014) has noted that smoking cessation programs, like other programs that treat addictions, often have a fairly low success rate. The ACS has stated that only about 4 to 7% of people are able to successfully quit smoking on any given attempt without medications or other help. However, the success rate increases for patients who use adjunct therapies with nicotine replacement therapy. According to the ACS, studies in medical journals have reported that about 25% of smokers who use medications can stay smoke-free for more than 6 months. Clinicians should consider adding medications combined with counseling and other types of emotional support to boost success rates.

REVIEW Nicotine Use

RELATE Link the Concepts and Exemplars

Linking the exemplar of nicotine use with the concept of oxygenation:

1. Describe the pathophysiology of the respiratory system and the ability of the alveoli to oxygenate the tissues when a patient smokes.
2. While caring for a patient who is known to have smoked for more than 30 years, how would you amend your nursing plan of care as related to oxygenation?

Linking the exemplar of nicotine use with the concept of grief and loss:

3. The nurse is caring for a patient with terminal lung cancer and is talking with the family. The patient's daughter says, "If Dad wanted to stay around and be with us, he wouldn't have made the choice to smoke." How would you respond to this statement and help the family members deal with their anger over the patient's lifestyle choices?
4. Why might a patient with acute COPD who continues to smoke be denied a lung transplant? How can you help this patient

(and family) deal with the grief and loss they experience as a result of this decision?

- Nursing Care Plan for a Patient with Nicotine Addiction

REFLECT Apply Your Knowledge

Mr. Wojikowski, a 50-year-old professional, has pneumonia and is currently being treated with antibiotics. He smokes two packs of cigarettes a day. Since this bout of pneumonia, he voices concern about his smoking and wonders if he should try to quit again. He states,

"I've tried everything and nothing works. The longest I last is about 1 month." He admits to being 30 pounds overweight and states that his wife and he have started walking 30 minutes every evening. His wife also has started making low-fat meals. He is concerned that if he quits smoking, he will gain more weight.

1. What information or knowledge is important for the nurse to remember when assisting a patient to advance to the next stage of change?
2. Each contact between a nurse and a patient is an opportunity for health promotion. Based on the knowledge or key concepts listed above, what question(s) would you ask Mr. Wojikowski?
3. In which state of change is Mr. Wojikowski relating to his cigarette smoking? What strategies could you, the nurse, consider?

Exemplar 22.C Substance Abuse

Exemplar Learning Outcomes

22.C Analyze manifestations and treatment considerations for patients who abuse substances.

- Describe the pathophysiology of substance abuse.
- Describe the etiology of substance abuse.
- Compare the risk factors and prevention of substance abuse.
- Identify clinical manifestations of substance abuse.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual who abuses substances.
- Differentiate care of patients across the lifespan who abuse substances.
- Apply the nursing process in providing culturally competent care to an individual who abuses substances.

Overview

Substance abuse refers to the use of any chemical in a manner inconsistent with medical or culturally defined social norms despite physical, psychologic, or social adverse effects. A substance use disorder (SUD) is a cluster of cognitive, behavioral, and physiologic symptoms that indicate continued use of a substance despite significant negative consequences such as illness, functional impairment, or disruption of relationships (APA, 2013). Although all SUDs have common psychologic symptoms, researchers recently have been focusing on the underlying physiologic changes in brain circuitry that often persist even after detoxification, especially in individuals with severe disorders. It is believed that these permanent brain changes cause the behavioral effects characteristic of individuals with SUD, such as repeated relapses and intense substance craving (APA, 2013).

To be diagnosed with an SUD, an individual must exhibit a problematic pattern of substance use and a pathologic pattern of behaviors related to substance use. Patterns of symptoms recognized as part of the diagnostic criteria for SUD from the DSM-5 include symptoms related to impaired

control, social impairment, and risky use, as well as pharmacologic criteria (APA, 2013).

Symptoms of **impaired control** include taking a substance in larger amounts over a longer period of time; wanting to reduce use and reporting multiple unsuccessful attempts to cut down or quit; spending a lot of time obtaining, using, or recovering from the effects of the substance; and having daily activities that revolve around the substance. **Craving**, an intense desire for the substance, where it is difficult to think of anything else, also falls in the category of impaired control (APA, 2013). Craving often causes individuals to start using substances again.

Social impairment or dysfunction due to substance use may exhibit as failure to fulfill major roles at work, school, or home; continued substance use despite ongoing or recurrent social or interpersonal problems caused by the substance; and abandonment of or withdrawal from family, occupational, social, and/or recreational obligations and activities (APA, 2013).

Risky use is defined as repeated use of substances in situations in which it is physically hazardous and despite knowledge that the individual has a persistent physical or

psychologic problem caused or worsened by substance use (APA, 2013). Pharmacologic criteria or symptoms include **tolerance**, needing a markedly larger dose of substance to achieve the desired effect of the substance. When attempting **withdrawal**, that is, abstinence from substances, the individual experiences uncomfortable withdrawal symptoms that often prompt resumed consumption of the substance (APA, 2013). Withdrawal occurs when an individual reduces or stops a drug that has been used heavily over a long period of time; it consists of a cluster of substance-specific behavioral symptoms with physiologic and cognitive components. Withdrawal causes clinically significant distress or impairment in social, occupational, or other important areas of function (APA, 2013). When an individual stops using a substance, uncomfortable, distressing, or even dangerous withdrawal symptoms can occur within hours. Depending on the amount of drugs consumed, withdrawal may put the patient in medical danger and may last up to several days.

The DSM-5 includes 10 separate classes of substances, ranging from alcohol, caffeine, and tobacco to cannabis, hallucinogens, opioids, sedatives, and stimulants (APA, 2013). For the purpose of this exemplar, the term *substance abuse* refers specifically to drugs, both legal and illegal, that lead to addiction and dependence. Because alcohol and nicotine are often abused, they are covered in separate exemplars in this concept. Three other commonly abused substances are cannabis (marijuana), opioids, and stimulants, which are discussed later in this exemplar.

Substance use disorders can range in severity from mild to severe, depending on the number of symptoms displayed by the individual. Substances can also induce disorders, such as psychosis experienced from taking hallucinogens. Substance use or abuse may co-occur with other mental health disorders, such as anxiety and depression. Approximately 20% of Americans with an anxiety or mood disorder such as depression also have an alcohol or other substance use disorder (Anxiety and Depression Association of America [ADAA], 2015). Substance use disorders by themselves are second only to mood disorders as the most frequent risk factors for suicidal behaviors (Office of the Surgeon General and National Action Alliance for Suicide Prevention, 2012).

Pathophysiology and Epidemiology

Pathophysiology

The pathophysiology of substance abuse was discussed earlier in the module. In summary, it is a complex, multifactorial process that involves a combination of biological, genetic, psychologic, and sociocultural factors. These factors and others may affect the process of recovery. For example, the craving that an individual has for a particular substance may be heightened by a phenomenon known as the **kindling effect**. **Kindling** refers to long-term changes in brain neurotransmission that occur after repeated detoxifications (Breese, Sinha, & Heilig, 2011). Recurrent detoxifications increase neuron sensitivity and are thought to intensify obsessive thoughts or cravings for a substance. Eventually, the brain responds spontaneously in a dysfunctional manner even when the substance is no longer being

used (Alterman, 2014). This phenomenon may explain why subsequent episodes of withdrawal from a substance tend to get progressively worse.

Etiology and Epidemiology

As stated earlier, the etiology of substance use is multifactorial, and it varies among individuals. Adolescents, for example, may begin to use if friends or peers are using, and then continue to use when they find that the drug activates the brain's reward center and results in a desired effect. In contrast, an adult who experiences a severe injury may initially take an opiate, such as OxyContin, for pain relief and find himself needing more of the drug to continue to cope with psychologic consequences of the injury well after the injury has physically healed. Regardless of the initial reasons for use, however, most individuals experience similar patterns of tolerance and dependency the longer they continue to use a substance. Individuals who use substances within the context of a drug culture may be more resistant to treatment and are at greater risk for relapse (see the Focus on Diversity and Culture feature).

As stated earlier, in 2015, more than 27 million Americans reported the current use of illicit drugs of misuse or prescription drugs (Surgeon General, 2016). The most commonly used illicit drug is marijuana. Approximately 22.5 million people age 22 or older used marijuana in 2014. An estimated 6.5 million people reported nonmedical use of psychotherapeutic drugs in the past month, including 4.3 million nonmedical users of prescription pain relievers. Thus, the number of current nonmedical users of pain relievers was second to marijuana among specific illicit drugs. Over half of first-time users (54.1%) were younger than age 18 when they first used, and more than half of new users were female. The 2013 average age of first use among those age 12 to 49 was 19.0 years. Of those using illicit drugs for the first time in 2013, 70.3% reported marijuana as their first drug (CBHSQ, 2014).

Substance use disorders in the United States cost over \$700 billion a year, including the costs of treatment, related health problems, absenteeism, lost productivity, drug-related crime and incarceration, and education and prevention. This includes \$224 billion for alcohol, and \$193 billion for illicit drugs, and \$295 billion for tobacco (NIDA, 2015b, 2015d). The relapse rates for drug addiction are 40–60%, comparable to relapse rates of other chronic illnesses, such as diabetes, hypertension, and asthma (NIDA, 2014a). Although cocaine, hallucinogens, inhalants, and heroin continue to be popular, marijuana use has experienced the greatest increase (CBHSQ, 2014).

In 2012, an estimated 2.1 million people in the United States experienced SUD related to prescription opioid pain relievers, and an estimated 467,000 were addicted to heroin (NIDA, 2014d). Use of prescription opioids (including OxyContin, hydrocodone, and morphine) is being increasingly examined, and individuals with chronic pain are being referred more often to pain specialists who frequently rely on nonopioid analgesics. Regulatory agencies and third-party payers have tightened control of prescriptions, and pharmaceutical manufacturers have introduced abuse-deterrent formulations of opioid medications. The result has been a transition to abuse of heroin, which is

cheaper and in some communities easier to obtain than prescription opioids (NIDA, 2014d). Heroin abuse is dangerous because of the drug's addictiveness and its high risk for overdosing. With heroin, this danger is compounded by the lack of control over the purity of the injected drug and its possible contamination with other drugs. Heroin use has increased across the United States among men and women, most age groups, and all income levels. Some of the greatest increases occurred in demographic groups with historically low rates of heroin use: women, the privately insured, and people with higher incomes. As heroin use has increased, so have heroin-related overdose deaths. Between 2002 and 2013, the rate of heroin-related overdose deaths nearly quadrupled, and more than 8200 people died in 2013 (CDC, 2015e).

SAFETY ALERT Naloxone hydrochloride is a lifesaving medication that can stop or reverse the effects of an opioid or heroin overdose. Drug overdose deaths, driven largely by prescription drug overdoses, are now the leading cause of injury death in the United States—surpassing motor vehicle crashes. Naloxone (also known as Narcan) is available in nasal spray and injectable forms over the counter, can be used in adults or children, and is easily administered by anyone, even those without medical training (Food and Drug Administration, 2015). Family members and support persons of individuals with known addiction problems should acquire these rescue medications and prepare themselves to administer them in case of an overdose.

Focus on Diversity and Culture

Key Characteristics of a Drug Culture

Besides needing an understanding of current drug cultures—to help prevent infiltration of related behaviors and attitudes within the treatment environment—mental health clinicians also must help patients understand how such cultures support use and pose dynamic relapse risks (SAMHSA, 2014b). Drug cultures can change rapidly and vary across racial and ethnic groups, geographic areas, socioeconomic levels, and generations. Some of the questions used to obtain information about a particular drug culture center on the group's processes for establishing trust and credibility; socialization and values; obtaining status; gender roles and relationships; concepts of sanction, punishment, and conflict mediation; symbols, images, and dress; language and communication; and attitudes.

While there may be overlap among members, drug cultures differ based on substance used—even among people from similar ethnic and socioeconomic backgrounds (SAMHSA, 2014b). Drug cultures can differ according to geographic area as well as other social factors, such as socioeconomic status. For example, the drug culture of young, affluent people who use heroin can mirror the drug culture of street users, but it will also have notable differences. Finally, drug cultures change over time: Older people from New York who use heroin and who entered the drug culture in the 1950s or 1960s feel marginalized within the current drug scene, which they see as promoting a different set of values (SAMHSA, 2014b).

Risk Factors

Risk factors for drug abuse are multifactorial and can affect individuals of any age, gender, or economic status. Some factors that affect the likelihood and speed of developing an addiction include a family history of addiction; the presence of another mental disorder; the use of drugs as a coping mechanism to manage anxiety or depression; peer pressure; and lack of family involvement. Although men are more likely to experience problems with drugs than women, progression of addiction is faster among women than men (Mayo Clinic, 2015b).

Clinical Manifestations

Clinical manifestations, and their severity, depend on amount, frequency, and specific combination of substances used. Combining two CNS depressants, for example, will produce far more significant manifestations than using only one CNS depressant. Some symptoms can be alarming or even fatal. For example, long-term crack use can result in sensory hallucinations, and even the first use of cocaine can result in death for individuals with undiagnosed cardiac disorders. Clinical manifestations are linked to specific substances in the following sections.

Caffeine

Caffeine is a stimulant that increases the heart rate and acts as a diuretic. Although commonly consumed daily in soft drinks, coffee, tea, chocolate, and some pain relievers, an excessive amount of caffeine can cause negative physiologic effects, especially cardiac-related risks. Approximately 300 mg/day is safe for most healthy adults, but over 600 mg is considered excessive and is not recommended (Kneisl & Trigoboff, 2013). Individuals with a history of cardiac disease should be advised to cut down caffeine intake or eliminate it altogether. Caffeine, if consumed in large quantities, also can cause higher total cholesterol levels and insomnia.

Many individuals recognize the adverse effects of too much caffeine in their system and voluntarily cut down by drinking decaffeinated beverages. An individual who is addicted to caffeine and abruptly withdraws from it will most likely experience headaches and irritability. However, even with evidence of withdrawal symptoms, some clinicians do not consider caffeine as addicting, because it does not have a major action on the mesolimbic dopamine system (McNeece & DiNitto, 2012).

A rising number of adolescents are developing symptoms of caffeine dependence from consuming sizable quantities of caffeinated energy drinks. Energy drinks contain caffeine that ranges from 50 mg to 500 mg per can or bottle, compared with the average can of cola that has 35 mg (CDC, 2014). Researchers predict an increase in caffeine intoxication and problems with caffeine dependence and withdrawal, including sleep issues. Genetic factors may also play a role in these clinical manifestations.

According to the CDC (2014), young people who ingest energy drinks are more likely to participate in unhealthy behaviors, including alcohol use. Of particular concern are alcoholic beverages mixed with energy drinks, because the

caffeine in these drinks can mask the depressant effects of alcohol. Individuals who consume alcohol mixed with energy drinks are three times more likely to binge drink and are twice as likely to report being taken advantage of sexually, to report taking advantage of someone else sexually, and to report riding with a driver who was under the influence of alcohol than drinkers who do not mix caffeine with alcohol (CDC, 2015a). Furthermore, researchers have found that recent traumatic brain injury (TBI) is more strongly related to consuming alcohol, energy drinks, and energy drinks and alcohol mixed. Consumption of these substances may be a coping mechanism to deal with the effects of TBI, or they may predispose adolescents to TBI, or both (Ilie et al., 2015).

Cannabis

Cannabis sativa is the source of marijuana. The greatest concentrations of psychoactive substances are in the flowering tops of the cannabis plant. Marijuana (also known as grass, weed, pot, dope, joint, and reefer) and hashish are the most common derivatives. The psychoactive component of marijuana is an oily chemical known as delta-9-tetrahydrocannabinol (THC). THC activates specific cannabinoid receptors in the brain and may act like opioids and cocaine in producing a pleasurable sensation.

The physiologic effects of cannabis are dose related and can cause an increase in heart rate and bronchodilation with short-term use. Chronic long-term use can lead to airway constriction and inflammation, and increased incidence of acute and chronic bronchitis (World Health Organization [WHO], 2013). Cannabis use also causes decreased spermatogenesis and testosterone levels in men and suppresses follicle-stimulating, luteinizing, and prolactin hormones in women, making breastfeeding impossible for new mothers. Birth defects also may be associated with cannabis use. Marijuana crosses the placental barrier and is spread to fetal tissues.

Euphoria and relaxation are the pleasurable effects most associated with marijuana use. Other subjective effects of marijuana include sedation and hallucinations. With increased use, marijuana can result in amotivational behaviors such as apathy, dullness, poor grooming, reduced interest in achievement, and disinterest. Memory impairment is common, because of the alteration of how information is processed in the hippocampus.

It is estimated that 9% of people who use marijuana will become dependent on it. The number increases to about 17% in those who start using at a young age (in their teens) and to 25 to 50% among daily users (NIDA, 2015c). Marijuana addiction is linked to a mild withdrawal syndrome, with frequent users reporting irritability, mood and sleep difficulties, decreased appetite, cravings, restlessness, and/or various forms of physical discomfort that peak within the first week after quitting and last up to 2 weeks.

A new health concern is the potency of cannabis, which has steadily increased over the past few decades. In the early 1990s, the average tetrahydrocannabinol (THC, a psychoactive substance) content in confiscated cannabis samples was roughly 3.7% for marijuana and 7.5% for *sinsemilla*, a higher-potency marijuana from

specially tended female plants (NIDA, 2015c). In 2013, the THC content was 9.6% for marijuana and 16% for *sinsemilla*. Also, new methods of smoking or eating THC-rich hash oil extracted from the marijuana plant (a practice called “dabbing”) may deliver very high levels of THC to the user. The average marijuana extract contains over 50% THC, with some samples exceeding 80% (NIDA, 2015c). These trends raise concerns that the consequences of marijuana use could be worse than in the past, particularly among new users or in young people, whose brains are still developing.

The 2013 *National Survey on Drug Use and Health* found that marijuana continues to be the most common illicit drug used (CBHSQ, 2014). In 2013, there were 19.8 million current users age 12 or older (7.5%), with as many as 11.7% of 8th graders reporting marijuana use in the past year. By 12th grade, 35.1% had used marijuana during the year prior to the survey and 21.2% were current users, with 5.8% saying they used marijuana daily or near daily (NIDA, 2015c).

Central Nervous System Depressants

Central nervous system (CNS) depressants, including barbiturates, benzodiazepines, paraldehyde, meprobamate, and chloral hydrate, also are subject to abuse. Cross-dependence exists among all CNS depressants, and cross-tolerance can develop to alcohol and general anesthetics. Chronic users of barbiturates require progressively higher doses to achieve subjective effects as tolerance develops, but they develop little tolerance to respiratory depression. The depressant effects related to barbiturates are dose dependent and range from mild sedation to sleep to coma to death. With larger doses over time and a combination of alcohol and barbiturates, the risk of death increases greatly.

The risk of accidental overdose and death resulting from barbiturates has resulted in decreased use, yet barbiturates are still clinically useful in treating seizure disorders and alcohol withdrawal. Benzodiazepines remain an option for short-term treatment of anxiety. Benzodiazepines alone are safer than barbiturates because an overdose of oral benzodiazepines rarely results in death. However, when taken together, CNS depressants (for example, alcohol and benzodiazepines) can result in death.

Psychostimulants

Psychostimulants such as cocaine and amphetamines have a high potential for abuse. Euphoria is the main subjective effect associated with cocaine and amphetamines, leading to addiction. Powdered cocaine has been “snorted” (inhaled through the nostrils) for thousands of years, but a more dangerous method is freebasing. Cocaine base (freebased cocaine, or “crack”) is heat stable and is usually “cooked” in a baking soda solution and smoked (freebasing). Cocaine hydrochloride is diluted or cut before sale, and the pure form (“rocks”) can be administered intranasally (snorted) or injected intravenously. “Skin popping” is a subcutaneous

method that many substance abusers are using to administer drugs, perhaps leading to the formation of abscesses under the skin.

The duration of euphoria achieved by cocaine depends on the route of administration. Regardless, the pleasurable effects do not last long, and its highly addictive properties can easily lead to overdose. A mild overdose of cocaine produces agitation, dizziness, tremor, and blurred vision. A severe overdose produces anxiety, hyperpyrexia, convulsions, ventricular dysrhythmias, severe hypertension, and hemorrhagic stroke with possible angina or myocardial infarction.

Long-term intranasal use of cocaine can cause atrophy of the nasal mucosa, necrosis and perforation of the nasal septum, and lung damage. Crack cocaine injection requires serious attention because this drug use is associated with increased rates of high-risk behaviors (NIDA, 2013a).

Amphetamine is a powerful stimulant that poses a severe health risk to society because of its devastating physical and neurologic consequences, including amphetamine-induced mental disorders. Methamphetamine is a highly addictive form of amphetamine whose use is widespread because its manufacturing process can be carried out by individuals without special knowledge or expertise in chemistry. Methamphetamine is often taken in combination with other drugs such as cocaine and marijuana. Smoking or injection provides the greatest euphoria, although it may also be inhaled or ingested. Chronic use or abuse can result in paranoia, hallucinations, and compulsions. Some users experience delusions that insects are crawling over them, resulting in obsessive scratching. Psychosis characterized by violent behavior may also result (Partnership at Drugfree.org, 2013).

Amphetamines cause arousal and an elevation of mood with a sense of increased strength, mental capacity, and self-confidence and a decreased need for food and sleep. Tolerance to mood elevation, appetite suppression, and cardiovascular effects develops with amphetamines; however, dependence is more psychologic than physical.

Withdrawal from amphetamines produces dysphoria and craving with fatigue, prolonged sleep, excessive eating, and depression. Methamphetamine addiction can be successfully treated. Programs using a combination of individual and group therapy designed to promote behavioral changes as well as incentive-based programs have been cited as effective. Although there is currently no proven pharmacologic therapy, research in that area continues (NIDA, 2013b).

Opiates

Opiates such as morphine, meperidine, codeine, hydrocodone, oxycodone, and oxycodone are narcotic analgesics. Some common brand names include Vicodin, Percocet, OxyContin, and Opana. Narcotic analgesics are a type of pain reliever derived from natural or synthetic opiates. It is estimated that between 26.4 million and 36 million people abuse opioids worldwide, with an estimated 2.1 million people in the United States experiencing substance use disorders related to prescription opioid pain relievers in 2012 (NIDA, 2014d). The consequences of this abuse have been devastating. For

Source: From CDC. (2015). *Drug-poisoning deaths involving heroin: United States, 2000–2013*. Retrieved from <http://www.cdc.gov/nchs/data/databriefs/db190.htm>

Figure 22-6 While the age-adjusted rate for drug-poisoning deaths involving opioid analgesics has leveled in recent years, the rate for deaths involving heroin has almost tripled since 2010.

example, the number of unintentional overdose deaths from prescription pain relievers in the United States has more than quadrupled since 1999, although it is now leveling off (**Figure 22-6**). Further, drug abuse–related ED visits involving narcotic analgesics increased 153% in the nation from 2004 to 2011, with 420,040 ED visits in 2011 (Crane, 2015). Although the use of narcotic analgesics for acute pain management looks benign, long-term use has been associated with significant rates of abuse or addiction. Three problematic physiologic effects are hyperalgesia, hypogonadism, and sexual dysfunction (Manchikanti et al., 2010).

Heroin is an opiate that has been abused for many centuries and is usually administered intravenously. It induces a “rush” or “kick” that lasts less than a minute, followed by a sense of euphoria lasting several hours. Tolerance develops to the euphoria, respiratory depression, and nausea, but not to constipation and miosis. Physical dependence occurs with long-term use of opiates (**Figure 22-7**). Initial withdrawal symptoms such as drug craving, lacrimation (tear production), rhinorrhea, yawning, and diaphoresis usually take 10 days to run their course. The second phase of opiate withdrawal lasts for months, with insomnia, irritability, fatigue, and potential GI hyperactivity and premature ejaculation as problems.

Methadone is a synthetic opiate used to treat chronic pain and addiction to other opiates. Methadone does not hinder ability to function productively as other narcotics do, and it is a viable support for withdrawal (NIDA, 2014b).

Hallucinogens

Hallucinogens, also called *psychedelics*, include PCP, 3,4-MDMA, D-lysergic acid diethylamide (LSD), mescaline, dimethyltryptamine (DMT), and psilocin. Psychedelics bring on the same types of thoughts, perceptions, and feelings that occur in dreams. PCP (also called *angel dust*) was developed in the 1950s as an anesthetic similar to ketamine.

Source: Derek Davis/Portland Press Herald/Getty Images.

Figure 22-7 » Paramedics monitor a 29-year-old woman after she was found unconscious from a heroin overdose. The woman thanked the paramedics, one of whom recognized her from an overdose about a month ago. “At least I still have my shoes this time” said the woman who told the paramedics that she normally uses $\frac{1}{2}$ gram of heroin twice a day, but had cut her dose to $\frac{1}{4}$ gram that night because she had heard that it was stronger than usual.

Because of its severe side effects, its development for human use was discontinued. The most common route of administration is smoking tobacco, marijuana, or herbal cigarettes laced with PCP powder or the liquid form of PCP. In the clinical setting, patients experiencing PCP intoxication are often violent and difficult to control physically. A chemical restraint is frequently needed to protect other patients and staff from an agitated PCP user. Haloperidol (Haldol) has been evaluated as an effective medical intervention that does not cause harm to the patient (MacNeal et al., 2012).

MDMA, commonly known as Ecstasy, was very popular in the 1980s as a recreational “club drug” associated with dance clubs and “raves” and has reappeared in recent years as a date or rape drug. According to the 2013 *National Survey on Drug Use and Health* data, among people age 12 or older, 0.2%, some 609,000 people, used Ecstasy (CBHSQ, 2014). Ecstasy use from 2002 to 2014 has been fairly stable. Parties where other drugs such as marijuana and alcohol are present may lead to easier access or availability of Ecstasy, thereby increasing the chances for first-time Ecstasy use.

LSD affects serotonin receptors at multiple sites in the brain and spinal cord. LSD is usually taken orally but can be injected or smoked, as in tobacco- or marijuana-laced cigarettes. The individual’s response to a trip, the experience of being high on LSD, cannot be predicted. Psychologic effects (e.g., seeing bursts of radiant colors and seeing objects that appear to breathe) and flashbacks are common. Serotonin imbalance is thought to affect impulse control and may be responsible for uninhibited sexual responses in women who

have been given the drug without their knowledge. Other hallucinogens are similar to LSD but have a different potency and course of action. Because physical dependence to hallucinogens does not appear to occur, withdrawal symptoms are not present.

Inhalants

Inhalants are categorized into three types: anesthetics, volatile nitrites, and organic solvents. Nitrous oxide (laughing gas) and ether are the most abused anesthetics. Amyl nitrite, butyl nitrite, and isobutyl nitrite are volatile nitrites used especially by homosexual men to induce venodilation and anal sphincter relaxation. Amyl nitrite is manufactured for medical use, but butyl and isobutyl nitrites are sold for recreational use. Other names for butyl and isobutyl nitrites are *climax*, *rush*, and *locker room*. Street names for amyl nitrite are *poppers* and *snappers*. Brain damage or sudden death can occur the 1st, 10th, or 100th time an individual uses an inhalant, resulting in “sudden sniffing death.” This danger makes the use of inhalants more hazardous than some other substances. Inhalant use is highest among adolescents (NIDA, 2012a).

Another danger is the wide assortment of organic solvents that are available to and inhaled by young children. Organic solvents are ingested by three different methods: bagging, huffing, and sniffing. *Bagging* involves pouring the solvent in a plastic bag and inhaling the vapor. *Huffing* refers to pouring the solvent on a rag and inhaling. *Sniffing* refers to inhaling the solvent directly from the container. Common organic solvents are toluene, gasoline, lighter fluid, paint thinner, nail polish remover, benzene, acetone, chloroform, and model airplane glue. The effects from inhaling organic solvents are similar to those of alcohol. Prolonged use can lead to multiple toxicities. There are no antidotes for these inhalants; therefore, management of overdose is supportive.

Inhalant users have a compulsion to continue using inhalants, particularly if they have abused inhalants for prolonged periods. A mild withdrawal syndrome can occur with long-term inhalant abuse (NIDA, 2012a). Research suggests that inhalant users, on average, initiate use of cigarettes, alcohol, and almost all other drugs at younger ages and display a higher lifetime prevalence of substance use disorders, including abuse of prescription drugs, when compared with substance abusers without a history of inhalant use. Research has also discovered a link between eating disorders and inhalant use among both male and female students (NIDA, 2012a).

Collaboration

Effective treatment of substance abuse and dependence results from the efforts of an interprofessional team specializing in the treatment of psychiatric and substance use disorders. Therapies may include detoxification, aversion therapy to maintain abstinence, group and individual psychotherapy, psychotropic medications, cognitive-behavioral strategies, family counseling, and self-help groups. Patients who are abusing substances can be treated in either an inpatient or outpatient setting. A substance overdose is a

life-threatening condition that requires emergency hospitalization to stabilize the patient medically before any of the interventions mentioned are implemented. Several diagnostic tests can provide valuable information about the patient's physical condition and set the course for treatment.

Diagnostic Tests

The body fluids most often tested for drug content are blood and urine, although saliva, perspiration, and hair may be tested. More invasive procedures such as serum drug levels are useful in the ED and other hospital settings to treat drug overdoses or complications. Urine drug screening (UDS), which is noninvasive, is the preferred method for detecting substances in the body. The length of time that drugs can be found in blood and urine varies from 24 hours to 30 days according to dosage and metabolic properties of the drug. THC, the psychoactive substance found in marijuana, is stored in fatty tissues (especially the brain and reproductive system) and can be detected in the body for up to 6 weeks (Kneisl & Trigoboff, 2013).

Pharmacologic Therapy

Common drugs used in the treatment of substance abuse and withdrawal are presented in the Medications feature in The Concept of Addiction.

Emergency Care for Overdose

Overdose of a patient on any substance is a serious medical emergency. Respiratory depression may require mechanical ventilation. The patient may become severely sedated and difficult to arouse. Every effort must be made to keep the patient awake; however, stupor and coma often result. A seizure is another serious complication that requires emergency treatment. If the overdose was intentional, the patient must be monitored constantly for further signs of suicidal ideation. An actively suicidal patient must never be left alone. Signs of overdose and withdrawal from major substances are summarized in **Table 22-4** » along with recommended treatments.

Complementary Health Approaches

Auricular (ear) acupuncture has been used throughout the world as an adjunctive treatment during opioid detoxification for about 30 years. Although not subjected to rigorous controlled research, auricular acupuncture has been shown in smaller studies to benefit patients dependent on heroin. Patients with mild habits appeared to benefit more than those with severe withdrawal symptoms, which acupuncture did not alleviate. The 1997 National Institute of Health Consensus Statement on acupuncture stated that acupuncture treatment for addiction could be part of a comprehensive management program. The National Acupuncture Detoxification Association has developed protocols involving ear acupuncture in group settings that originated at Lincoln Hospital in the Bronx and are used by more than 400 drug treatment programs and 40% of drug courts (SAMHSA, 2015b).

Lifespan Considerations

At various stages of life, individuals become involved with substances for an assortment of reasons. Some of the salient lifespan factors associated with substance use disorder are discussed in the following section.

Substance Abuse in Adolescents

By the time they are seniors, 50% of high school students will have taken an illegal drug and more than 20% will have used a prescription drug for nonmedical reasons (NIDA, 2014e). Teens are particularly vulnerable to substance use disorders because of their developmental stage and because their brains are still developing and malleable until the mid-20s (NIDA, 2014e).

Adolescents use illicit substances for a variety of reasons, including the desire for new experiences, an attempt to deal with problems or perform better in school, and peer pressure. Many factors influence adolescent drug use, including the availability of drugs within the neighborhood, community, and school and whether the adolescent's friends are using drugs (NIDA, 2014e). Factors such as violence, physical or emotional abuse, mental illness, or drug use in the home increase the likelihood that an adolescent will use drugs. Adolescents who use drugs may have an inherited genetic vulnerability. Personality traits such as poor impulse control, a heightened need for excitement, and mental health conditions such as depression, anxiety, or ADHD make substance use more likely (NIDA, 2014e). Drug use at an early age is an important predictor of development of a substance use disorder later.

Substance Abuse in Pregnant Women

During pregnancy, the fetus is exposed to chemicals or substances that have the potential to harm the fetus. These teratogens can cause the fetus to experience alterations ranging from developmental delays to death. Substances commonly misused include cocaine, amphetamines, barbiturates, hallucinogens, club drugs, heroin, and other narcotics. Poly-substance use, which involves combining multiple substances with alcohol, tobacco, and illicit drugs, is common. Of pregnant women age 15 to 44, an estimated 5.4% annually are illicit drug users based on data averaged across 2012 and 2013 (CBHSQ, 2014). An overview of the potential effects of selected drugs is provided in **Table 22-5** ».

Use of opiates during pregnancy can result in a drug withdrawal syndrome in newborns called **neonatal abstinence syndrome (NAS)**. NAS is occurring in epidemic numbers: There was a fivefold increase in the proportion of babies born with NAS from 2000 to 2012, when an estimated 21,732 infants were born with NAS—equivalent to one baby experiencing opiate withdrawal born every 25 minutes in the United States (NIDA, 2015a). Newborns with NAS are more likely than other babies to also have low birth weight and respiratory complications and require an average of 16.9 days in the hospital (compared to 2.1 days for other newborns), costing hospitals an estimated \$1.5 billion. The majority of these charges (as high as 81%) are paid by state Medicaid programs, reflecting the tendency of opiate-abusing mothers to be from lower-income communities (NIDA, 2015a).

TABLE 22–4 Signs and Treatment of Overdose and Withdrawal

Drug	Overdose		Withdrawal	
	Signs	Treatment	Signs	Treatment
CNS Depressants				
Alcohol Barbiturates Benzodiazepines	Cardiovascular or respiratory depression or arrest (mostly with barbiturates) Coma Shock Convulsions Death	<i>If awake:</i> 1. Keep awake 2. Induce vomiting 3. Use activated charcoal to absorb drug 4. Vital signs (VS) q 15 minutes <i>Coma:</i> 1. Clear airway, intubate IV fluids 2. Perform gastric lavage 3. Take seizure precautions 4. Administer hemodialysis or peritoneal dialysis if ordered 5. Assess VS as ordered 6. Assess for shock and cardiac arrest.	Nausea and vomiting Tachycardia Diaphoresis Anxiety or agitation Tremors Marked insomnia Grand mal seizures Delirium (after 5–15 years of heavy use)	Carefully titrated detoxification with similar drug <i>Note:</i> Abrupt withdrawal can lead to death
Stimulants				
Cocaine/crack Amphetamines	Respiratory distress Ataxia Hyperpyrexia Convulsions Coma Stroke Myocardial infarction Death	Management for: 1. Hyperpyrexia 2. Convulsions 3. Respiratory distress 4. Cardiovascular shock 5. Acidic urine (ammonium chloride for amphetamine).	Fatigue Depression Agitation Apathy Anxiety Sleepiness Disorientation Lethargy Craving	Antidepressants (desipramine) Dopamine agonist Bromocriptine
Opiates				
Heroin Meperidine Morphine Methadone	Pupil dilation due to anoxia Respiratory depression arrest Coma Shock Convulsions Death	Narcotic antagonist (Narcan) quickly reverses CNS depression	Yawning, insomnia Irritability Rhinorrhea Panic Diaphoresis Cramps Nausea and vomiting Muscle aches Chills and fever Lacrimation Diarrhea	Methadone tapering Clonidine-naltrexone detoxification Buprenorphine substitution
Hallucinogens				
LSD	Psychosis Brain damage Death	1. Reduce environmental stimuli 2. Have one person “talk down patient”; reassure 3. Speak slowly and clearly 4. Administer diazepam or chloral hydrate for anxiety as ordered	No pattern of withdrawal	
PCP	Possible hypertensive crisis Respiratory arrest Hyperthermia Seizures	1. Acidify urine to help excrete drug (cranberry juice, ascorbic acid); in acute stage: ammonium chloride 2. Minimize stimuli 3. Do <i>not</i> attempt to talk down; speak slowly in low voice 4. Administer diazepam or Haldol as ordered	No pattern of withdrawal	
Inhalants				
Volatile solvents such as butane, paint thinner, airplane glue, and nail polish remover	Intoxication Agitation Drowsiness Disinhibition Staggering Light-headedness Death	Support affected systems	No pattern of withdrawal	
Nitrites	Enhanced sexual pleasure	Neurologic symptoms may respond to vitamin B ₁₂ and folate	No pattern of withdrawal	
Anesthetics such as nitrous oxide	Giggling, laughter Euphoria	Chronic users may experience polyneuropathy and myelopathy	No pattern of withdrawal	

TABLE 22–5 Potential Effects of Selected Drugs on Fetus/Newborn

Maternal Drug	Effect on Fetus/Newborn
Heroin	Withdrawal symptoms, convulsions, intrauterine growth restriction (IUGR), tremors, irritability, sneezing, vomiting, fever, diarrhea, and abnormal respiratory function
Methadone	Fetal distress, meconium aspiration; with abrupt termination of the drug, severe withdrawal symptoms, preterm labor, rapid labor, abruption
Phenobarbital	Withdrawal symptoms Fetal growth restriction
Phenothiazine derivatives	Withdrawal, extrapyramidal dysfunction, delayed respiratory onset, hyperbilirubinemia, hypotonia or hyperactivity, decreased platelet count
Diazepam (Valium)	Hypotonia, hypothermia, low Apgar score, respiratory depression, poor sucking reflex, cleft lip
Lithium	Congenital anomalies
Amphetamine sulfate (Benzedrine)	Generalized arthritis, learning disabilities, poor motor coordination, transposition of the great vessels, cleft palate
Dextroamphetamine sulfate (Dexedrine)	Congenital heart defects, biliary atresia, limb reduction defects
Cocaine	Cerebral infarctions, microcephaly, learning disabilities, poor state organization, decreased interactive behavior, CNS anomalies, cardiac anomalies, genitourinary anomalies, sudden infant death syndrome (SIDS)
Nicotine (half to one pack cigarettes/day)	Spontaneous abortion, placental abruption, small for gestational age (SGA), small head circumference, decreased length, SIDS, attention-deficit/hyperactivity disorder (ADHD) in school-age children
PCP ("angel dust")	Withdrawal symptoms Behavioral and developmental abnormalities
LSD	Chromosomal breakage
Marijuana	IUGR

Since the late 1980s, policymakers have debated the question of how society should deal with the problem of women's substance abuse during pregnancy. At the time of this writing, only one state, Tennessee, has specifically criminalized drug use during pregnancy; however, the state court systems have relied on existing criminal laws on the books to attack prenatal substance abuse (Guttmacher Institute, 2015). Several state supreme courts have upheld convictions ruling that a woman's substance abuse in pregnancy constitutes criminal child abuse. Meanwhile, other states have expanded civil child-welfare requirements to include prenatal substance abuse, so that prenatal drug exposure can provide grounds for terminating parental rights because of child abuse or neglect. To protect the fetus, some states have authorized civil commitment, such as forced admission to an inpatient treatment program, of pregnant women who use drugs and alcohol. Some states require healthcare professionals to report or test for prenatal drug exposure, which can be used as evidence in child-welfare proceedings. In order to receive federal child abuse prevention funds, states must require healthcare providers to notify child protective services when a provider who cares for an infant is affected by illegal substance abuse (Guttmacher Institute, 2015).

» **Stay Current:** In 2014, the FDA published the Pregnancy and Lactation Labeling Rule, which requires that drug labels be formatted to assist healthcare providers in assessing risk versus benefit for pregnant women and nursing mothers who need to take medication. See samples of the new drug labels at <http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/Labeling/ucm093307.htm>.

Substance Abuse in Older Adults

Substance abuse in older adults is likely to increase as the population ages: It is estimated that the number of adults 50 years and older with a substance use disorder will double from 2.8 million in 2006 to 5.7 million in 2020 (CBHSQ, 2014).

Individuals 65 years and older make up only 13% of the population, yet account for more than one third of total outpatient spending on prescription medications in the United States (NIDA, 2014c). Older patients are more likely to be prescribed long-term and multiple prescriptions, and some experience cognitive decline, which may lead to improper use of medications. Also, older adults on a fixed income may abuse another person's remaining medication to save money. The high rates of comorbid illnesses in older populations, age-related changes in drug metabolism, and the potential for drug interactions make these practices more dangerous than in younger populations.

The negative consequences of substance use are more critical in older adults. Substance abuse increases the risk of falls by affecting alertness, judgment, coordination, and reaction time. Substance abuse and dependence are less likely to be recognized in older adults because many of the symptoms of abuse (e.g., insomnia, depression, loss of memory, anxiety, musculoskeletal pain) may be confused with conditions commonly seen in older patients. This results in treating the symptoms of abuse rather than diagnosing and treating the abuse itself.

Older adults can have several potentially protective factors preventing illicit and nonmedical drug use: being married, never using alcohol or tobacco, and regularly attending religious services (SAMHSA, 2015b).

NURSING PROCESS

Nurses may interact with patients experiencing substance abuse or substance dependence in a variety of settings. The most common setting is an alcohol and drug abuse treatment program where patients are hospitalized for 20 to 30 days for detoxification and inpatient therapy. Patients in these settings may be admitted voluntarily or ordered by the court to undergo treatment. Patients with substance abuse or dependence have impaired senses and risk-taking behaviors that lead to injuries from falls and accidents requiring medical attention. Therefore, nurses frequently encounter them in emergency departments and medical-surgical units. Occupational nurses and community health nurses also interact with substance-abusing patients in outpatient or assertive community treatment programs, employee assistance programs, and community health departments. Urgent care centers, pain clinics, and ambulatory care centers are other settings in which patients with substance use disorders frequently appear for minor health problems associated with chronic disorders related to substance abuse or dependence.

Nursing care of the patient with substance abuse or dependence is challenging and requires a nonjudgmental atmosphere promoting trust and respect. Nurses should provide adults with information on healthy coping mechanisms and relaxation and stress reduction techniques to decrease the risks of substance abuse. Nurses have a responsibility to educate their patients about the physiologic effects of substances on the body. Nurses must encourage and support periods of abstinence while assisting patients to make major changes in lifestyles, habits, relationships, and coping methods.

Health promotion efforts are aimed at preventing drug use among children and adolescents and reducing the risks among adults. Adolescence is the most common phase for the first experience with drugs; therefore, teenagers are a vulnerable population, often succumbing to peer pressure. Healthy lifestyles, parental support, stress management, good nutrition, and information about ways to steer clear of peer pressure are important topics for the nurse to provide in school programs.

Assessment

Observation and Patient Interview

Many high-functioning substance abusers do not fit the stereotypical picture of someone who abuses drugs or alcohol. They are often members of the community, functioning in many responsible roles. They may not drink or use drugs every day. They may avoid the serious consequences that befall most individuals with addictions and their families. High-functioning individuals with SUDs can spend years, even decades, in denial. The high-functioning substance abuser's denial may be compounded by family and friends who fail to recognize or confront the problem.

A comprehensive approach to the assessment of all patients for substance use is essential to ensure adequate and appropriate intervention. Many patients who abuse substances struggle with communication and with trust, so it is essential that nurses use therapeutic communication techniques to establish trust prior to beginning the assessment process. Open-ended questions that elicit more than a simple

yes or no answer are more effective in eliciting truthful information and may help determine the direction of future counseling. Examples of open-ended questions include:

- On average, how many days per week does the patient use substances?
- On a typical day when the patient uses, how much does he or she use?
- What is the greatest number of substances the patient has used at any one time during the past month?
- What specific substance(s) did the patient take before coming to the hospital or clinic?
- How long has the patient been using substances?
- How often and how much does the patient usually use?
- What problems has substance use caused for the patient and his/her family, friends, finances, and health?

History of Past Substance Use

A thorough history of the patient's past substance use is important in order to ascertain the possibility of tolerance, physical dependence, or withdrawal syndrome. The following questions are helpful in eliciting a pattern of substance use behavior:

- How many substances has the patient used simultaneously in the past?
- How often, how much, and when did the patient first use the substance(s)?
- Is there a history of blackouts, delirium, or seizures?
- Is there a history of withdrawal syndrome, overdoses, and complications from previous substance use?
- Has the patient ever been treated in a substance abuse clinic or program?
- Has the patient ever been arrested or charged with any criminal offense while using any substance?
- Is there a family history of substance abuse?

Medical and Psychiatric History

The patient's medical history is another important area for assessment and should include the existence of any concomitant physical or mental condition (e.g., HIV, hepatitis, cirrhosis, esophageal varices, pancreatitis, gastritis, Wernicke-Korsakoff syndrome, depression, schizophrenia, anxiety, or personality disorder). The nurse should ask about prescribed and over-the-counter medications as well as any allergies or sensitivity to drugs. A brief overview of the patient's current mental status is also significant, including any history of abuse, family violence, or other trauma; current feelings of anxiety, sadness, or depression; and history or presence of suicidal or homicidal ideation.

Psychosocial Issues

Information about the patient's level of stress and other psychosocial concerns can help in the assessment of substance use problems. Ask if the patient's substance use has affected relationships with others or the patient's ability to hold a job. Inquire about stress and coping mechanisms such as avenues of social support and activities.

Screening Tools

Screening tools such as the Brief Drug Abuse Screening Test (B-DAST or DAST) (Skinner, 1982) may help the nurse determine the degree of severity of substance abuse or dependence. Screening tools provide a nonjudgmental, brief, and easy method to ascertain patterns of substance abuse behaviors. The B-DAST is a yes/no self-administered 20-item questionnaire that is useful in identifying people who may be addicted to drugs other than alcohol. A positive response to one or more questions suggests significant drug abuse problems and warrants further evaluation. Because people do not always answer self-report tools truthfully, all patients who screen positive for drug addiction should be evaluated according to other diagnostic criteria.

Nurses working with patients who experience opiate withdrawal find two scales useful for assessing symptoms: First, the *Objective Opiate Withdrawal Scale* (OOWS) has the nurse rate 13 common, physically observable signs of opiate withdrawal as being either absent or present. Second, the *Subjective Opiate Withdrawal Scale* (SOWS) asks the patient to rate 16 symptoms on a scale of 0 (not at all) to 4 (extremely). In either case, the summed total score can be used to assess the intensity of opiate withdrawal and determine the extent of a patient's physical dependence on opioids. Higher scores mean a more intense withdrawal and more physical dependence (Handelsman et al., 1987). The two scales have also proven useful in clinical research studies in the 25 years since their creation. One example used the SOWS to measure withdrawal symptoms of patients with chronic low back pain taking extended-release hydromorphone (Jamison et al., 2013).

Diagnosis

Nursing diagnoses for patients with substance abuse problems are highly individualized depending on the substance abused, the length of time the patient has abused the chemical, and the sources of support available to the patient. Common diagnoses used in the care of these patients include the following:

- *Injury, Risk for*
- *Violence, Risk for Other- or Self-Directed*
- *Denial, Ineffective*
- *Coping, Ineffective*
- *Imbalanced Nutrition: Less Than Body Requirements*
- *Chronic or Situational Low Self-Esteem*
- *Knowledge, Deficient*
- *Family Processes, Dysfunctional*
- *Confusion, Acute or Chronic.*

(NANDA-I © 2014)

Planning

When planning care for a patient who is abusing substances, it is important to keep goals and expectations reasonable.

Substance abuse recovery takes many months and often requires several attempts before abstinence is obtained and maintained. As a result, setting both short- and long-term goals for the patient is often most effective.

Short-term goals may include the following:

- The patient will admit having a substance abuse problem and having lost control of her life as a result.
- The patient will seek help to stop using the substance.
- The patient will experience no complications as a result of drug withdrawal symptoms.
- The patient will enter a drug rehabilitation program to change the behavior.

Long-term goals may include the following:

- The patient will explore the impact of the substance addiction on family, job, and friends.
- The patient will describe and recognize her denial in avoiding the problems related to substance abuse.
- The patient will change her thinking and behavior as a result of understanding the negative consequences of substance abuse.
- The patient will regularly attend a support group to maintain sobriety from substance use.
- The patient will remain free of substance and maintain sobriety.

Implementation

Because patients with substance use disorders have difficulty communicating and maintaining relationships, it is important that the nurse convey an attitude of acceptance and promote healthy coping and appropriate behaviors. Teach and model assertive communication, as patients may have become dependent on unhealthy and less successful communication techniques. Set limits on manipulative behaviors and maintain consistency in responses. Encourage patients to focus on strengths and accomplishments rather than ruminating on weaknesses and failures. Minimize attention to any such ruminations. Help patients explore dealing with stressful situations rather than resorting to substance use, and teach healthy coping mechanisms such as physical exercise, deep breathing, meditation, and progressive muscle relaxation. Encourage participation in therapeutic group activities.

Other specific interventions for patients with substance abuse and addiction address patient safety related to abuse and withdrawal and adherence to treatment. The following interventions have implications for nursing care in both acute and home care settings.

Promote Safety

- Assess the patient's level of disorientation to determine specific risks to the safety of the patient, family members, and others.
- If the patient cannot withdraw from substances safely in the home or community setting, consider a higher level of care.

- Obtain a drug history as well as urine and blood samples for laboratory analysis of substance content. A patient may not admit to using drugs at all or may admit to using only one drug recreationally, when in truth, the patient is using one or more drugs regularly. Urine and blood samples provide accurate, objective information.
- Place the patient in a quiet, private room to decrease excessive stimuli and related agitation, but do not leave the patient alone if excessive hyperactivity or suicidal ideation is present.
- If the patient is disoriented, frequently orient the patient to reality and the environment, ensuring that potentially harmful objects are stored away from the patient. The patient may harm self or others if disoriented and confused.
- Monitor vital signs every 15 minutes until stable. If treatment is dependent on blood or urine levels of a specific drug, reevaluate as instructed by the treating physician.

Promote Patient Safety During Withdrawal

- Observe the patient for withdrawal symptoms. Monitor vital signs. Provide adequate nutrition and hydration. These actions provide supportive physical care during detoxification.
- Assess the patient's level of orientation frequently. Orient and reassure the patient of safety in the presence of hallucinations, delusions, or illusions.
- Explain all interventions before approaching the patient. Avoid loud noises and talk softly to the patient. Decrease external stimuli by dimming lights. Excessive stimuli increase agitation.
- Administer medications according to the detoxification schedule. Benzodiazepines may help minimize the discomfort of withdrawal symptoms.
- Provide positive reinforcement when thinking and behavior are appropriate or when the patient recognizes that delusions are not based in reality. Drugs and alcohol can interfere with the patient's perception of reality.
- Use simple step-by-step instructions and face-to-face interaction when communicating with the patient. The patient may be confused or disoriented.
- Express reasonable doubt if the patient relays suspicious or paranoid beliefs. Reinforce accurate perception of people or situations. It is important to communicate that you do not share the false beliefs as reality.
- Do not argue with the patient experiencing delusions or hallucinations. Convey acceptance that the patient believes a situation to be true, but that you do not see or hear what is not there. Arguing with the patient or denying the belief serves no useful purpose because it does not eliminate the delusions.
- Talk to the patient about real events and real people. Respond to feelings and reassure the patient that she is safe from harm. Discussions that focus on the delusions may aggravate the condition. Verbalization of feelings in a nonthreatening environment may help the patient develop insight.

Patient Teaching

Substance Abuse

Teach the patient and family the following:

- The negative effects of substance abuse, including physical and psychologic complications of substance abuse.
- The signs of relapse and the importance of aftercare programs and self-help groups to prevent relapse.
- Information about specific medications that help reduce cravings and maintain abstinence, including the potential side effects, possible drug interactions, and any special precautions to be taken (e.g., avoiding over-the-counter medications such as cough syrup that may contain alcohol).
- Ways to manage stress, including techniques such as progressive muscle relaxation, abdominal breathing techniques, imagery, meditation, and effective coping skills.

In addition, suggest resources such as the National Institute on Drug Abuse (NIDA; <http://www.drugabuse.gov>) for information on the science of addiction; AA, NA, and other self-help groups; employee assistance programs; individual, group, and family counseling; community rehabilitation programs; and the National Alliance for the Mentally Ill (NAMI).

Finally, for families of individuals with substance addiction issues, offer emotional support but do not enable the addiction; know your limits; and do not accept unacceptable behavior.

Provide Patient Education

- Assess the patient's level of knowledge and readiness to learn the effects of drugs and alcohol on the body. Baseline assessment is required to develop appropriate teaching material.
- Develop a teaching plan that includes measurable objectives. Include short-term goals so that the patient sees some level of success at an early stage. Include significant others if possible. Lifestyle changes often affect all family members.
- Begin with simple concepts and progress to more complex issues. Use interactive teaching strategies and written materials appropriate to the patient's educational level. Include information on physiologic effects of substances, the propensity for physical and psychologic dependence, and risks to the fetus if the patient is pregnant. Active participation and handouts enhance retention of important concepts.

Evaluation

The patient is evaluated based on the ability to meet goals designed during the planning phase of nursing care. Potential positive outcomes may include the following:

- The patient experiences no complications from withdrawing from substance.
- The patient admits a problem with substance abuse and seeks help.

- The patient enters a substance abuse program.
- The patient can describe choices made that contributed to substance abuse.
- The patient attends daily support group meetings after leaving the rehabilitation facility.
- The patient remains substance free for (insert time period—days, weeks, months—depending on progress and time sober).

While some sources have reported that as many as 90% of addicted individuals are unsuccessful in becoming substance free, the National Institute on Drug Abuse (NIDA, 2014a) estimated that the relapse rate of 40 to 60% for substance abuse is similar to that for other chronic illnesses, such as diabetes, hypertension, or asthma. NIDA has recommended that clinicians treat substance addiction like any other chronic illness for which relapse serves as a trigger for renewed intervention.

Nursing Care Plan

A Patient with Substance Abuse

Donna Smith is brought to the ED by her husband. She is agitated and can't stand still. Her husband tells the nurse that she has been getting high on crack cocaine on a regular basis. When she didn't come home last night, he called their cell phone company to activate her GPS and found her outside a motel on the highway. He

took her home, where she began shouting, yelling, and throwing things and talking about the "men in the trees" who are after her. The nurse conducting the assessment determines that they have two children, ages 11 and 15, living at home.

ASSESSMENT	DIAGNOSES	PLANNING
<p>The nurse collects the following data during assessment:</p> <p>Temperature 99.4°F axillary; pulse 114 bpm; respirations 20/min; BP 168/92 mmHg</p> <p>Pupils constricted and equally responsive to light</p> <p>Patient is muttering to herself in mostly unintelligible sentences, with phrases such as "men in trees," "gonna get me," and "don't worry" understood among gibberish words. Patient says she hears voices and points out things that are not there—apparently having both visual and auditory hallucinations.</p> <p>Peripheral pulses are 3+ and bounding, sinus tachycardia is noted on ECG with frequent premature ventricular contractions, hyperreactive reflexes.</p> <p>Patient is admitted to monitored unit (telemetry) for observation until cardiac and neurologic systems are stable.</p>	<ul style="list-style-type: none"> ■ <i>Injury, Risk for</i> ■ <i>Family Processes, Interrupted</i> ■ <i>Coping, Ineffective</i> ■ <i>Confusion, Acute</i> ■ <i>Violence, Risk for Other- or Self-Directed</i> <p>(NANDA-I © 2014)</p>	<p>Goals of care include the following:</p> <ul style="list-style-type: none"> ■ Experience no adverse cardiac event. ■ Orient to time and place. ■ ECG will return to normal sinus rhythm. ■ Neurologic assessment will return to pre-substance use baseline. ■ Agree to psychosocial intervention to assist in substance avoidance.

IMPLEMENTATION

- Monitor cardiorespiratory function.
- Assess orientation and maintain safety while hallucinating.
- Maintain low-stimulation environment until effects of drug subside.
- Maintain hydration to promote excretion of drug from system.
- Obtain complete history of substance use when patient's cognitive function returns.
- Administer sedatives and antiarrhythmics as required per orders.
- Refer Mr. Smith to a support program for spouses and children.
- Refer to substance abuse program to assist in abstinence once drugs have been cleared from system if patient is willing to participate.

EVALUATION

- Evaluation of patient response may be based on the following expected outcomes:
- The patient experiences no cardiac event as the result of cocaine use.

- The patient's cognition returns to prior baseline.
- The patient admits to having a problem and agrees to seek treatment.

CRITICAL THINKING

1. While the patient is experiencing both auditory and visual hallucinations, how will the nurse respond if the patient insists there is something in the room that is not seen by the nurse?
2. What actions will the nurse implement to maintain the patient's safety?
3. After detoxification, the patient regains normal cognitive function and informs the nurse she is leaving the facility because she wants to "get high again." What is the nurse's legal obligation to this patient?

REVIEW Substance Abuse

RELATE Link the Concepts and Exemplars

Linking the exemplar of substance abuse with the concept of safety:

1. The nurse had surgery a few days ago and is taking a narcotic analgesic to control pain. Is it safe for the nurse to work assigned shifts while taking this medication? Why or why not?
2. You suspect that a coworker whom you admire for his experience and knowledge may be using an illegal drug. What is your best action to maintain patient safety? How would you handle this issue?

Linking the exemplar of substance abuse with the concept of trauma:

3. How does the abuse of substances affect the risk for violence committed by the patient?
4. When working in a substance abuse treatment facility, how can you, as the nurse, encourage spouses at risk for acts of domestic violence by your patients seek support for their own health?

REFLECT Apply Your Knowledge

Casey Holmes is a physically fit 23-year-old man who had a troubled youth. His parents divorced when he was very young, and he bounced back and forth between parents—both of whom remarried. Growing

up, he often saw his father hit his stepmother when angry. As an adolescent, Mr. Holmes became involved with a gang and was arrested a few times for petty crimes, such as shoplifting and vandalism. He never finished high school and moved out on his own at the age of 18. Since that time, he has held a number of odd jobs and has made an effort to stay out of trouble.

Mr. Holmes lives with his pregnant girlfriend Jessica Riley and her son Ryan. He does not particularly like Ryan and thinks Jessica spoils him. He is very proud of the fact that Jessica is pregnant with his baby. He is controlling of Jessica and does not want anybody else looking at her. On most days after work and into the evening, Mr. Holmes drinks beer and smokes dope with his buddies. He is irritated that Jessica does not party with him as much as she did when they first met. Mr. Holmes also uses other drugs when he can afford to buy them.

1. What are the priority nursing diagnoses for Mr. Holmes?
2. What are the implications of his substance abuse on the family?
3. Mr. Holmes accompanies Jessica to the clinic for one of her prenatal visits. The nurse is aware of Mr. Holmes's drug use, which Jessica admitted on a prior visit. What should the nurse say to Mr. Holmes during this visit regarding the impact of his behavior on Jessica and the baby?

Module 23

Cognition

Module Outline and Learning Outcomes

The Concept of Cognition

Normal Cognition

23.1 Analyze the physiology of normal cognition.

Alterations to Cognition

23.2 Differentiate alterations in cognition.

Concepts Related to Cognition

23.3 Outline the relationship between cognition and other concepts.

Health Promotion

23.4 Explain measures to promote optimal cognition.

Nursing Assessment

23.5 Differentiate common assessment procedures and tests used to examine cognition.

Independent Interventions

23.6 Analyze independent interventions nurses can implement for patients with alterations in cognition.

Collaborative Therapies

23.7 Summarize collaborative therapies used by interprofessional teams for patients with alterations in cognition.

Lifespan Considerations

23.8 Differentiate considerations related to the assessment and care of patients with alterations in cognition throughout the lifespan.

Cognition Exemplars

Exemplar 23.A Alzheimer Disease

23.A Analyze Alzheimer disease as it relates to cognition.

Exemplar 23.B Delirium

23.B Analyze delirium as it relates to cognition.

Exemplar 23.C Schizophrenia

23.C Analyze schizophrenia as it relates to cognition.

>> The Concept of Cognition

Concept Key Terms

Adaptive behavior, 1707	Cognition, 1705	Executive function, 1707	Limbic system, 1707	Praxis, 1707
Agnosia, 1709	Confabulation, 1709	Fetal alcohol syndrome (FAS), 1710	Lobes, 1708	Proprioceptive, 1706
Alogia, 1709	Confusion, 1708	Fragile X syndrome, 1710	Long-term memory, 1707	Psychosis, 1708
Amnesia, 1709	Delirium, 1714	Hallucinations, 1708	Metacognition, 1705	Sensory memory, 1706
Anomia, 1709	Delusions, 1708	Intellectual disability, 1710	Neurons, 1707	Short-term memory, 1706
Aphasia, 1709	Dementia, 1714	Learning disabilities, 1710	Neurotransmitters, 1707	Social cognition, 1707
Apraxia, 1709	Down syndrome, 1710		Orientation, 1706	Tic, 1709
Ataxia, 1709	Dyspraxia, 1709		Physiologic tremor, 1709	Tremor, 1709
Avolition, 1710	Echolalia, 1709			Trisomy 21, 1711
Carphologia, 1709	Essential tremor, 1709			

Cognition is the complex set of mental processes by which individuals acquire, store, retrieve, and use information. Cognition primarily involves activities that are controlled by the cerebral hemispheres, including perception, attention, memory, communication, decision making, and problem solving. The ability to think and reason is

an essential component of human identity and function. **Metacognition** is a related term that refers to the human ability to think about thinking. A current understanding of cognition is drawn from the disciplines of cognitive psychology, neurology, computer science/artificial intelligence, philosophy, and anthropology.

Normal Cognition

A definition of normal cognition depends on social and cultural norms and the environment in which the individual operates. In general, the desired and most basic consequences of normal cognition are to obtain a level of survival and adaptation, to function effectively as a social being, and to engage in meaningful and purposeful activity. There is a great deal of variation in cognitive function among healthy individuals. Normal variations in cognition can be better understood by looking at some of the related components and categories associated with this concept. For an overview of cognitive development and related theories, see the module on Development.

Key Components and Categories

The key components that make up human cognition include perception, attention, and memory. Communication and social cognition, motor function, and planning, executive, and intellectual functions are broader categories of mental processing that are necessary for adaptive behavior.

Perception

Perception refers to an interpretation of stimuli or inputs that takes place in the brain. The process of perception depends on the sensory reception of internal and external data and is discussed in depth in the module on sensory perception. External stimuli or inputs include touch, taste, vision, hearing, and smell. Internal stimuli include **proprioceptive** sensations that contribute to motor function and spatial awareness. Perceptual variations are normal among individuals across the lifespan and can be influenced by factors such as genetics and culture. **Orientation** is a component of normal perception that includes four basic elements: person, place, time, and situation. **Orientation to person** is the ability to correctly identify one's own name. **Orientation to place** is the ability to identify one's location. **Orientation to time** is the ability to correctly identify the time of day, the date, and the season. **Orientation to situation** is the ability to describe the global circumstances surrounding a particular event.

Attention

Attention refers to the brain's ability to remain alert and aware while selectively prioritizing concentration on a stimulus (such as something that is seen or heard) or mental event (thinking and problem solving). The reticular activating system, thalamus, and frontal cortex are the structures that are primarily involved in arousal and attention. The neurotransmitters dopamine and norepinephrine both play a major role in regulating attention.

The human capacity to sustain attention and attend to multiple stimuli is limited. Variations in attention span are typical among healthy individuals and may be impacted by development, genetics, biological rhythms, culture, and other environmental factors (Rosenberg et al., 2015). Attention is significantly altered by the experience

of illness or stress. An individual's level of awareness and attention span often signifies an underlying change or alteration in biophysical and psychosocial status. Individual safety depends on the ability to attend and focus.

Memory

Memory refers to the process by which individuals retain, store, and retrieve information gained from previous experiences. The ability to remember meaningful information provides the foundation for learning and adaptation from birth to death. Because memory represents the totality of human experience, alterations in memory have a significant impact on the holistic needs of the individual. Most models of memory classify subtypes according to their sequence and duration. These include sensory, short-term, and long-term memory (see **Figure 23-1** »).

Sensory memory refers to the earliest stage of memory, in which visual input and auditory information are retained for less than a few seconds. Sensory information that receives attention from an individual passes into short-term memory.

Short-term memory refers to the active processing and manipulation of information in conscious awareness. Short-term memory only lasts several seconds, but it can be rehearsed or repeated and transferred into long-term memory. The total amount of information that can be managed in short-term memory is also finite. For example, most research has demonstrated that longer strings of information, such as a sequence of numbers exceeding 5 to 9 digits, cannot be retained (Freberg, 2016). One aspect of short-term memory

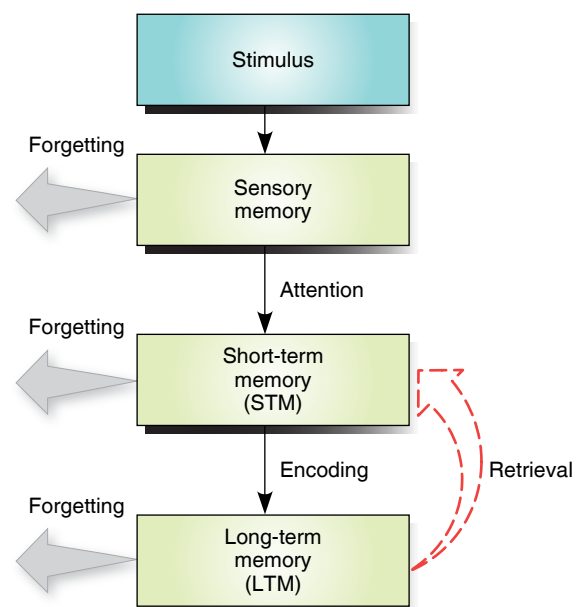

Figure 23-1 » An information-processing model of memory. Many stimuli register in sensory memory. Those that are noticed are briefly stored in short-term memory, and those that are encoded are transferred to a more permanent facility. As shown, forgetting may be caused by failures of attention, encoding, or retrieval.

that deserves further explanation is *working memory*. Working memory is defined as the capacity to manipulate information stored in short-term memory. Examples include following a sequence of directions and performing mental mathematical calculations (D'Esposito & Postle, 2015; Ma, Husain, & Bays, 2014).

Long-term memory is used to describe the final sequence or destination of information that can be stored indefinitely. Long-term memory is further broken down into declarative and nondeclarative memories. *Declarative memories* are those that are explicit and can be consciously accessed; they are distinguished according to semantic and episodic types. *Semantic memory* consists of a collection of facts and verbal information. *Episodic memory* is composed of personal experiences. *Nondeclarative memories* are characterized by information that is outside of our conscious awareness. *Procedural memories* are a type of implicit memories that enable individuals to perform learned skills and tasks. Examples include such activities as walking, riding a bike, and driving a car (Zimmerman, 2014).

Communication and Social Cognition

The ability to receive, interpret, and express communication is an essential component of cognitive function (see the module on Communication). Memory plays a significant role in communication and speech.

Social cognition is the ability to process and apply social information accurately and effectively. It depends on the integrated function of the areas responsible for visual motor processing, language, and executive function. Scientists now believe that the neurohormone oxytocin plays an important role in social cognition (Lancaster et al., 2015). Individuals are normally able to apply an understanding of the needs of others and to interpret both verbal and nonverbal information or social cues with some degree of proficiency (American Speech Language and Hearing Association, 2016). Researchers have demonstrated that social cognition is essential for adaptive functioning across the lifespan (Bradford, Jentzsch, & Gomez, 2015).

Motor Coordination

Motor coordination refers to the planning, organizing, and execution of complex motor tasks. Cognitive function and motor coordination are carried out by shared neuronal pathways in the brain (Papadopoulos, Parrila, & Kirby, 2015). Normally the ability to plan and coordinate motor functions progresses through the expected stages of development, with adults exercising the ability to control movement in a deliberate, smooth, and coordinated fashion, called **praxis**. Individuals with intact cognition exhibit normal variations in motor function and coordination. Impaired motor function is characteristic of many of the alterations discussed in this module.

Executive Function

Executive function is an umbrella term that is used to describe the mental skills involved in planning and executing complex tasks. It incorporates coordination of the previously mentioned attributes of normal cognition, enabling individuals to selectively focus, control emotions, problem solve, and organize speech and motor activity. Examples

include following multistep directions and prioritizing to manage time on a project.

Intellectual Function

Intelligence is a general term used to describe the mental capacity of the individual in relation to learning, reasoning, and problem solving. It is generally measured through the administration of one or more psychometric tests. The most commonly administered tests are the Stanford-Binet Intelligence Scales and Wechsler Intelligence Scales. Subtest scores for both are used to compare performance in areas such as general knowledge, quantitative and verbal reasoning, visual spatial processing, and working memory. The average of the scores is used to calculate an overall or full-scale intelligence quotient (IQ); however, subtest scores are also used to provide insight into individual strengths and weaknesses (Lerner & Johns, 2014).

Adaptive Behavior

Adaptive behavior refers to a set of practical skills people need to function in their everyday lives. Although the concept of adaptive behavior was originally intended to address the degree of limitations experienced by individuals with intellectual disabilities, the principles can be applied across the lifespan to patients experiencing alterations in cognitive function. The three categories of adaptive behavior are conceptual skills (use of language, reading, or telling time), social skills (ability to follow rules and interact appropriately with others) and practical skills (ability to engage in work and perform activities of daily living [ADLs]).

Physiology Review

Cognition largely depends on brain and nervous system functioning. The structural integrity of and complex physiologic processes that occur within the cerebral cortex are responsible for most aspects of the individual's ability to process sensory information. However, the **limbic system**, reticular activating system, and cerebellum also play a role in arousal, motivation, emotional regulation, and balance (see the module on Intracranial Regulation for more information).

The physiologic processes that occur in the brain have particular significance in the maintenance and regulation of cognitive processes. **Neurons** are the specialized cells of nervous system that have the capacity to carry messages through electrical and chemical signals. Microglia are the resident immune cells of the brain. They play an important role in regulating response to inflammation. **Neurotransmitters** are specialized chemicals that carry nerve impulses across the synaptic gaps between neurons. Research has demonstrated that abnormalities in cellular and neurotransmitter function are associated with many cognitive disorders. Various neurotransmitters are discussed in some detail in the modules on Mood and Affect and on Stress and Coping.

Normal Genetic Variations

Research demonstrates that genetic makeup accounts for up to 70% of the variations in cognition found in the general

population. Different genes can be linked to particular components of cognitive function, such as attention in working memory in healthy adults (Störmer et al., 2012; Tucker-Drob, Briley, & Harden, 2013).

Alterations to Cognition

Although the etiology, presentation, and course of diseases impacting cognitive function vary, the key clinical manifestations of alterations in mental processing all relate to dysregulation of one or more of the key components or categories of normal cognition.

General Manifestations of Altered Cognitive Function

Alterations in perception, attention, memory, executive function, communication, social cognition, intellect, and adaptive behavior occur to varying degrees and are found in a number of conditions associated with this concept. The pathophysiology of these conditions is generally related to conditions causing abnormalities in the structure and function of the brain. An understanding of the general manifestations of cognitive dysfunction is essential for providing nursing care to individuals presenting with cognitive problems, regardless of the patient's specific medical diagnosis or condition.

Alterations in Perception

Altered perception and thinking are hallmarks of many of the conditions that impact cognition across the lifespan. Perceptual disturbances may be a function of structural and physiologic brain abnormalities in several areas of the cerebral cortex. They may be related to a primary cognitive disorder, such as dementia or schizophrenia, or to an underlying medical condition. Illogical thinking may be the result of frontal lobe dysfunction and dopamine imbalance. Distortions in perceptual processing are often the result of abnormalities in the **lobes** responsible for that aspect of sensory processing. Terms related to thinking and perception include the following:

- **Confusion** is a general term used to describe increased difficulty in thinking clearly, making judgments, and focusing attention.

- **Disorientation** is an element of confusion in which the individual is unable to correctly identify one or more of the following: person, place, time, and situation.
- **Psychosis** is a general term used to describe an abnormal mental state that alters an individual's thought processes and content in a manner that impacts the individual's perception of reality. Indicators of altered thought processes and content are most often observed through the patient's speech and behaviors. Common indicators of disorganized thinking are outlined in **Table 23-1** >>.
- **Delusions** are rigid, false beliefs—for example, believing that members of a healthcare team are actually government spies assigned to gather information that will be used to harm the patient or others. Common types of delusions include delusions of persecution, in which the individual believes that others are hostile or trying to harm him; delusions of reference, in which the individual falsely believes that public events or people are directly related to her; and delusions of grandeur, in which an individual has an inflated sense of self-worth and abilities.
- **Hallucinations** are sensory experiences that do not represent reality, such as hearing, seeing, feeling, or smelling things that are not actually present. Sometimes the type of hallucinations experienced by an individual provides clues to the underlying cause. Types of hallucinations include **auditory**, in which the individual hears voices or sounds that are not there; **visual**, in which the individual sees things that are not there or sees distortions of things that are there; or **tactile**, in which the individual feels things that are not present.

Alterations in Attention

Individuals with attention difficulties demonstrate deficits in the ability to focus, shift, and sustain attention consistently. Attention deficits are characteristic of many of the cognitive disorders discussed in this module and may also occur as a distinct disorder classified in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) as attention-deficit disorder (ADD) or attention-deficit/hyperactivity disorder (ADHD). More information on ADD and ADHD

TABLE 23-1 Indicators of Disordered Thinking

Indicator	Description
Loose associations	Pattern of speech in which a person's ideas slip off track onto another unrelated or obliquely related topic; also known as derailment.
Tangentiality	Occurs when a person digresses from the topic at hand and goes off on a tangent, starting an entirely new train of thought.
Incoherence/word salad/neologisms	Speaking in meaningless phrases with words that are seemingly randomly chosen, often made up, and not connected.
Illogicality	Refers to speech in which there is an absence of reason and rationality.
Circumstantiality	Occurs when the person goes into excessive detail about an event and has difficulty getting to the point of the conversation.
Pressured/distractible speech	Can be identified when the patient is speaking rapidly and there is an extreme sense of urgency or even frenzy as well as tangentiality. It is nearly impossible to interrupt the person.
Poverty of speech	The opposite of pressured speech; identified by the absence of spontaneous speech in an ordinary conversation. The person cannot engage in small talk and gives brief or empty responses.

can be found in the module on Development. Short-term difficulties with attention can also occur under conditions such as acute stress and anxiety and during periods of acute illness. Problems with attention can be related to any conditions that impact the structure and function of the brain. Such problems are manifested by alterations in one or more aspects of attention. For example, deficits in mental energy manifest in the ability to sustain effort required to complete certain tasks. Individuals with altered attention have difficulty determining what information is salient and connecting new information to what they already know. Issues in processing arise from the inability to control output—meaning that an individual may lack the ability to preview and inhibit an inappropriate or unsafe response or action.

Alterations in Memory

Individuals with cognitive alterations commonly have impairments in memory that may be an initial manifestation of a cognitive disorder with one or more memory functions impacted at any given time. Imbalances of acetylcholine, dopamine, gamma-aminobutyric acid (GABA), and glutamate have been implicated in memory problems (Khakpai, Nasehi, & Zarrindast, 2016; Marx & Gilon, 2014; Wu et al., 2014). Memory impairments may be temporary or chronic and may range from mild to severe. They may also be related to an underlying illness or trauma or be caused by a medical treatment or medication. **Amnesia** is a general term that is used to refer to the loss of recent or remote memory. Patients experiencing memory loss may unconsciously attempt to compensate for memory gaps by filling them in with fabricated events through a process known as **confabulation**.

Memory loss may manifest as problems related to short-term or long-term memory. Individuals with **short-term memory loss** may retain the ability to remember events that occurred 15 years ago but have difficulty recalling something that happened several minutes ago. Issues with working memory include difficulty following multistep directions, remembering the sequencing of numbers, or performing simple calculations. Individuals with **long-term memory problems** have difficulty recalling events and learning that occurred in the distant past. Examples include forgetting work skills that were learned 10 years ago or the inability to remember important life events, such as a wedding or the death of a loved one. Deficits in semantic memory can be manifested as **agnosia**, the inability to recognize objects through the use of one or more senses.

Alterations in Communication and Social Cognition

The ability to communicate with others is contingent on adequate perception, attention, and memory. In addition, any injury or insult to the areas of the brain responsible for the use of gestures and written and spoken words can impair communication and social cognition. Alterations in communication are common findings in many neurocognitive disorders. Common related terms include the following:

- **Aphasia** is the inability to use or understand language. Aphasia may be classified as expressive aphasia, receptive aphasia, or mixed (global) aphasia. Aphasia is discussed in greater depth in the module on Intracranial Regulation.

- **Anomia** is a type of aphasia where the individual is not able to recall the names of everyday objects and is often related to the progressive degeneration and loss of semantic memory that occurs with dementia.
- **Alogia** refers to a lack of (sometimes called impoverished) speech.

Frontal lobe and right brain dysfunction impact spatial awareness to the extent that affected individuals have difficulty gauging physical aspects of social communication, such as how close to stand to someone else. Impaired visual processing can result in the inability to accurately read and respond to nonverbal cues. Sometimes these individuals are mistakenly believed to be deliberately demonstrating rude or annoying behaviors. The deficits in communication and social function place patients at significant risk for health problems, social isolation, victimization, depression, and anxiety (Cacioppo & Cacioppo, 2014).

Alterations in Motor Coordination

The pathways used for cognitive processing and motor coordination and function are shared. Problems with the speed, fluency, and quality of movement are associated with many cognitive disorders and may be a side effect of medications that alter neurotransmitter function. **Dyspraxia** is a general term used to describe difficulty with the acquisition of motor learning and coordination through the process of growth and development. **Apraxia** refers to alterations in speech as a result of impaired motor function. **Ataxia** is a term used to describe problems with balance and coordination associated with neurologic dysfunction.

Involuntary movements include those that are not completely purposeful and occur without initiation by the patient, such as tics and tremors (Mansen & Gabiola, 2015). **Tics** are semi-involuntary movements that are sudden, repetitive, and non-rhythmic. They may involve muscle groups or vocalizations (motor or phonic). Suppression of a tic may be possible but results in discomfort or anxiety for the patient (Prastaro & Giratti, 2015). Sudden, brief, meaningless movements involving one muscle group are classified as simple tics. Examples of simple tics include eye blinking and head jerking (motor tics) and throat clearing and humming (phonic tics). Complex tics involve a cluster of movements that appear coordinated and more purposeful and thus may be more difficult to identify. Complex motor tics include pulling at clothing or touching people or objects; **echopraxia**, imitating the movements of others; **copropraxia**, performing obscene or forbidden gestures; and **carphologia**, lint-picking behavior that is often seen in dementia. Examples of complex phonic tics include **echolalia**, the meaningless repetition of phrases spoken by another (Mansen & Gabiola, 2015).

Tremors are unintentional rhythmic movements manifested in shaking of the affected part of the body. **Essential tremors** are those that are not associated with another condition and may be genetic in origin. **Physiologic tremors** occur normally as a result of physiologic exhaustion or emotional stress. Common tremors include *resting tremors*, a coarse, rhythmic tremor often observed in resting arms and hands that is characteristic of Parkinson disease and sometimes seen as a side effect of certain medications; and

dystonic tremors, sustained involuntary muscle contractions causing twisting repetitive movements and painful or abnormal postures (Mansen & Gabiola, 2015).

Dyskinesia represents a general category of difficulty with or distortions of movement. It may be associated with acquired disorders such as Parkinson disease or as side effect of some medications. Types of dyskinesias are:

- **Akathisia:** An internal feeling of restlessness that may lead to rocking, pacing, or other constant movement
- **Akinesia:** Diminished movement as a result of difficulty initiating movement
- **Bradykinesia:** Dyskinesia characterized by slow movement
- **Dystonia:** An acute episode of muscle contractions (may result from a neurodegenerative disease or a reaction to medication)
- **Rigidity:** Resistance to movement. *Cogwheel rigidity* refers to ratchet-like resistance when attempting to move the joints.

Alterations in Executive Function

Executive function is significantly affected by structural and physiologic abnormalities impacting the frontal cortex (Funahashi & Andreau, 2013; Hosenbocus & Chahal, 2012). Manifestations of impaired function include emotional dysregulation; poor judgment and decision making; reduced insight; forgetfulness; difficulty in planning, organizing, and concrete thinking; and personality changes. Difficulties can range from mild to severe. **Avolition** is decreased motivation, or the inability to initiate goal-directed activity, and may be in part related to deficits in executive dysfunction (Carpenter et al., 2016).

Alterations in Intellectual Function and Learning

Alterations in intellectual function and learning may be either developmental or acquired. The DSM-5 classifies both intellectual disabilities and specific learning disabilities that manifest in childhood as neurodevelopmental disorders (American Psychiatric Association [APA], 2013). Nurses should recognize that there are a broad range of issues impacting learning and intellectual function and that many individuals may demonstrate deficits in adaptive function without meeting the current diagnostic criteria (Gaddes, 2013). For more information on learning and associated problems, refer to the module on Development.

Learning disabilities are a group of disorders that impact an individual's ability to process information. The cause of learning disabilities is not entirely understood, but researchers believe that subtle variations in brain structure and function may be responsible. Both genetics and environmental factors probably contribute to these variations. In general, individuals with learning disabilities have average to above-average intelligence but demonstrate a gap between their actual and potential achievement. The impact of learning disabilities goes well beyond difficulty with basic academic skills. Most individuals with specific learning difficulties also experience one or more related problems with social cognition, executive function, memory, processing speed, attention, and motor coordination. As a result, they often

face significant challenges with interpersonal relationships and other aspects of adaptive function (Learning Disabilities Association of America [LDA], 2016). Nurses are in a key position to assess for variations in development that may suggest an underlying learning issue.

Intellectual disabilities are characterized by significant limitations in intellectual functioning and adaptive behavior that begin prior to age 18. An IQ score of 70–75 or below is considered indicative of limited intellectual functioning. Intellectual disability can result from prenatal errors in central nervous system (CNS) development, external factors that damage the CNS, or pre- or postnatal changes in an individual's biological environment. Sometimes, these changes produce only mental limitations. Other times, intellectual disability is one of a constellation of symptoms linked to a particular cause (American Association of Intellectual and Developmental Disabilities, 2013).

Selected Alterations for Cognition

The exemplars included in this module represent only a fraction of the disorders that impair cognition. The classification of these disorders in the DSM-5 provides a context for understanding both similarities and differences in the exemplars and related conditions; however, the nursing care focuses primarily on supporting adaptive function and collaborating with healthcare professionals to provide holistic care that meets the unique needs of affected individuals regardless of medical diagnosis.

Selected Learning Disabilities

Although the DSM-5 has changed the classification of specific learning disabilities to include three specific categories limited to impairment in reading, impairment in written expression, and impairment in mathematics, many associated difficulties with cognitive function, such as communication processing disorders, have been reclassified under neurodevelopmental disorders (APA, 2013). **Table 23-2** » identifies some of the most common learning issues nurses may encounter, using both common or umbrella terms and their associated DSM-5 classifications. Implications for nursing practice are included. For all patients with learning difficulties, support them and their families in seeking appropriate services and accommodations, and encourage activities that focus on strengths and build self-esteem.

Selected Intellectual Disabilities

Of the various conditions associated with intellectual disability, three deserve special mention because of the range of physical and cognitive alterations they involve. **Down syndrome, fragile X syndrome, and fetal alcohol syndrome (FAS)** are all caused by problems during prenatal development, although the first two conditions involve genetic errors while the third involves alcohol consumption during pregnancy. All three conditions are present at birth and affect an individual for the rest of his life. See **Table 23-3** » for a summary of physical traits associated with these conditions.

Down Syndrome

Down syndrome occurs when an individual's cells contain a third full or partial copy of the 21st chromosome (National Down Syndrome Society, 2012). Usually, a full copy of the

Alterations and Therapies

Cognition

ALTERATION	DESCRIPTION	MANIFESTATIONS	INTERVENTIONS AND THERAPIES
Perceptual disturbances/ psychosis	Alterations in ability to interpret environmental stimuli, think clearly and logically, and maintain orientation to person, place, time, and situation	<ul style="list-style-type: none"> Hallucinations Delusions Disordered thinking Disorientation/confusion 	<ul style="list-style-type: none"> Identify and treat underlying cause Reduce environmental stimulation Reality orientation and validation therapy

Memory problems	Impairment in ability to recall information	<ul style="list-style-type: none"> Getting lost Difficulty with word finding and recognition Difficulty remembering recent events Difficulty remembering remote events 	<ul style="list-style-type: none"> Identify and treat underlying cause Cognitive remediation Provide compensatory strategies and memory aids
Problems with communication/ social cognition	Impairments in the ability to process social information and communicate with others	<ul style="list-style-type: none"> Difficulty adhering to social conventions Receptive and expressive language problems 	<ul style="list-style-type: none"> Refer for speech therapy Provide accommodations and modifications Provide social skills training
Problems with motor function/ control	Inability to carry out smooth, purposeful movement	<ul style="list-style-type: none"> Tic Tremors Dyskinesia 	<ul style="list-style-type: none"> Identify and treat underlying cause Provide environmental modifications Refer for occupational therapy (OT) and physical therapy (PT)
Problems with executive function	Weaknesses in key mental skills required for adaptive function	<ul style="list-style-type: none"> Difficulty organizing Difficulty planning Poor impulse control Problems with attention and memory 	<ul style="list-style-type: none"> Provide compensatory strategies (lists, organizers) Refer for OT Support safety needs
Problems with intellectual function and learning	Problems with global intellectual function or acquisition of knowledge required for adaptive function	<ul style="list-style-type: none"> Low IQ Problems with adaptive function Academic problems Social/emotional problems 	<ul style="list-style-type: none"> Provide modifications and accommodations Provide remediation Focus on strengths

extra chromosome is present, a situation known as **trisomy 21**. In either case, the excess genetic material leads to intellectual disability and physical impairments that can range from mild to severe (**Figure 23-2** »).

Individuals with Down syndrome are at increased risk of several problems not normally seen in childhood. Roughly 50% are born with congenital heart defects. Children with Down syndrome are also more likely to experience hearing loss, gastrointestinal blockages, celiac disease, vision problems, thyroid disease, skeletal abnormalities, orthodontic problems, leukemia, and eventual dementia. With appropriate support, affected individuals can lead healthy lives and sometimes live and work independently. Average life expectancy for individuals with Down syndrome is about 60 years, although some individuals live 10

or even 20 years longer (Centers for Disease Control and Prevention, 2016; National Down Syndrome Society, 2012).

TABLE 23-2 Comparison of Common Learning Problems and Their Implications for Nurses

Common Terms and Associated DSM-5 Terms	Defining Characteristics	Nursing Implications
Common term <ul style="list-style-type: none"> Auditory Processing Disorder (APD) and Language Processing Disorder (LPD) DSM-5 <ul style="list-style-type: none"> Communication Disorder: Language Disorder Communication Disorder: Speech Sound Disorder 	<p>Individuals with APD and related language-based communication disorders have difficulty processing sounds and discriminating differences in where sounds come from.</p> <p>Problems learning verbally, focusing, remembering and applying auditory information and language.</p>	<ul style="list-style-type: none"> Refer patients with communication deficits for evaluation. Anticipate collaboration with speech pathologists and learning specialists. Adapt teaching to show rather than tell. Reduce auditory distractions. Vary pitch and tone, space directives, and allow additional time for verbal processing.
Common term <ul style="list-style-type: none"> Dyscalculia DSM-5 <ul style="list-style-type: none"> Specific Learning Disorder (in the area of mathematics) 	<p>Difficulty understanding numbers and learning math facts.</p> <p>Poor understanding of math symbols, difficulty with related tasks, such as telling time.</p>	<ul style="list-style-type: none"> Refer patients with academic and occupational problems related to math for evaluation. Recognize that patients may have difficulty calculating doses and taking medications on schedule. Encourage the use of devices (pill minders, single-dose dispensers) to promote safety.
Common term <ul style="list-style-type: none"> Dysgraphia DSM-5 <ul style="list-style-type: none"> Specific Learning Disorder (in the area of written expression) 	<p>Disability impacting fine motor skills and the ability to write clearly and legibly.</p> <p>May have difficulty focusing or thinking while performing fine motor tasks.</p>	<ul style="list-style-type: none"> Refer patients with academic/occupational problems related to written expression for evaluation. Anticipate collaboration with occupational therapy. Encourage the use of word processing devices, dictation software. Recognize that patients may have difficulty performing fine motor skills necessary for self-care (e.g., dressing changes) and modify care to address.
Common term <ul style="list-style-type: none"> Dyslexia DSM-5 <ul style="list-style-type: none"> Specific Learning Disorder (in the area of reading) 	<p>Difficulty with reading and language-based skills impacting reading fluency, decoding, and comprehension.</p>	<ul style="list-style-type: none"> Refer patients with academic/ occupational problems related to reading for evaluation. Anticipate collaboration with learning specialists. Use nonverbal teaching strategies. Recognize that the ability to follow written directions may be limited, supplement with visual aids, and record information if necessary.
Common term <ul style="list-style-type: none"> Non-verbal Learning Disabilities (NVLD) DSM-5 <ul style="list-style-type: none"> Communication Disorder: Social/Pragmatic Communication Disorder Motor Disorder: Developmental Coordination Disorder 	<p>Often a significant gap between high verbal skills and low perceptual skills (motor, visual-spatial skills, social skills).</p> <p>Typically impacts interpretation of nonverbal cues, such as body language. Difficulty understanding and adhering to social conventions.</p> <p>Difficulty integrating sensory information.</p> <p>Because of the devastating social implications of this disorder, individuals may present first with a mental health issue (e.g., depression, anxiety).</p>	<ul style="list-style-type: none"> Screen for alterations in social development. Consider learning issues when patients present with mental health issues. Assess patient safety—may be at risk for bullying and abuse because of poor social skills and attempts to compensate with maladaptive behavior. Anticipate collaboration with occupational therapy, speech pathology and psychologists, developmental pediatricians. Use verbal strategies and avoid diagrams and images. See strategies under associated problems: dyscalculia, dysgraphia, and visual perceptual motor deficit. Teach social skills explicitly. Assess for depression, anxiety, social isolation. Recognize that the disorder may be poorly understood by family, teachers, and other healthcare professionals. Advocate for patient.
Common term <ul style="list-style-type: none"> Visual Perceptual/Visual Motor Deficit DSM-5 <ul style="list-style-type: none"> Motor Disorder: Developmental Coordination Disorder 	<p>Difficulty performing tasks that require the integration of visual processing and application to motor tasks (e.g., copying, finding images in a field, keeping place, reading maps).</p>	<ul style="list-style-type: none"> Address implications for self-care; provide lists for organizing items, navigating unfamiliar environments. Anticipate collaboration with occupational therapy, physical therapy, speech pathology, and psychologists. Recognize that patients may have difficulty adhering to treatments as a result of visual motor deficits. Coordination disorders may discourage individuals from taking part in physical activity; encourage patients to find appropriate forms of exercise. Preview before going to appointments in unfamiliar settings. Use of devices such as pill organizers may promote safety. Provide lists and step-by-step verbal instructions.
Common terms <ul style="list-style-type: none"> Global Intellectual Delays Previously called Mental Retardation DSM-5 <ul style="list-style-type: none"> Intellectual Disability: Intellectual Developmental Disorder 	<p>Impairment related to both IQ (below 70–75) and deficits in adaptive function/behavior.</p>	<ul style="list-style-type: none"> Assess patient safety—may be at risk for bullying and abuse because of poor social skills and attempts to compensate with maladaptive behavior. Anticipate collaboration with occupational therapy, speech pathology, psychologists, and developmental pediatricians Address common comorbid health problems, including associated congenital defects (if present).

TABLE 23-3 Physical Traits Associated with Three Causes of Intellectual Disability

Down Syndrome See Figure 23-2	Fragile X Syndrome See Figure 23-3	Fetal Alcohol Syndrome See Figure 23-4
Broad hands with a single transverse palmar crease	Crossed eyes	Small eyes
Congenital cataracts	Enlarged testicles	Abnormal joints and bones
Decreased muscle tone	Epicanthic eye folds	CNS abnormalities
Epicanthic eye folds	Excessively flexible joints	Flattened nasal bridge
Flattened nose	High palate	Growth deficits
Hearing impairment	Increased likelihood of middle ear infections	Hearing impairment
Increased likelihood of diabetes, leukemia, and heart defects	Increased seizure risk	Lack of coordination
Protruding tongue	Large ears	Small nose that turns up at the tip
Short, stocky neck	Long head with protruding jaw	Small palpebral fissures
Small ears located low on the head	Scoliosis	Smooth philtrum
Small head		Thin vermilion border
Wide space between first two toes		

Fragile X Syndrome

Fragile X syndrome arises from a single recessive abnormality on the X chromosome. Specifically, a mutation in the *FMR-1* gene causes a small section of DNA to be repeated 200 or more times, rather than the normal 5–40 times. This change renders the gene unable to make its associated protein, and absence of the protein leads to errors in brain development and function (National Human Genome Research Institute, 2016).

A variety of signs and symptoms are associated with fragile X syndrome (**Figure 23-3** »). The most notable is intellectual disability, typically accompanied by behavioral problems such as ADHD. Affected children may also exhibit autistic behaviors; speech problems; anxiety and mood problems; delays in learning to sit, walk, and talk; and enhanced sensitivity to environmental stimuli. Most individuals with fragile X syndrome are in generally good health and have a normal lifespan. Still, approximately 15% of affected males and 6–8% of females will experience seizures and require anticonvulsant medications (Consensus of the Fragile X Clinical & Research Consortium on Clinical Practices, 2012). Interestingly, boys usually experience the effects of fragile X syndrome to a much greater degree than girls. Because girls have two copies of the X chromosome, one X chromosome's *FMR-1* gene is able to produce enough protein to partially compensate for the amount normally produced by the other copy. Boys, however, have just one X chromosome, so no

compensatory mechanism is available (National Human Genome Research Institute, 2016).

Fetal Alcohol Syndrome

Unlike Down syndrome and fragile X syndrome, FAS is a completely preventable condition caused by maternal alcohol intake during pregnancy. (See the Patient Teaching feature.) FAS is the most severe of several fetal alcohol spectrum disorders (FASDs), all of which involve some degree of physical, intellectual, behavioral, and/or learning disability (**Figure 23-4** »).

FAS and related disorders result from the presence of alcohol in a woman's bloodstream. Because alcohol crosses the placenta and the fetal liver cannot process it, the fetus has the same blood alcohol content as its mother, regardless of the type or amount of alcohol consumed (National Organization on Fetal Alcohol Syndrome, 2014a). Even small amounts of alcohol can dramatically disrupt prenatal development, causing facial, skeletal, and organ abnormalities, along with a variety of other problems. However, for a diagnosis of FAS (as opposed to another fetal alcohol spectrum disorder), a child must exhibit all of the following conditions:

- Growth deficits
- Characteristic facial abnormalities, including a smooth philtrum (ridge between the nose and upper lip), thin vermilion border (line between the lips and surrounding skin), and small palpebral fissures (separations between the upper and lower eyelids)

Patient Teaching

Fetal Alcohol Syndrome

In the United States, about 1 in 10 women admit consuming at least one alcoholic drink during pregnancy, while about 2% report having five or more drinks at one time. These statistics indicate that all women need clear, timely messages about the damaging effects of alcohol on the fetus (Alshaarawy, Breslau, & Anthony, 2016).

Patient teaching must emphasize that the **only** way to prevent FAS is to abstain from all alcohol of all types for the entire duration of pregnancy. This message should be communicated to all female patients of childbearing age, including teenagers, so they understand how important it is to stop drinking immediately should they become pregnant. Nurses should also explain that the most dangerous time for fetal alcohol exposure may be early in pregnancy—often before a woman even knows she's expecting.

- Central nervous system abnormalities (structural, neurologic, and/or functional) (National Organization on Fetal Alcohol Syndrome, 2014b).

These nervous system abnormalities almost always result in some degree of mental impairment, such as intellectual disability, learning disability, communication problems, poor memory, or limited attention span. Although the many effects of FAS last a lifetime, early treatment can help lessen some symptoms and improve an affected individual's quality of life.

Other Preventable Causes of Intellectual Disability

- Maternal drug use, smoking, malnutrition, exposure to environmental toxins, and illness during pregnancy.
- Prematurity and low birth weight forecast disability more reliably than any other conditions. Difficulties at delivery, such as oxygen deprivation or birth injury, may also cause problems in intellectual functioning.
- Head injuries, near-drowning, and diseases such as whooping cough, chickenpox, measles, and *Haemophilus influenzae* type B (Hib) can damage the brain in childhood. Childhood exposure to lead, mercury, and other toxins can also cause irreparable damage to the nervous system.
- Malnutrition, childhood diseases, exposure to environmental health hazards, and a lack of intellectual stimulation early in life also are factors have been linked to intellectual disability.

In the United States and in other countries around the world, prevalence rates of intellectual disability have dropped thanks to public health measures that mandate newborn screening for phenylketonuria (PKU) and require vaccinations for Hib, measles, encephalitis, and rubella. Comprehensive prenatal care, including testing for diseases and administering folic acid to expectant mothers, also reduces the risk of intellectual disability.

Delirium

Delirium is usually an acute change in mental state that is characterized by confusion; inability to focus, shift, or sustain attention; disorientation; sleep-wake cycle disturbances;

disorganized thinking; perceptual abnormalities; mood changes; and both psychomotor retardation and agitation. Delirium typically results from a medical condition, trauma, or chemical/substance exposure or withdrawal and is a common complication observed during stays in acute-care settings. Delirium is presented as an exemplar in this module.

Dementia

Dementia is a general term used to describe the loss of one or more cortical functions or cognitive attributes as a result of degeneration of the neurologic systems of the brain. The DSM-5 now uses the term **mild and major neurocognitive disorders** (NCDs) to replace the term **dementia**. Individuals with mild NCDs are those who demonstrate limited impairment and are able to maintain independent functioning with some modifications. They are often in the initial stages of disease progression. NCDs are classified as major when additional cortical functions are lost and the individual can no longer maintain independence (Blazer, 2013). Dementia can be caused or exacerbated by other conditions and variables, including metabolic problems, nutritional deficiencies, infections, poisoning, medications, and any conditions that compromise oxygenation and perfusion (National Institute for Neurological Disorders and Stroke, 2016). Subtypes of NCDs are classified by etiology and are discussed briefly below and in more detail in the exemplar on Alzheimer disease. The terms **major neurocognitive disorder** and **dementia** are both used in clinical practice and are used interchangeably in this module.

Alzheimer disease is the most common form of dementia, accounting for about 80% of all cases and affecting more than 5 million adults in the United States (Alzheimer's Association, 2014). Alzheimer-related NCD is included as an exemplar in this module. **Vascular** or **neurocognitive dementia** results from multiple small strokes or infarcts to the brain and is often manifested in a more abrupt change in cognitive function. Vascular dementia can occur alone or in combination with other forms of dementia and is thought to represent at least 10% of all cases of neurocognitive decline. Genetics and heritability appear to play a role in the development of most forms of dementia, although many impacted individuals have no family history. **Table 23-4** outlines other forms of dementia.

Nurses and other healthcare professionals need to recognize that a variety of conditions can mimic dementia, especially in older individuals. Depression and emotional problems may cause cognitive slowing and disorientation. It may be also difficult to distinguish symptoms of delirium from those of dementia. **Table 23-5** provides a comparison of the manifestations of delirium, dementia, and depression.

Schizophrenia Spectrum and Other Psychotic Disorders

As mentioned previously, psychotic disorders encompass a broad range of cognitive alterations that result in altered perceptions of reality and abnormal thinking in the absence of an underlying condition. Schizophrenia represents one type of psychotic disorder and is discussed in detail as an exemplar for cognition. The DSM-5 has been updated to change the classification of "Schizophrenia and Other Psychotic Disorders" to "Schizophrenia Spectrum and Other Psychotic Disorders," often collectively referred to as

TABLE 23–4 Selected Neurocognitive Disorders Resulting in Dementia

Disorder	Etiology	Clinical Manifestations	Onset/Course
Dementia due to HIV	Infection with HIV-1 produces a dementing illness called HIV-1-associated cognitive/motor complex.	Symptoms vary in early stages. Severe cognitive changes, particularly confusion, changes in behavior, and sometimes psychosis, are not uncommon in the later stages.	At first symptoms are subtle and may be overlooked. The severity of symptoms is associated with the extent of the brain pathology.
Dementia due to traumatic brain injury	Any type of head trauma.	Amnesia is the most common neuro-behavioral symptom following head trauma.	A degree of permanent disturbance may persist.
Dementia due to Parkinson disease	Parkinson disease is a neurologic condition resulting from the death of neurons, including those that produce dopamine, the chemical responsible for movement and coordination. It is characterized by tremor, rigidity, bradykinesia, and postural instability.	Dementia has been reported in approximately 20–60% of people with Parkinson disease and is characterized by cognitive and motor slowing, impaired memory, and impaired executive functioning.	Onset and course are slow and progressive.
Dementia due to Huntington disease	Huntington disease is an inherited, dominant gene, neurodegenerative disease. The first symptoms typically are choreic movements that involve facial contortions, twisting, turning, and tongue movements.	Cognitive symptoms include memory deficits, both recent and remote, as well as significant problems with frontal executive function, personality changes, and other signs of dementia.	The disease begins in the late 30s or early 40s and may last 10–20 years or more before death.
Lewy body dementia	This disorder is distinguished by the presence of Lewy bodies—eosinophilic inclusion bodies—seen in the cortex and brainstem.	Clinically, Lewy body disease is similar to Alzheimer disease; however, there is an earlier appearance of visual hallucinations and parkinsonian features.	Irreversible and progressive; tends to progress more rapidly than Alzheimer disease.

Retrieved from <http://emedicine.medscape.com/269706>. Table first appeared in Potter, M. L., & Moller, M. D. (2016). *Psychiatric-mental health nursing: From suffering to hope*. Upper Saddle River, NJ: Pearson.

“SSDs” (APA, 2013). This change was partially intended to reflect a better understanding of the profound neurocognitive deficits associated with this disorder. Approximately 1–4% of the population experiences some type of psychotic disorder, and up to 1% of the worldwide population meets the criteria for schizophrenia (American Psychiatric Association, 2015). The DSM-5 identifies a number of psychotic disorders in addition to schizophrenia spectrum disorder. Because psychosis can result from an underlying medical condition or ingestion of one or more substances, diagnostic tests should be run to rule out any underlying illness or causative substance.

Risk Factors for Altered Cognitive Function

Although risk factors for impaired cognition vary according to the conditions described in this section, a few general

principles apply. Most developmental and acquired cognitive disorders have a nonmodifiable familial/genetic component that predisposes individuals to the development of a specific disorder, such as dementia or schizophrenia. Other categories of risk factors include population-specific factors, lifestyle/behaviors, environmental exposures, and certain health conditions. Most cognitive disorders are believed to be multifactorial or the consequence of genetic factors and age, sex, lifestyle/behaviors, environmental exposures, or other health conditions.

Case Study » Part 1

Victor Wallace is a 74-year-old man who was diagnosed with mild NCD due to Alzheimer disease 2 years ago. Mr. Wallace lives with his 50-year-old daughter, Anne Marie, who is his primary caregiver. His wife of 52 years died of pancreatic cancer 18 months ago.

TABLE 23–5 Comparison of Delirium, Dementia, and Depression

	Delirium	Dementia	Depression
Onset	Acute, sudden, rapid	Slow, progressive	Variable
Duration	Hours to days	Months to years	Episodic
Cognitive impairment	Memory, consciousness	Abstract thinking, memory	Memory and concentration
Mood	Rapid mood swings	Depression, apathy	Sadness, anxiety
Delusions/hallucinations	Both; often visual	May present in later stages	Delusions only
Outcome	Recovery possible	Poor	Recovery possible

Source: Potter, M. L., & Moller, M. D. (2016). *Psychiatric-mental health nursing: From suffering to hope*. Reprinted and electronically reproduced by permission of Pearson Education, Inc., New York, NY.

Mr. Wallace presents at his gerontologist's office at 9:30 on Thursday morning. Ms. Wallace requested the appointment because she is concerned about the changes she has seen in her father over the past month. As the nurse working with Mr. Wallace's gerontologist, you conduct an initial assessment and interview with Mr. Wallace and Ms. Wallace. Ms. Wallace reports that Mr. Wallace has exhibited increased confusion and anxiety at home and at the adult daycare center he attends each day while she is at work. In the past, Mr. Wallace had these problems only in unfamiliar settings. He is also experiencing a decline in language, increasingly using the wrong words to describe common objects and relying on scanning speech to find words. However, Ms. Wallace's main concern is her father's refusal to carry out the basic ADLs he is still capable of performing. When you ask Mr. Wallace about the ADLs, he says, "There's no point in trying because I won't be able to do them much longer."

As you observe Mr. Wallace, you note that he seems agitated. He is sitting on the edge of his chair, tapping his foot and rapping his hands on his knees. When you ask him basic questions, he has a hard time coming up with answers. When he can't find the words he wants, he just repeats the phrase, "That's how it is."

Mr. Wallace's vital signs and weight are normal, and his physical condition is good for a man his age. You administer the Cornell Scale for Depression in Dementia and his score is 17, indicating high probability of depression. The gerontologist maintains Mr. Wallace's current dose of 28 mg of memantine (Namenda) per day to slow the progression of his Alzheimer symptoms. She then adds sertraline (Zoloft), a selective serotonin reuptake inhibitor (SSRI), to treat his depression symptoms. Mr. Wallace is to start out taking 50 mg of sertraline per day, gradually working up to 150 mg per day over a 6-week period.

Clinical Reasoning Questions Level I

1. How do your observations of Mr. Wallace correlate with the changes Ms. Wallace reports?
2. What aspects of Mr. Wallace's presentation prompt you to test him for depression?
3. Why might Mr. Wallace's increased confusion in familiar settings be a concern for Ms. Wallace?

Clinical Reasoning Questions Level II

4. Why is it important to distinguish between Mr. Wallace's refusal to perform ADLs and an inability to do so?
5. Would speech therapy be an appropriate intervention for Mr. Wallace? Why or why not?
6. Refer to the exemplar on Alzheimer disease in this module: How would a change in Mr. Wallace's Alzheimer medication from an angiotensin-converting enzyme inhibitor, like memantine, to a cholinesterase inhibitor, like donepezil, affect the doctor's choice of SSRI for depression?

Concepts Related to Cognition

Cognitive function and other systems tend to be interdependent, so determining the extent to which other concepts or systems is involved can be difficult. For example, cerebral perfusion is necessary for normal cognitive functioning but depends on the adequate intake of oxygen and osmotic pressure needed to maintain adequate blood flow. Any condition that impairs cerebral perfusion will result in inflammation and metabolic changes that further impair cognition. Even subtle variations in perfusion can result in acute alterations in cognitive function, such as delirium, with older adults being more sensitive to these changes because of diminished functional reserves (Fogel & Greenberg, 2015). The possible causes of diminished cerebral tissue perfusion are many and range from cerebral edema to shock. Chronic cerebral hypoperfusion from decreased cardiac output and vascular changes have been implicated in Alzheimer disease and

other chronic and degenerative neurologic disorders (Alosco et al., 2013).

Cerebral perfusion and cognitive integrity depend on normal gas exchange. Decreased oxygenation leads to respiratory acidosis, in which levels of carbon dioxide increase and vasodilation of blood vessels occurs, resulting in increased intracranial pressure. Symptoms of acute oxygen deprivation include headaches, confusion, and irritability. Chronic and subtle mechanisms involved in decreased oxygen supply to the brain (as seen in chronic obstructive pulmonary disease [COPD] and anemia) can negatively impact the neurochemical signaling and synaptic plasticity necessary for normal cognitive development and function (Mukandala et al., 2016).

Fluid and electrolyte balance is also necessary to maintain adequate perfusion and to support cellular function in the brain. A change in mental status, memory, or attention is often an early sign of dehydration in older adults. Cerebral cells are the first to be impacted by the shift of fluids from the vascular to the intracellular space that occurs as a result of fluid volume excess. Early signs of cerebral edema include headache, nausea, and vomiting, with changes in mental status (McCance & Huether, 2014).

Brain function depends on complex metabolic processes required to meet the energy needs of neuronal cells and maintain the synthesis and function of neurochemicals in cognition. Any alteration in normal glucose supply or the excess or deficiency of other metabolic products can result in either acute or chronic cognitive dysfunction (González-Reyes et al., 2016). Both hypoglycemia and hyperglycemic ketoacidosis can result in confusion, hallucinations, and changes in consciousness. Infection, inflammation, and alterations in thermoregulation increase overall metabolic demands and can precipitate changes in cognitive function.

Inflammation appears to play a key role in altered cognitive function. Stress, infection, surgery, and cancer all result in an inflammatory response and the release of cytokines. Inflammation can occur in the brain and central nervous system as a direct result of trauma, cerebral infarction, or bacterial, viral, fungi, or prion infections. Peripheral inflammation (outside of the central nervous system) causes a cascade of physiologic events that alter glutamate, serotonin, dopamine, and acetylcholine systems considered central in cognition, with implications for an array of affective, cognitive, and behavioral responses (Benros et al., 2015). Initially, these changes are adaptive, enabling individuals to conserve energy necessary for healing. However, chronic or persistent inflammation can lead to irreversible neuronal changes.

Substances such as alcohol, illicit drugs, and some pharmaceuticals can impact cognitive function. Immediate consequences of alcohol intoxication include confusion, decreased attention, impaired judgment, loss of inhibition, disorientation, hallucinations, and memory loss. Chronic alcohol abuse can lead to hematologic changes that can limit oxygenation to the brain and lead to encephalopathy. Older adults are at a higher risk of permanent cognitive changes as a result of excessive alcohol consumption (Kim et al., 2012).

Permanent brain injury caused by trauma or acute oxygenation deprivation is a common source of cognitive pathophysiology. Cognitive disorders such as schizophrenia and learning disabilities are associated with both obvious and subtle anatomic differences in brain development and

structure as well as developmental delays (Butterworth & Kovas, 2013; Ren et al., 2013).

Alterations in cognitive function have the potential to impact an individual's competency to make healthcare decisions and consent to certain treatments and procedures. Patients with mental health disorders, intellectual disabilities, and other cognitive conditions are often unable to advocate for themselves and are considered vulnerable populations. Establishing advance directives during mild stages of cognitive dysfunction or relapse is essential.

Individuals with a serious mental illness such as schizophrenia are at increased risk of involvement with the criminal justice system because of the behavioral manifestations of these disorders. Research demonstrates that individuals with psychotic disorders are overrepresented in the criminal justice system (Robertson et al., 2015).

The following feature links some, but not all, of the concepts related to cognition. They are presented in alphabetical order.

Concepts Related to Cognition

CONCEPT	RELATIONSHIP TO COGNITION	NURSING IMPLICATIONS
Addiction	Drugs and alcohol alter normal neuronal functioning, ↓ blood flow and/or waste removal → cognitive impairment.	<ul style="list-style-type: none"> Promote prevention of addiction behaviors, address risk factors. Monitor vital signs. Provide for patient safety. Watch for symptoms of withdrawal and provide supportive care as necessary. Pharmacotherapy, substance abuse counseling, patient education.
Development	Genetic factors, heredity, and environmental insults → cognitive dysfunction.	<ul style="list-style-type: none"> Refer for genetic counseling. Screen for conditions that may impact cognitive development (e.g., metabolic disorders). Assess for alterations in development. Refer for evaluation. Provide patient/family education and support; collaborate with special education services, psychologists, speech pathologists, occupational therapy, and others.
Inflammation	Inflammation → release of pro-inflammatory proteins that alter neurotransmitter function. Chronic and frequent inflammation → permanent cognitive decline.	<ul style="list-style-type: none"> Promote lifestyle behaviors that decrease inflammation (diet, exercise, prevention of infection, immunizations, injury prevention, use of helmets). Assess for infection or injury that may be causing inflammation. Implement measures to address inflammation/infection (antibiotics, anti-inflammatory agents).
Legal Issues	Recurring or chronic cognitive issues ↓ decision-making capacity and competency. Lack of appropriate services → involvement with the criminal justice system.	<ul style="list-style-type: none"> Provide safe environment. Recognize that a history of incarceration alone does not predict violent behavior. Advocate for community resources that can enable individuals with cognitive function to manage the symptoms of their disease and avoid encounters with the criminal justice system. Monitor for signs of abuse, caregiver role strain. Ask whether patient has established an advance directive or is interested in doing so. Document the advance directives and all conversations about it in the patient's chart. Advocate on the patient's behalf by ensuring that the advance directive is followed. <i>Anticipate:</i> Patient, family community education, referral to counseling resources, case management services.
Oxygenation	Decreased O ₂ reaching the brain → cognitive impairment, coma, and death.	<ul style="list-style-type: none"> Promote prevention of conditions that lead to impaired oxygenation; address modifiable risk factors. Monitor vital signs, arterial blood gases (ABGs), airway clearance, and for signs of impaired perfusion. Administer oxygen and carry out other interventions to support oxygenation.
Perfusion	Inadequate perfusion of brain tissue ↓ O ₂ levels and → acute changes in cognitive function. Chronic impairments in perfusion and oxygenation ↑ risk for neurodegeneration.	<ul style="list-style-type: none"> Promote healthy lifestyle; address modifiable risk factors for alterations in perfusion. Monitor vital signs, ABGs, and cardiac sounds. Assess perfusion, including pulses, nail beds, and skin color. <i>Anticipate:</i> Pharmacotherapy, intravenous (IV) fluids, stress/exercise tests, echocardiogram, possible cardiac catheterization and/or surgery.

Health Promotion

A health-promotion model for cognition views cognitive function on a continuum from optimal to impaired function, with the goal being to support independence and quality of life for all individuals at risk for or experiencing an alteration in cognitive function. The Centers for Disease Control has published the Healthy Brain Initiative (2013), which stresses the importance of proactive measures to address the public epidemic of cognitive disorders. Healthcare systems in the United States have largely emphasized the provision of services to individuals who require hospitalization or institutionalization. The focus is shifting toward allocating more resources to the prevention and early screening of cognitive disorders. When individuals are diagnosed with a cognitive disorder, the goal is to provide care that enables them to achieve their fullest potential, maintain their orientation to their families and communities, and live in environments that promote their inherent worth and self-efficacy.

Individuals with cognitive disorders are at greater risk for a variety of health problems as a result of both cognitive illnesses and their treatment. Research demonstrates that the health problems of individuals with cognitive problems are often ignored. Health promotion for individuals with cognitive disorders also incorporates the principle that no matter what the level of wellness, individuals have a right to care that addresses physiologic, psychosocial, and humanistic aspects of function.

Prevention

Prevention of cognitive disorders includes measures to reduce modifiable risk factors and enhance protective factors. **Universal prevention** of cognitive disorders targets the general population and includes interventions such as public health campaigns regarding the use of safety devices such as helmets and seatbelts. **Selective prevention** targets subgroups of the population whose risk of developing a cognitive disorder is higher than that of the general population based on an analysis of biological, psychologic, or socioeconomic factors. Examples include early intervention programs for children from disadvantaged backgrounds and counseling following exposure to trauma. **Indicated prevention** is aimed at individuals who have minimal but detectable manifestations of cognitive disorder. An example would be initiating treatment for an individual who demonstrates prodromal symptoms of schizophrenia or has biomarkers for a dementia.

Screening and Early Detection

The progression and or impact of many of the cognitive disorders described in this module can be positively impacted through early detection and intervention. A variety of screening tools are identified in the sections on assessment later in this module. Screening and detection of cognitive disorders occur in a number of settings, including but not limited to primary care settings, community health settings, and schools.

Nursing Assessment

A general assessment of cognitive status is an essential component of the nursing assessment of all patients. When a patient presents with the onset of any cognitive changes, the

priority assessment focuses on addressing potentially life-threatening factors that may be contributing to the problem through physical assessment, history, and diagnostic procedures, such as laboratory values.

SAFETY ALERT Any changes in cognition require immediate attention. Cognitive disturbances put patients at increased risk of injury, so rapid institution of safety measures is critical. Also, prompt assessment of a patient's cognitive impairment may allow the healthcare team to more quickly identify and treat the underlying cause.

Cognitive assessment is performed both for the purposes of initial screening for the presence or absence of cognitive problems and for monitoring changes in cognition over time. An assessment of cognitive status should be performed during an initial provider or home care visit, following any changes in medical treatment and pharmacotherapy, during any transitions in care, and prior to obtaining consent for procedures. Certain individuals are at increased risk for cognitive problems and warrant more frequent assessment of cognitive status. For example, clinical guidelines published by Tullman, Fletcher, and Foreman (2012a) suggest that older adults who are hospitalized should be assessed for cognitive changes a minimum of every 8 hours and within 6 weeks of discharge from the hospital setting.

Observation and Patient Interview

Data gathering begins with the initial observation of the patient and focuses on appearance and behavioral manifestations that may be indicative of cognitive function. Appearance and dress can provide cues to the patient's mental state and ability to maintain self-care. The nurse may also make general observations related to social skills, motor function, activity level, ability to attend and focus on the assessment, and ability to provide logical and coherent responses to questions. The best source of information comes directly from the patient. However, when assessing pediatric patients or patients with moderate to severe cognitive impairment, a family member or caregiver may be asked to provide information.

During the patient interview, ask direct questions to elicit information related to biophysical and psychosocial history, development, family history, and environmental factors. Use judgment in direct questioning of individuals with established cognitive and perceptual problems, as some may not have the capacity to respond logically. In addition, cognitive problems such as perceptual problems and delusional thinking are likely to increase the patient's anxiety and may result in an escalation of inappropriate behaviors during the patient interview and examination.

Biophysical and Psychosocial History

The medical history includes gathering information about both the presenting problem and the presence or development of altered health patterns across the lifespan.

History of the Current Problem

Initial questions focus on the patient's perception of the problem and what brings the patient to the healthcare setting currently. Initial questions may proceed from broad questions about a typical day, including ADLs, self-care

activities, and perceived level of health and wellness. When patients or family members report changes in cognitive function, ask non-threatening questions such as:

- Can you describe the changes?
- What do you think may be contributing to the changes?
- When did you begin experiencing these changes?
- Are these changes constant and, if not, how frequently do they occur?
- Have you previously sought medical advice or care related to these changes?

More focused questions include the following:

- Are you experiencing any changes in your ability to pay attention or remember things?
- Do you have difficulty planning and organizing things?
- Do you ever hear, see, or smell things that are not apparent to others?
- Have you been experiencing any problems that are making it difficult to learn or function in school (or work)?
- Have you been experiencing any problems expressing yourself or understanding others?
- Have you been diagnosed with any problems that might impact your thinking (e.g., learning disabilities, intellectual disabilities, Alzheimer or Parkinson disease, depression, mood disorders, anxiety, head injury, tumors, cerebral vascular problems, central nervous system infections)?

Depending on the patient's responses, seek additional detail about the impact on daily functioning, frequency and duration of symptoms, suspected causes or contributing factors, and how the patient has been treating or managing the symptoms. Be sure to obtain a list of all current medications with the dose, route, and frequency and to inquire about the use of any complementary health approaches.

History of Prior Biophysical and Psychosocial Alterations

Focused questions related to past medical history follow a structure similar to that under current medical history. Inquire about past health-related behaviors such as diet and exercise, access to routine care, and preventive health measures. Inquire about past use of alcohol and other substances, as these may have implications for care. Ask the patient about possible variables impacting prenatal health, childbirth and postnatal care, and childhood illnesses or exposures, and collect a psychosocial history to include evidence of overwhelming stressors, trauma, or violence.

Assess the patient's developmental history and developmental status, including evidence of achievement of expected milestones. This is especially important when performing an assessment of cognition in a child. Note any known factors that may impede normal growth and development, such as chronic illnesses and hospitalizations.

Ask if any family members had disorders such as dementia, schizophrenia, and/or developmental or learning problems. Because many patients may not have knowledge of the specific diagnoses in family members, use lay terms to ascertain whether any family members ever demonstrated

unusual behavior, experienced confusion or memory loss, or required treatment or hospitalization for mental health issues.

Assess for environmental factors that may be contributing to the patient's cognitive status, including but not limited to social supports, ability to access healthcare and maintain a healthy diet and lifestyle, living situation and safety of the home environment, and any accommodations or services in place to support independent function. When assessing cognition in children, consider parenting techniques and capabilities, as well as access to activities and stimulation that promote cognitive development, such as age-appropriate activities and toys. Assess for any cultural factors that may impact cognition, including traditional health practices. Determine the possibility of any current or past exposures to toxic substances at home or at work.

Physical and Mental Status Examination

Once the interview is completed and the patient's history has been obtained, the nurse progresses to a physical assessment of the patient and a mental status examination. The physical examination incorporates an organized pattern of assessment to identify alterations that may be contributing to cognitive dysfunction. The mental status exam includes a series of procedures and tools used to detect alterations in perception and thinking.

Physical Examination

Because changes in cognitive function are often an early sign of decreased oxygenation, perfusion, or an alteration in another biophysical process, begin by obtaining a complete set of vital signs and assessing the patient's level of pain. Auscultation of the heart and lungs may reveal an underlying problem with gas exchange or perfusion. Murmurs in infants and young children may indicate congenital heart defects associated with other neurodevelopmental problems. An assessment of peripheral perfusion may indicate vascular problems that are compromising cerebral perfusion. An assessment of neurologic signs is an essential component of cognitive evaluation (detailed information can be found in the module on Intracranial Regulation). An evaluation of hearing, vision, touch, taste, and smell can help rule out perceptual problems related to impaired sensory function. Skin integrity can provide clues to the patient's nutritional status, fluid balance, and the possibility of injury or infection.

Physical development and height, weight, and fat distribution should be within normal limits for the patient's age. Observable physical alterations may be associated with many cognitive syndromes, including intellectual disabilities and schizophrenia (Cheng et al., 2014; Jones, Jones, & Del Campo, 2013; Moeschler et al., 2014; Tikka et al., 2013). Examples include small head circumference, wide or close-set eyes, prominent forehead, folds on the inner corners of the eyes (epicanthic skin folds), asymmetry or malformation of facial features and ears, tongue protrusion, palate and mouth abnormalities, flattened face or nose, limb abnormalities, small stature, poor muscle tone, some birthmarks, palmar folds, and altered posture.

An important component of the physical examination includes an assessment of motor function. Movements should be consistent with age and development. Any changes in gait or other evidence of movement disorders should be noted.

TABLE 23–6 Common Tools Used to Assess Cognition and Mental Status

Assessment Name	Description
Ages & Stages Questionnaires (ASQ),	Set of questionnaires tailored to detect alterations in development in young children.
American Academy of Pediatrics—Bright Futures	Kit for health promotion and prevention published by the American Academy of Pediatrics that includes schedules for screening and care and a variety of questionnaires used to detect health problems, including developmental alterations.
Confusion Assessment Method (CAM)	Interview-style exam that can be conducted in about 5 minutes, screens specifically for signs of delirium. Pediatric versions available for children 5 years and older (pCAM).
Cornell Assessment of Pediatric Delirium	Validated, rapid observational tool for screening children in intensive care for delirium.
Cornell Scale for Depression in Dementia	Nineteen-question tool that involves interviews with both patients and their caregivers, assesses for signs of depression in individuals known to have dementia.
Edinburgh Depression Scale	Validated 10-item questionnaire used to screen for the presence and severity of symptoms of postnatal depression.
Geriatric Depression Scale (GDS)	Brief questionnaire (15 or 30 items) that asks patients how they've felt over the past 7 days; assesses for depression in older adults.
Hamilton Rating Scale for Depression (HRSD)	Seventeen-question, 20-minute examination, assesses severity of depression in adult patients. The Weinberg Depression Scale for Children and Adolescents (WDS-CA) and the Children's Depression Rating Scale (CDRS-R) are modeled on the HRSD and adapted for children over 5.
Mini-Mental State Examination (MMSE)	Thirty-question interview-style exam that assesses a patient's memory, language skills, attention level, and ability to engage in mental tasks, also known as the Folstein Mini-Mental State Examination. It may be modified for use in children after the age of 4.
Montreal Cognitive Assessment	One-page test that briefly assesses patient's ability in a variety of cognitive domains, including problem solving and sequencing (traits, similarities), attention (digit span, letter vigilance), memory (word list, orientation), visual-spatial construction and reasoning (cube, clock), and language (naming, repetition, word generation).
Nonverbal Learning Disabilities Scale (NVLD)	Deficits in the areas of motor skills, visual-spatial skills, and interpersonal skills.
Patient Health Questionnaire (PHQ)	Full-length 11-item tool that screens for depression and anxiety, somatic symptoms, and related disorders; abbreviated forms (PDQ-9 and PDQ-2) are used to more selectively screen for depression.
Positive and Negative Symptoms Scale (PANSS)	Registered nurses and other licensed healthcare providers can administer to detect positive, negative, and other manifestations of psychotic disorders and schizophrenia. May be useful in screening for perinatal psychosis.
Postpartum Depression Predictors Inventory (PDPI)	Validated short inventory that can be integrated into all phases of perinatal care to predict the risk of maternal depression.

Mental Status Examination

The mental status exam is a broad screening tool that is used to assess current cognitive functioning of the individual. Many specific tools exist to perform a mental status assessment, but most serve to capture data related to orientation, perception and thought content (including judgment and insight), attention and concentration, memory, speech/language/communication, mood and affect, and psychomotor activity. Other assessments may be used to rule out related conditions such as depression or other mood disorders or to gather information on developmental status or level of functional impairment. **Table 23–6** » lists a variety of common assessment and screening tools that may be used by healthcare professionals to detect alterations in cognitive function. The Mental Status Assessment feature presents an example of an organized formal mental status examination with a description of normal and abnormal findings and the patient-centered considerations. Formal assessment often serves to validate findings gathered through observation.

Diagnostic Tests

Nurses collaborate with other disciplines to support diagnostic assessment of individuals for cognitive disorders. When individuals present with alterations in cognition, nurses can anticipate that a number of laboratory values

and diagnostic tests will be ordered to rule out an underlying medical condition. Priority diagnostic assessment focuses on life-threatening conditions that may manifest in cognitive alterations. Analysis of blood and cerebral spinal fluid can identify biomarkers associated with Alzheimer disease and schizophrenia, although this is not typically used for diagnosis. Relevant laboratory tests include the following:

- **Toxicology screens** to rule out alcohol or substances as a causative factor for changes in mental status
- **Drug levels** to rule out mental status changes related to toxic levels of therapeutic agents
- **Liver function tests (LFTs), complete blood count (CBC), thyroid function, B₁ (thiamine), sedimentation rate, urinalysis, HIV titer, and fluorescent treponemal antibody absorption (FTA-abs)** to rule out metabolic, inflammatory, and infectious conditions that may contribute to alterations in mental status
- **VeriPsych** blood test to identify biomarkers for schizophrenia
- **Cerebrospinal fluid (CSF) and blood markers** to identify biomarkers for Alzheimer disease
- **Genetic testing** to identify risk factors or underlying causes of a variety of cognitive disorders

Mental Status Assessment

ASSESSMENT/ METHOD

NORMAL FINDINGS

ABNORMAL FINDINGS

PATIENT-CENTERED CONSIDERATIONS

Step 1: Prepare the Patient

Tell the patient you will be performing a series of tests. Describe what equipment you'll use. Explain that the exam should be comfortable, and ask the patient to inform you should difficulties arise. Provide an overview of the assessment activities and the order in which they will occur.

- Patient pays attention and asks questions as appropriate.
- Patient may be nervous, but this should not interfere with the assessment process.

- Patient displays high levels of confusion, anxiety, or agitation.
- Patient shows signs of delusions or hallucinations.
- Patient pays no attention to the information you provide.
- Patient is partially or fully uncommunicative.

- A number of assessment tools are available, with some tailored to specific conditions and/or populations.
- Direct questioning may not be appropriate for patients who are experiencing hallucinations, delusions, or extreme anxiety.
- Questions for children or individuals with intellectual disabilities should be modified.

Step 2: Position and Observe the Patient

Take note of the patient's general appearance, including hygiene, posture, body language, and expression. Observe the patient's ability to follow your instructions.

- Patient follows directions.
- Patient's hygiene and overall appearance are acceptable.
- Patient's expressions and body language are appropriate to the situation.

- Poor hygiene and/or inappropriate expressions and body language might be reflective of depression, schizophrenia, dementia, or another cognitive disorder.

- In many cases, a patient's appearance and hygiene may be negatively affected by socioeconomic and cultural factors rather than mental status.

Step 3: Assess the Patient's Language Abilities

Note the tone, rate, pronunciation and volume of the patient's speech throughout the course of the exam. Consider the patient's vocabulary and whether he seems to understand what you are saying.

- Patient's tone, rate, pronunciation, and volume are appropriate.
- Patient speaks easily and naturally, without searching for words.
- Patient understands what you are saying and indicates this through verbal and physical reactions.
- Social and language milestones have been met.

- Problems with language could be a result of anxiety, dementia, depression, or an expressive or receptive language disorder related to brain injury/illness.

- Consider whether the patient's hearing may be impaired, especially when working with older adults.
- Don't assume all patients are native English speakers. Some patients may simply be unable to communicate well in English.
- Consider the child's stage of development.

Step 4: Assess the Patient's Level of Orientation

Check whether the patient knows the date and time. Ask if the patient knows where she is and why. Gauge the patient's level of consciousness.

- Patient knows the correct date and time, where she is, and why.
- Patient is fully conscious and alert.

- Reduced or varying consciousness may be due to hypoglycemia, stroke, seizure, delirium, or organic brain disease.

- Noticeable decreases in consciousness during the exam may necessitate immediate medical attention.
- Modify questions for children according to developmental level.

Step 5: Assess the Patient's Memory

See whether the patient knows her name, birth date, and address. Ask the patient for a brief summary of places lived and jobs held. Attempt to verify all responses.

- Patient can recall basic personal information and provide an accurate biography appropriate to age and developmental level.

- Inability to recall events from one's past may be suggestive of dementia, especially Alzheimer disease.

- In Alzheimer disease, loss of short-term memory typically precedes loss of long-term memory.
- Alterations in memory in children may suggest a problem with learning or intellectual function.

(continued on next page)

Mental Status Assessment *(continued)*

ASSESSMENT/ METHOD	NORMAL FINDINGS	ABNORMAL FINDINGS	PATIENT-CENTERED CONSIDERATIONS
Step 6: Assess the Patient's Computational Ability			
Have the patient answer several arithmetic problems. Start with basic facts and work toward more complicated questions. The age and the developmental status of the patient should be considered.	<ul style="list-style-type: none"> ■ Patient can compute the correct values. Depending on age and cognitive stage, patient may be able to identify numeric symbols and count. 	<ul style="list-style-type: none"> ■ Inability to perform simple calculations may be suggestive of brain disease or learning problems. 	<ul style="list-style-type: none"> ■ Patient's responses may be negatively affected by language barriers, cognitive development, anxiety, and/or limited experience or education in mathematics.
Step 7: Assess the Patient's Emotions and Mood			
Note the patient's affect. Ask the patient how he feels and whether this is typical. If not, ask about events that may have prompted the change. Modify questions for children. Children may be asked to draw pictures of how they are feeling or to select from a visual scale.	<ul style="list-style-type: none"> ■ Patient's affect corresponds with the tone and content of his speech. ■ Patient's emotions and mood are appropriate given past events and current situation and developmental status. 	<ul style="list-style-type: none"> ■ Mismatch between the patient's affect and speech may reflect neurologic or psychologic problems. ■ Absent, excessively subdued, or excessively animated expressions and responses may be indicative of psychologic disorders. 	<ul style="list-style-type: none"> ■ Culture, temperament, and development impact emotional expression. Certain developmental stages are associated with increased lability.
Step 8: Assess the Patient's Perceptions and Thinking Abilities			
Note whether the patient's statements are complete, rational, and pertinent, and whether he/she seems aware of reality. Ask the patient to compare two different things or explain the meaning of a common phrase. Ask the patient if he sees, hears, smells, or feels things that are not apparent to others.	<ul style="list-style-type: none"> ■ Patient is aware of reality. ■ Patient's statements are logical and complete. ■ Patient correctly compares two objects and/or explains the meaning of a phrase. ■ Patient denies hallucinations of any kind, or perceptual differences may be explained by level of cognitive development or sociocultural factors. 	<ul style="list-style-type: none"> ■ Patients who are unaware of reality may be experiencing neurologic disturbances or a mental disorder. ■ Illogical, incomplete statements suggest problems with concrete thought and may be indicative of a mental disorder. ■ Absent or strange comparisons and explanations are frequent symptoms of psychologic disorders. 	<ul style="list-style-type: none"> ■ Patient's responses may be negatively affected by language barriers, education level, and/or intellectual disability or level of cognitive development. ■ Perceptual differences in young children may be related to magical thinking and animism. Children may have difficulty distinguishing between what is imagined and what is real.
Step 9: Assess the Patient's Decision-Making Ability			
Ask the patient about a personal situation that requires good judgment. Determine whether the patient's responses reflect consideration of viable options and logical decision making.	<ul style="list-style-type: none"> ■ Patient considers possible, probable, and appropriate options. ■ Patient's thinking and decision-making capabilities are appropriate for age and stage of development. 	<ul style="list-style-type: none"> ■ Patient considers impossible, improbable, or inappropriate options. ■ Patient's decision reflects absent or inadequate consideration of available options. 	<ul style="list-style-type: none"> ■ Consider whether the patient's options and decisions make sense—not whether they reflect the choice you would make. ■ Decision-making capacity depends on the stage of cognitive development; refer to normal characteristics of thinking associated with each stage.

- **Metabolic screening**—Newborn screens for 26–40 metabolic disorders that can cause learning and intellectual disabilities
- **Diagnostic imaging** to detect conditions requiring emergency management, such as cerebral edema, cerebral vascular accidents, tumors, and traumatic injuries
- **MRIs and CT** to detect abnormalities that are suggestive of some neurocognitive, neurodevelopmental and psychotic disorders.

Psychometric tests include a variety of standardized tests that are usually administered by a psychologist or neuropsychologist to measure cognitive function in a variety of areas. Comprehensive neuropsychologic testing may include the use of a number of tests administered over a period of several days. Nurses, teachers, parents, and patients may be asked to complete one or more rating scales to contribute to an overall understanding of the presentation of the problem across a variety of domains.

Case Study » Part 2

In the winter after his visit to the gerontologist, Mr. Wallace begins experiencing increased agitation and wanders in the afternoons and evenings. One afternoon at the adult daycare center, Mr. Wallace slips out the door undetected. By the time the daycare providers realize he is gone, he has left the grounds and is wandering the neighborhood. The daycare providers call Ms. Wallace, his daughter, and 911, and a search for Mr. Wallace commences. Ms. Wallace and two police officers find Mr. Wallace 2 miles from the daycare center. He has no idea where he is or how he got there. He has taken a fall, and his face and hands are covered in scrapes.

The officers radio for an ambulance as Ms. Wallace attempts to talk to her father. Mr. Wallace panics because he does not recognize his daughter, and he pushes her to the ground. He then throws punches at the officers when they prevent him from running away. The paramedics arrive and restrain Mr. Wallace. Once he is restrained, Ms. Wallace is able to calm him down. He is then transported to the emergency department (ED), where you are the admitting nurse.

Mr. Wallace is calm on arrival to the hospital, and you are able to treat his injuries without incident. You attempt to speak with him, but he indicates he is tired and promptly falls asleep. You use this opportunity to interview Ms. Wallace. She states that aggression has become common during her father's increasingly frequent periods of confusion. Sometimes he doesn't recognize her; other times, he mistakes her for his sister. He is also increasingly unable to use basic objects—such as pencils, toothbrushes, and combs—and relies on Ms. Wallace for many basic ADLs. In addition, he occasionally experiences urinary and fecal incontinence. Ms. Wallace is shaken by the day's events and the situation in general, and she begins to cry.

When Mr. Wallace's gerontologist arrives in the ED, you inform her of these developments. She adds 7.5 mg of buspirone (BuSpar) two times daily (bid) to Mr. Wallace's treatment regimen to lessen his agitation and aggression. The doctor also tells Ms. Wallace that Mr. Wallace is starting to transition from moderate to severe Alzheimer disease, and she recommends that Ms. Wallace might consider looking for a nursing home that specializes in the care of individuals with this condition.

Clinical Reasoning Questions Level I

1. What are the priorities for Mr. Wallace's care to decrease his risk of wandering and injury during his remaining time at home?
2. What independent interventions can you perform to address the caregiver role strain felt by Ms. Wallace?
3. What additional information or education do you anticipate Ms. Wallace will need in light of the doctor's recommendation?

Clinical Reasoning Questions Level II

Referring to the exemplar on Alzheimer disease in this module:

4. Which of Mr. Wallace's symptoms indicate he is transitioning from moderate to severe AD?
5. What steps can Ms. Wallace take at home to lessen the incidence and severity of Mr. Wallace's sundowning episodes?
6. Why is it important for Ms. Wallace to find an institutional care situation for Mr. Wallace now rather than waiting until he reaches a more severe stage of AD?

Independent Interventions

Given an understanding of the importance of health promotion with respect to cognitive disorders, nurses should be prepared to carry out a variety of interventions across settings. Nursing interventions include teaching prevention, coordinating care and making appropriate referrals, implementing measures to promote individual/family safety and well-being, and advocating for the needs of individuals impacted by alterations in cognition.

Prevention and Coordination of Care

Nurses in community health and primary care settings play a critical role in addressing health-related behaviors and protective measures that can reduce the risk of developing cognitive disorders. Nurses accomplish this through teaching and providing anticipatory guidance. They also independently carry out routine assessments for cognitive problems using a variety of tools, and they refer patients for further diagnosis and treatment. Examples of independent interventions in this category include:

- Teaching about healthy diet, lifestyle, and the importance of preventive healthcare
- Ensuring that patients use protective headgear during sports and activities such as bike riding
- Stressing the importance of developmentally appropriate activities
- Administering routine developmental and cognitive screenings
- Making referrals to other members of the interprofessional team.

Promoting Safety and Well-Being

Nurses in all settings often plan care for individuals that promotes safety and adaptive functioning. For example, the home health nurse may work with individuals with schizophrenia or Alzheimer disease, monitoring adherence to treatment, providing emotional support to the patient and family, and assessing comorbid health conditions.

When patients do require hospitalization for acute changes in cognition, the priority is to identify and manage underlying conditions that may be contributing to the problem. Priority interventions address immediate safety. Secondary interventions include teaching patients and families about the illness and prescribed treatments, providing emotional support, and preparing for discharge to settings where they can receive the support necessary to achieve optimal functioning and prevent future hospitalization.

Even when patients are unable to return to their homes or families, nurses provide care that supports interpersonal functioning and the ability to engage in goal-directed activities. Examples of interventions across settings include:

- Evaluating risk of injury or suicide
- Implementing environmental modifications to support patient safety
- Educating patients and families about diseases, medications, and other therapeutic interventions
- Identifying patient and family strengths
- Encouraging the use of adaptive coping skills
- Supporting cultural and spiritual needs
- Providing ongoing emotional support to both patients and families
- Ensuring healthcare needs are met
- Monitoring the effectiveness of care.

Advocating for Patients

Because cognitive disorders have the potential to reduce decision-making capacity, nurses have a role in ensuring that patients are not abused or exploited and are able to partner in healthcare decisions to the greatest degree possible. This includes encouraging patients in remission or in the early stages of neurocognitive dysfunction to establish advance directives and providing teaching about legal protections that may apply to them (see the Patient Teaching feature). Other interventions related to advocacy include providing teaching related to legal rights and assisting caregivers and community members to understand cognitive disorders.

Collaborative Therapies

When working with individuals at risk for or experiencing alterations in cognitive function, nurses should anticipate collaborating with the patient, family, other members of the healthcare team, and potentially professionals from other

Patient Teaching
Legal Protections for Patients with Cognitive Dysfunction

Nurses should teach individuals with cognitive alterations and their families about several key laws that may affect them. For example:

- The Americans with Disabilities Act of 1990 ensures that individuals with disabilities have equal access to government services, employment, and public accommodations.
- The Education for All Handicapped Children Act of 1975 requires that children with any type of disability have access to free public education. An amendment to this act in 1986 provides federal funding to states that offer early intervention services.
- The Developmental Disabilities and Bill of Rights Act of 2000 provides federal funding to state, public, and nonprofit agencies that provide community-based training activities and education to individuals with developmental disabilities. The law also created the U.S. Administration on Developmental Disabilities to oversee these efforts.

disciplines, such as education and law. **Table 23-7** » provides an overview of select members of the interprofessional team and their roles with respect to the collaboration and management of cognitive disorders. For a more extensive list, please refer to the module on Collaboration. Additional resources may be available through local chapters of organizations such as the LDA, the Alzheimer’s Association, the American Psychiatric Association, the American Association of Intellectual and Developmental Disabilities, and the National Alliance on Mental Illness.

Pharmacologic Therapy

Nurses play a key role in medication administration, education, and adherence, and they must be familiar with the different classes of drugs prescribed to individuals with

TABLE 23-7 Selected Members of the Interprofessional Team for Management of Cognitive Disorders

Team Member	Role Description
Advocates (disability, patient care, special education advocates)	Individuals with varying levels of specialized training in advocacy for individuals with disabilities, mental illness, or related health concerns. Because levels of expertise and experience vary, patients should be encouraged to seek referrals from government agencies, reliable associations, and legal firms.
Developmental pediatricians	Board-certified pediatricians with specialized training and certification in the identification and management of developmental disorders that impact cognition and psychosocial function.
Occupational therapists	Master’s prepared professionals that possess specialized education and training in determining and managing the impact of cognitive disorders on everyday functioning across the lifespan.
Neuropsychologists	Doctoral prepared clinical psychologists with specialized training in the area of central nervous system function and its relationship to human behavior. Qualified to perform comprehensive assessment and diagnosis of neurocognitive and neurodevelopmental function. Also collaborate with nurses and other professionals in the management of these disorders.
Special education professionals	Generally master’s prepared educators with specialized training to work with students who have a wide range of learning, mental, emotional, and physical disabilities. Teach reading, writing, and math to students with mild and moderate disabilities through modified methods. Also, facilitate the acquisition of basic skills, such as literacy and communication techniques, to students with severe disabilities.
Speech language pathologists	Master’s prepared professionals who have a primary role in the screening, assessment, diagnosis, and treatment of infants, children, adolescents, and adults with cognitive-communication disorders.
Psychiatric or psychosocial rehabilitation specialists	Assist patients with mental illness to function within the community. Levels of training vary, but most specialists have a master’s degree in rehabilitation training. Additional certification as a Psychiatric Rehabilitation Practitioner can also be obtained through Psychiatric Rehabilitation Association (2016).

cognitive alterations. Drugs that are available for treating neurocognitive disorders are primarily aimed at slowing further brain changes. Medications used to treat psychosis, anxiety, and depression target the symptoms of the disorder. The Medications feature provides an overview of medications used to treat cognitive disorders and the implications for nursing practice.

SAFETY ALERT Nurses must assess patients with cognitive alterations to determine their ability to self-administer medication. Many patients will require caregiver administration of pharmaceuticals.

Missed doses may result in a return or exacerbation of symptoms and increase the patient's risk for injury. Long-acting formulations may enhance adherence. Assess for factors that affect adherence at each healthcare interaction.

Lifespan Considerations

Cognitive function is mediated by the interaction of genes and experience, both of which provide the foundation for cognitive changes that occur across the lifespan. Nurses use knowledge of these changes to modify assessment and interventions

Medications

Cognitive Disorders

CLASSIFICATION AND DRUG EXAMPLES

Acetylcholinesterase Inhibitors

Drug examples:

Donepezil (Aricept)
Galantamine (Razadyne, Reminyl)
Rivastigmine (Exelon)

N-Methyl-D-aspartate (NMDA) Receptor Antagonists

Drug examples:

Memantine (Namenda)
combination NMDA receptor antagonist and acetylcholinesterase inhibitors
Memantine hydrochloride extended-release and donepezil hydrochloride (Namzaric)

MECHANISMS OF ACTION

Acetylcholinesterase inhibitors reduce acetylcholine breakdown, whereas NMDA receptor antagonists limit the effects of glutamate. Both drugs have a modest effect in slowing an individual's rate of cognitive decline in Alzheimer disease.

May also be used for:

- Vascular dementia
 - Parkinson-related dementia.
- Combination agent (Namzaric) used only after patients have been stabilized on memantine and donepezil

NURSING IMPLICATIONS

- Explain the importance of taking medication as directed; teach about discontinuation and decline in function.
- Provide patient education regarding dizziness, headache, gastrointestinal (GI) upset, and fatigue.
- Promote adequate fluid intake.
- Monitor patient's pulse rate.
- Use with caution in patients with respiratory conditions (e.g., asthma, COPD).
- Avoid the use of tricyclics and anticholinergic drugs because of their antagonistic effects.

Conventional Antipsychotics

Phenothiazines

Drug examples:

Chlorpromazine (Thorazine)
Fluphenazine
Perphenazine
Prochlorperazine (Compazine)
Thioridazine
Trifluoperazine

Nonphenothiazines

Drug examples:

Haloperidol (Haldol)
Loxapine (Loxitane)
Pimozide (Orap)
Thiothixene (Navene)

Both phenothiazines and nonphenothiazines block D₂ dopamine receptors in the brain, increasing synaptic levels of dopamine and leading to a decrease in symptoms of psychosis (including delusions and hallucinations).

May also be used for:

- Schizophrenia and other psychotic disorders
- Tourette syndrome.

- Monitor for anticholinergic symptoms, such as dry mouth, orthostatic hypotension, constipation, urinary retention, sedation, and sexual dysfunction.
- Teach patient strategies to address anticholinergic effects (e.g., rising slowly, increasing fluid intake, and increasing fiber intake).
- Monitor for extrapyramidal symptoms (EPS), such as acute dystonia, akathisia, parkinsonism, and tardive dyskinesia (TD).
- Monitor for signs of hyperprolactemia (menstrual irregularities, decreased libido, gynecomastia, and osteoporosis). Adjunctive therapies, counseling, or changing to a different agent may improve some aspects of sexual dysfunction.
- Monitor for autonomic instability associated with neuroleptic malignant syndrome.
- Teach patients importance of adhering to medication regimen and not to abruptly discontinue medication.
- Teach patients importance of wearing sunscreen.

(continued on next page)

Medications (continued)

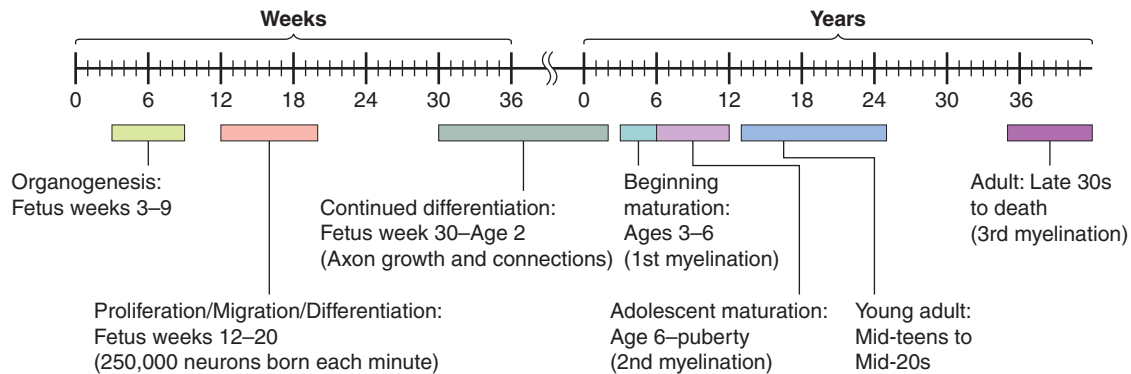

CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION	NURSING IMPLICATIONS
Atypical Antipsychotics Drug examples: Risperidone (Risperdal) Olanzapine (Zyprexa) Clozapine (Clozaril) Asenapine (Saphris) Paliperidone (Invega) Quetiapine (Seroquel) Ziprasidone (Geodon)	Block D ₂ and serotonin receptors; treat both positive and negative symptoms of schizophrenia and psychotic disorders, exert mood-stabilizing effect. May also be used for: <ul style="list-style-type: none"> Schizophrenia and other psychotic disorders Bipolar disorder. 	<ul style="list-style-type: none"> Monitor for adverse effects, such as alterations in glucose metabolism, hyperlipidemia, cardiovascular and cerebrovascular alterations and blood abnormalities. Teach importance of healthy diet and exercise. Monitor for EPS and neuroleptic malignant syndrome.
Third-generation Antipsychotics Drug examples: Aripiprazole (Abilify) Brexpiprazole (Rexulti)	Partial agonists of D ₂ receptors, also block serotonin receptors.	<ul style="list-style-type: none"> Although generally well tolerated, patients should still be monitored for EPS, neuroleptic malignant syndrome (NMS), and medical effects associated with atypical antipsychotics. Akathisia and restlessness may be more pronounced with this medication. Teaching should address healthy diet and exercise, importance of adherence, and recognizing and reporting adverse effects.
Anxiolytics Nonbenzodiazepines Drug examples: Buspirone (BuSpar)	Probably inhibits serotonin reuptake and activates dopamine receptors in the brain, leading to a decrease in symptoms of anxiety.	<ul style="list-style-type: none"> Monitor for dependency, drowsiness, hypotension, tolerance, dizziness, and GI upset. These agents may increase confusion. Abrupt discontinuation may lead to rebound anxiety.
Selective Serotonin Reuptake Inhibitors (SSRIs) Drug examples: Sertraline (Zoloft), Fluoxetine (Prozac)	Inhibits reuptake of serotonin in the central nervous system, leading to a decrease in symptoms of depression and anxiety. May also be used for: <ul style="list-style-type: none"> Depression Anxiety Obsessive-compulsive disorder Posttraumatic stress disorder Social anxiety disorder. 	<ul style="list-style-type: none"> Monitor for suicide risk. Monitor for serotonin syndrome. Abrupt discontinuation may cause serotonin withdrawal. Provide patient education regarding dizziness, insomnia, somnolence, GI upset, nausea or diarrhea, and avoiding over-the-counter (OTC) preparations that may increase risk of serotonin syndrome.
CNS Stimulants Drug examples: Methylphenidate (Ritalin) Amphetamine sulfate (Adderall)	It is believed that methylphenidate activates the brainstem arousal system and cortex. Also acts as a dopamine and norepinephrine reuptake inhibitor, resulting in a prolongation of dopamine receptor effects.	<ul style="list-style-type: none"> Monitor for insomnia, decreased appetite, increased heart rate, and hypertension or cardiac dysrhythmias. Monitor patients with diabetes for decreased glycemic control. Educate patients about the high potential for abuse.

Source: Based on Adams, M. P., Holland, L.N., & Urban, C. (2017). *Pharmacology for nurses: A pathophysiologic approach*. (5th ed.). Hoboken, NJ: Pearson Education.

with individuals who are at risk for or experiencing alterations in cognitive function. A major consideration is the impact of normal growth and development. **Figure 23-5** » provides a timeline for normal brain development.

The best-known theory of cognitive development comes from the work of Swiss psychologist Jean Piaget (1896–1980). Piaget claimed that cognitive development is an orderly, sequential process in which children form adaptive cognitive structures—called *schemes*—in response to environmental

stimuli. According to Piaget, as children learn more about the world by physically interacting with it, they actively revise their schemes to better fit with the reality they observe. Over time, as their brains mature and they are exposed to additional stimuli, children become capable of building more complex schemes—and as they do so, they move from one stage of development to the next. In fact, Piaget proposed that all children pass through four universal stages of cognitive development, as described in **Table 23-8** »: sensorimotor,

Source: Potter, M. L., & Moller, M. D. (2016). *Psychiatric–mental health nursing: From suffering to hope*. Reprinted and electronically reproduced by permission of Pearson Education, Inc., New York, NY.

Figure 23–5 » Timeline of brain development.

preoperational, concrete operational, and formal operational (Piaget, 1966, 1972; Shaffer & Kipp, 2014).

Cognition from Conception to Adolescence

Simple neuronal connections that shape cognition first occur shortly after the period of conception. These simple connections are then followed by increasingly complex circuits. Any insults during the period of embryonic development, including exposure to toxic substances, maternal stress, nutritional deficits, and illness, can have a devastating impact on cognition (Harvard University Center on the Developing Child, 2016).

Rapid proliferation of neuronal connections occurs during the first few years of life and corresponds with the process through which children assimilate new information, revise cognitive constructs through a process called accommodation, and form new thinking structures or schemes to facilitate adaptation. One aspect of normal development is called *pruning*, a process by which unused connections are remodeled or eliminated in order to strengthen cognitive efficiency. Remodeling occurs during sensitive periods of time in brain development. During infancy and early childhood, for example, brains are primed for stimulation of visual pathways and language. If these pathways are not activated, the neuronal pathways required for them will be eliminated, impacting overall cognitive capabilities.

Both stress and illness predispose children to alterations in cognitive development and mental function. Nurses recognize

that young children have some limitations in the functional reserves required to compensate for certain conditions, such as dehydration, fever, infection, and the effects of anesthesia. As a result, young children may be more likely to manifest cognitive changes such as confusion or hallucinations when any of these are present.

Cognition from Adolescence to Adulthood

Significant changes in brain structure continue to occur in adolescents, with another period of rapid generation of neuronal pathways and remodeling. Changes in activity in the limbic system are believed to account for increased sensation-seeking and need for arousal; at the same time, the underdeveloped prefrontal cortex is unable to mediate impulse control (Oettingen & Gollwitzer, 2015). Deficits in decision making can place adolescents at increased risk for head injuries. These deficits may also make adolescents more prone to use alcohol and other substances. Recent evidence, however, suggests that changes in dopamine systems shift adolescent orientation toward reward-seeking behavior, and that self-regulation may be enhanced through the provision of positive reinforcement (Steinberg, 2014).

Adolescents may experience a variety of alterations in cognition, including intellectual and learning disabilities. Alterations in neurocognitive function indicate early psychotic symptoms. Adolescents experiencing cognitive dysfunction

TABLE 23–8 Piaget’s Stages of Cognitive Development

Stage and Age Range	Description	Developments
Sensorimotor Birth to 2 years	Infants use motor and sensory capabilities to explore the physical environment. Learning is largely trial and error.	Children develop a sense of “self” and “other” and come to understand object permanence. Behavioral schemes begin to produce images or mental schemes.
Preoperational 2–7 years	Young children use symbols (images and language) to explore their environment. Thought is egocentric, and children cannot adopt the perspectives of others.	Children participate in imaginative play and begin to recognize that others don’t see the world the same way they do.
Concrete operational 7–11 years	Older children acquire cognitive operations, or mental activities that are an important part of rational thought. Logical reasoning is possible but limited to concrete (observable) problems.	Children are no longer fooled by appearances. They understand the basic properties of and relations among objects and events, and they are proficient at inferring motives.
Formal operational 11 years and beyond	Adolescents’ cognitive operations are organized in a way that permits them to think about thinking. Thought is now systematic and abstract.	Logical thinking is no longer limited to the concrete or observable. Children engage in systematic, deductive reasoning and ponder hypothetical issues.

are at increased risk for a number of problems, including depression, suicide, substance abuse, and antisocial behavior.

For adolescents, the social implications of cognitive disorders can have a devastating impact on self-esteem and peer relationships. Adherence to treatment may be negatively impacted by concerns about being different. Parents of adolescents with cognitive disorders may need assistance navigating issues that normally accompany this period of development, including the achievement of increased independence, hormonal shifts, and sexual development, as well as a greater need for interaction with peers. Teaching focuses on providing developmentally and cognitively appropriate information on issues such as safety, sexuality, adaptive coping, and the management of the cognitive condition.

Cognition from Adulthood through Middle Age

Recent research suggests that brain maturation and, in particular, areas responsible for executive function are not fully mature until the mid- to late 20s (Friedman et al., 2016). Evidence also suggests that full maturation for men may not occur until the early 30s (Lim et al., 2015). Middle-aged adults demonstrate an enhanced ability to read other people's emotional state (Hartshorne & Germine, 2015). Vocabulary and other elements of accumulated facts and knowledge have been found to peak even later in life. Nurses can apply this information to dispel myths that surround the belief that cognitive decline is an inevitable aspect of aging, while focusing on cognitive strengths of patients across the lifespan.

Young adults with cognitive problems, such as intellectual disabilities or schizophrenia, often struggle to achieve the psychosocial tasks associated with this period of time. Nursing care should consider the patient's need to establish intimate relationships and pursue vocational goals. Teaching about family planning and sexually responsible behaviors should be incorporated into care.

Research is mixed related to the impact of pregnancy and childbirth on maternal cognition, with some studies indicating reduced function in the areas of processing speed, verbal recall, and attention (Henry & Sherwin, 2012; Logan et al., 2014). The hormonal shifts probably account for these changes and are largely adaptive, enabling the mother to be more in tune with the needs of the newborn. Fatigue and sleep deprivation may also contribute to cognitive alterations and may have a role in triggering other mental health issues.

Cognition in Older Adults

As the brain ages, typical changes account for subtle differences in cognitive processing. These may be caused by

modest shrinkage of brain tissue and decreased blood flow to the areas of the brain responsible for memory, executive function, and cognitive flexibility. Older adults typically have more difficulty with cognitive functions, such as word retrieval and episodic memory; however, the impact on overall cognitive function should be minimal. The ability to perform visual-spatial tasks like drawing may diminish slightly. Nurses should recognize that moderate to severe cognitive decline is not a normal function of aging and that changes may signify an underlying medical or mental health issue (Koen & Yonelinas, 2014).

Psychologic problems such as anxiety and depression in older adults may also result in clinical manifestations that may be mistaken for dementia. Screening tools for depression and other mental health issues are used as part of a comprehensive assessment of cognition in older adults (see Table 23–7).

Case Study » Part 3

After his wandering episode, Mr. Wallace's condition rapidly declines. His communication skills are almost completely gone; he speaks infrequently and uses only two- or three-word sentences. He no longer recognizes Ms. Wallace, cannot perform ADLs, and is indifferent to food. His tendency toward wandering and aggression has disappeared. In fact, he rarely leaves his room. For his safety and to allow for provision of the care he needs, Mr. Wallace is admitted to an extended care facility that specializes in treating patients with Alzheimer disease.

You are the nurse assigned to care for Mr. Wallace. As part of his daily assessment, you obtain his vital signs, which include temperature 99.8°F oral, pulse 92 bpm, respirations 32/min, and blood pressure 108/74 mmHg. Auscultation of Mr. Wallace's lungs reveals faint bibasilar crackles. On reviewing his chart, you note that he has experienced a 5% weight loss since the previous month. You notify the attending physician about Mr. Wallace's vital signs, breath sounds, and weight loss. The physician orders a chest x-ray and CBC.

Clinical Reasoning Questions Level I

1. What is the significance of Mr. Wallace's vital signs and breath sounds?
2. What effect might Mr. Wallace's weight loss have on his cognitive condition?
3. What important pieces of information might be gleaned from tracking Mr. Wallace's food intake and weight?

Clinical Reasoning Questions Level II

4. What is the priority nursing diagnosis for Mr. Wallace at this time?
5. What independent interventions can you perform to optimize Mr. Wallace's respiratory status? What positive effects might these have on other aspects of his health?
6. *Refer to the exemplar on Alzheimer disease in this module:* Would Mr. Wallace's condition improve with the addition of a cholinesterase inhibitor to his treatment regimen? Why or why not?

REVIEW The Concept of Cognition

RELATE Link the Concepts

Linking the concept of cognition with the concept of perfusion:

1. Describe how alterations in perfusion can affect a patient's risk for specific types of dementia.
2. What measures might you implement when caring for a patient with impaired perfusion to limit the risk of dementia?

Linking the concept of cognition with the concept of development:

3. What considerations should a nurse apply when designing developmentally appropriate activities for an 8-year-old with Down syndrome?
4. What treatment measures used for patients with ADHD might also be useful for patients with fragile X syndrome? Why?

Linking the concept of cognition with the concept of family:

5. How might a family's normal processes and interactions be affected when one member is diagnosed with a cognitive disorder?
6. What actions can nurses take to support family members of patients with cognitive alterations?

REFLECT Apply Your Knowledge

Hannah Lister is a 6-year-old first-grade student who frequently presents to the school nurse's office with somatic complaints. Hannah's teacher is increasingly concerned that she is missing valuable class time. The nurse learns that Hannah has a history of learning and behavior problems and was recently diagnosed with nonverbal learning disability. The nurse and classroom teacher meet to discuss the issue with Hannah's parents. Hannah's mother is tearful as she talks about how anxious Hannah is. She states Hannah complains about having to go to school and complains that other students and teachers are "mean" to her. Hannah's mother says that her oldest child never had any of these problems, and she is at a loss as to how to help Hannah. Hannah's teacher believes that since Hannah is so articulate and has good reading skills, she is capable of doing much better in school. The teacher explains that she has worked with many children with learning disabilities who are not as bright as Hannah. She believes that Hannah should be held accountable for some of her rude and socially inappropriate behaviors and should receive consequences for missing class.

1. What might explain the teacher's misperceptions of Hannah's skills/capabilities?
2. What may make Hannah's learning problems different from those of students with language-based learning disabilities?
3. As the nurse, what kind of teaching could you provide to help teachers and parents understand some of the emotional and behavioral needs of children like Hannah?
4. When providing health teaching to Hannah, what kind of approach is most likely to be effective?
5. What types of independent and collaborative interventions may be appropriate to address Hannah's social and emotional needs?

Exemplar 23.A Alzheimer Disease

Exemplar Learning Objectives**23.A Analyze Alzheimer disease as it relates to cognition.**

- Describe the pathophysiology of Alzheimer disease.
- Describe the etiology of Alzheimer disease.
- Compare the risk factors and prevention of Alzheimer disease.
- Identify the clinical manifestations of Alzheimer disease.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with Alzheimer disease.
- Differentiate care of patients with Alzheimer disease across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with Alzheimer disease.

Overview

Alzheimer disease (AD) accounts for approximately 60–80% of all dementia cases in individuals age 65 and older. More than 5 million Americans suffer from AD, and this number is predicted to reach 7 million by 2025 and 14 million by 2050.

Exemplar Key Terms

Alzheimer disease (AD), 1729
 Amyloid plaques, 1731
 Biomarkers, 1732
 Caregiver burden, 1730
 Early-onset familial AD (eFAD), 1730
 Neurofibrillary tangles, 1731
 Relocation syndrome (transfer trauma), 1737
 Sporadic AD, 1730
 Sundowning, 1732

AD is currently the sixth leading cause of death in the United States (Alzheimer's Association, 2015).

Although AD usually manifests after age 65, some individuals experience symptoms as early as their 30s. Most individuals with AD survive between 4 and 8 years after diagnosis; those who are diagnosed at younger ages may

live up to two decades. Patients typically spend more time in the moderate stage of AD than in any other stage. Eventually, they die from complications of the disease.

One important aspect of AD disease is **caregiver burden**. Caregiver burden refers to the psychologic, physical, and financial cost of caring for an individual with Alzheimer disease (Bevans & Sternberg, 2012). AD is associated with the higher levels of stress and caregiver burden than most other chronic illnesses. Nurses must consider both patient and caregiver needs when working with individuals with AD.

Pathophysiology and Etiology

Pathophysiology

There are two types of AD: familial and sporadic. **Early-onset familial AD (eFAD)** is an inherited disease. It is also called *early-onset AD* because it usually manifests before age 65. **Sporadic AD** shows no clear pattern of inheritance, although genetic factors may increase risk. Because it typically develops after age 65, sporadic AD is sometimes referred to as *late-onset AD*, and it is more common than its early-onset counterpart, accounting for 95% or more of all cases (Ridge, Ebbert, & Kauwe, 2013). Although the triggers may be different, eFAD and sporadic AD both involve the same set of pathophysiologic changes.

Individuals with AD show a pattern of degenerative changes related to neuronal death throughout the brain. The cells die in a characteristic order, beginning with neurons in the limbic system, including the hippocampus. Damage to this region results in emotional problems and loss of recent memory. From there, the destruction spreads up and out toward the cerebral surface (see **Figure 23-6** >>). Eventually, neuronal death in the cerebral lobes produces a range of symptoms, including loss of remote memory, as outlined in **Table 23-9** >>.

As AD progresses and more neurons die, two characteristic abnormalities develop in the brains of affected individuals. The first is thick protein clots called *neurofibrillary tangles*, and the second is insoluble deposits known as *amyloid plaques*. Researchers continue to investigate whether these abnormalities are a cause or a result of AD, as described in the section on etiology.

Etiology

Researchers are not sure why most cases of AD arise, although a variety of genetic and environmental factors appear to be involved. Moreover, the exact biochemical origins of AD remain unknown, even in patients who clearly have an inherited form of the disease. Researchers have therefore proposed several theories that seek to explain the disease process, including the cholinergic, amyloid, and tau hypotheses.

Cholinergic Hypothesis

The cholinergic hypothesis emerged in the early 1980s after nearly 20 years of investigation into the role of neurotransmitters. Researchers noted that lowered levels of acetylcholine (a cholinergic neurotransmitter) appeared to produce memory deficits. Autopsies also revealed that brains of indi-

Source: Scott Camazine/Alamy Stock Photo.

Figure 23-6 >> CT scan of 84-year-old man with Alzheimer disease. Note atrophy of the brain.

viduals with AD had markers characteristic of decreased acetylcholine function. These findings suggested that AD was caused by below-normal production of acetylcholine in the brain and led to the development of acetylcholinesterase inhibitors. Because these agents have demonstrated only a modest effect on the disease, other theories have gained more attention (Rafii & Aisen, 2015).

Amyloid Hypothesis

Today, the amyloid and tau hypotheses are considered more likely explanations of the biochemistry of AD. The amyloid

TABLE 23-9 Cerebral Effects of AD

Region	Symptoms of Damage
Limbic system (including hippocampus)	Loss of memory (recent before remote); fluctuating emotions; depression; difficulty learning new information
Frontal lobe	Problems with intentional movement; difficulty planning; emotional lability; loss of walking, talking, and swallowing ability
Occipital lobe	Loss of reading comprehension; hallucinations
Parietal lobe	Difficulty recognizing places, people, and objects; hallucinations; seizures; unsteady movement; expressive aphasia; agnosia
Temporal lobe	Impaired memory; difficulty learning new things; receptive aphasia

hypothesis states that AD arises when the brain cannot properly process a substance called *amyloid precursor protein (APP)*. Incorrect processing leads to the presence of short, sticky fragments of APP known as *beta-amyloid*. Eventually, the fragments clump together, forming insoluble deposits called **amyloid plaques**. These plaques damage the surrounding neurons, killing them and provoking an inflammatory response that may result in further brain damage (Khan, 2013).

Tau Hypothesis

The tau hypothesis focuses on a protein known as *tau*. Normally, tau holds together the microtubules responsible for intracellular transport within the axons of neurons. With AD, however, individuals have abnormal tau proteins that join and twist, forming **neurofibrillary tangles** instead of the microtubule network necessary for cellular survival.

Risk Factors

Nonmodifiable risk factors for Alzheimer disease include age, sex, family history, and genetic factors (Alzheimer's Association, 2016a, 2016b). Alzheimer disease disproportionately affects Hispanic and African American individuals, although it is not clear whether this relates to underlying biophysical characteristics or socioeconomic or cultural factors that increase modifiable risk factors. Individuals with a family history of AD are more likely to develop the disease, even in the absence of known genetic factors that predict or increase the risk of the disease. AD is almost 3 times more common in women than in men.

Although developing AD is not a normal or expected consequence of aging, the most prominent risk factor for Alzheimer disease is advancing age. Once an individual reaches the age of 65, the risk of developing the disease doubles every 5 years. After the age of 85, individuals have a 50% chance of developing the disease.

A summary of evidence recently conducted at the request of the Alzheimer's Association identifies a variety of modifiable risk factors associated with the disease that have been substantiated through valid and reliable research (Baumgart et al., 2015). For example, research has identified cardiovascular risk factors that include diabetes, mid-life obesity, mid-life hypertension, and hyperlipidemia. Evidence suggests that diabetes increases AD risk through both vascular and metabolic pathways (De Felice & Ferreira, 2014; Mushtaq, Khan, & Kamal, 2014, 2015). Mid-life obesity is correlated with vascular, metabolic, and inflammatory changes that appear to increase the risk of AD (Loef & Walach, 2013).

Lifestyle risk factors have been demonstrated to increase the risk of AD. There is a strong body of evidence linking cigarette smoking to cognitive decline and dementia. In addition, there is evidence to support the fact that individuals who lead a sedentary lifestyle are at increased risk for AD (Baumgart et al., 2015; Durazzo et al., 2014; Espeland et al., 2015).

Other risk factors appear to include lower level of formal education, a history of traumatic brain injury, depression, and disordered sleep. It is hypothesized that formal education provides a type of cognitive training that strengthens

neuronal cognitions and increases cognitive reserves (Sattler et al., 2012). Several strong and reliable studies have also linked the incidence of traumatic brain injury to AD, with individuals exposed to repeated trauma being at the greatest risk. It is believed that axonal injury, hypoxia, and inflammatory changes trigger neuronal degeneration associated with AD (Johnson, Stewart, & Smith, 2013; LoBue et al., 2015; Sivanandam & Thakur, 2012).

Depression is considered to be both a symptom of and risk factor for Alzheimer disease with overlapping neurobiological mechanisms responsible for both diseases (Wuwongse et al., 2013). There is research to suggest that the early management of depression with antidepressants may prevent cognitive decline associated with dementia (Chi et al., 2014). However, several new studies suggest that the use of antidepressants, especially SSRIs, may actually increase cortical changes associated with dementia and AD (Lebedev et al., 2014; Lee et al., 2016; Wang et al., 2016).

Another area of investigation has been the impact of sleep disorders on dementia and AD. Cohort and observational studies have linked sleep disorders to AD, with some research suggesting that the early use of continuous positive airway pressure (CPAP) in individuals with disorders such as apnea may reduce the incidence of decline (Osorio et al., 2015). Recent research also suggests that some of the agents used to treat insomnia, such as benzodiazepines and anticholinergic antihistamines, may actually accelerate cognitive deterioration (Defrancesco et al., 2015; Wurtman, 2015; Yaffe & Boustani, 2014).

Prevention

Evidence-based teaching for the general public with regard to increasing protective factors for AD includes reducing the incidence of cardiovascular disorders and other health problems by adopting a healthy lifestyle. For example, quitting smoking and using safety measures (e.g., safety belts) can reduce risk for developing Alzheimer disease, and even modest levels of exercise have been demonstrated to improve cognitive function (Baumgart et al., 2015; Intlekofer & Cotman, 2013). Other strategies include:

- **Adopt a heart-healthy diet such as the Mediterranean diet.** Although many dietary studies are inconclusive, there is some evidence to suggest that antioxidant- and polyphenol-rich foods such as tea, cocoa, grapes, and colorful fruits and vegetables may interrupt formation of amyloid plaques and prevent AD (Feng et al., 2015; Pasinetti et al., 2015).
- **Consume alcohol moderately.** Moderate alcohol consumption may be protective against AD. However, evidence is insufficient to suggest that individuals who do not already drink should start drinking (Baumgart et al., 2015).
- **Stay socially active and connected with others.** Studies demonstrate that social engagement may improve cognitive function and have some protective effects against AD (Baumgart et al., 2015; Beckett, Arden, & Rotondi, 2015; de Bruijn et al., 2015).
- **Engage in activities that exercise cognitive function.** Evidence demonstrates that cognitive activities such as

reading, completing puzzles, and learning new information or tasks build cognitive resilience and protect against cognitive decline (Beckett et al., 2015).

- **Utilize stress management techniques.** And seek appropriate treatment for depression and alterations in sleep.

Clinical Manifestations

The initial symptoms of AD emerge gradually and may be almost unnoticeable. The first manifestation is usually subtle memory loss that becomes increasingly apparent as time passes. Other early signs include difficulty finding words and performing familiar tasks; impaired judgment and abstract thinking; disorientation to time and place; and frequently misplacing things. These alterations go beyond the changes sometimes seen with normal aging, as described in the introduction to this module. Diurnal changes in cognitive function are typical, with patterns of diminished capacity in the evening (also known as **sundowning**). Changes in mood or personality are also common. Early in the course of AD, many individuals exhibit decreased initiative, odd behavior, and signs of depression. As the disease progresses, the continued deterioration in patients' cognition is accompanied by physical decline. At some point, affected individuals lose the ability to perform everyday tasks and must rely entirely on their caregivers.

AD is described in terms of three general stages: stage 1 (early), stage 2 (moderate), and stage 3 (severe). The Clinical Manifestations and Therapies feature outlines the clinical manifestations associated with each stage along with interventions. Individuals' rate of progression is affected by a variety of factors, including their overall health and the type of care they receive following diagnosis.

Collaboration

The care of patients with AD depends on collaboration among nurses, physicians, physical, occupational and speech therapists, psychologists, family members, volunteers, personal care assistants, social workers, and case managers. In the early to moderate stages of the disease, care is generally community based and involves outpatient visits to primary providers and a variety of services, including counseling, support groups, in-home care, day-care programs, and assisted living. When individuals are no longer able to be managed in the community setting, they may need to transition to a skilled nursing facility. In this section, diagnostic tests and therapies employed by members of the interprofessional team across settings are summarized.

Diagnostic Tests

There is no definitive way to diagnose AD other than performing a brain autopsy. Instead, practitioners rely on differential diagnosis, ruling out potential causes of a patient's symptoms until AD remains the most likely explanation. When individuals present with signs and symptoms of AD, the nurse can anticipate standard laboratory tests being ordered, including thyroid-stimulating hormone (TSH),

complete blood count (CBC), serum B₁₂, folate, complete metabolic panel, and testing for sexually transmitted infections. Screening tools and tests that aid in the diagnosis of AD are discussed in detail in the sections on assessment of and diagnosis of cognitive disorders.

Genetic testing may be conducted under certain clinical guidelines. Individuals with a parent with early-onset or eFAD have a 50/50 chance of inheriting the associated mutation. If genetic testing of offspring reveals the presence of the mutation, it confers an almost 100% probability of developing the disease. Individuals with a certain type of allele (ApoE4) are at a 12- to 15-fold increased *risk* of developing the disease and represent about 20% of all individuals impacted by the disease (Goldman et al., 2011; Loy et al., 2014). Other genetic factors are believed to be involved, and it is important to remember that lack of genetic findings does not mean that any individual will not develop the disease or that AD can be ruled out.

One emerging approach to diagnosis of AD that deserves mention is the analysis of biomarkers for the disease. **Biomarkers** are physiologic, chemical, or anatomic measures associated with certain conditions. Currently several biomarkers have been demonstrated to be associated with AD. These include morphologic or structural abnormalities detected through brain imaging techniques. Positron emission tomographic (PET) scan findings demonstrate hypometabolism and the presence of amyloid deposits in certain areas of the brain. In addition, an analysis of CSF may reveal the presence of certain proteins associated with neurodegeneration (Blennow & Zetterberg, 2013; Jack & Holtzman, 2013). Biomarkers for AD may be present even before the manifestations of the disease are present; therefore their identification in certain susceptible individuals may facilitate early intervention and planning.

Pharmacologic Therapy

There is currently no cure for AD. Two classes of medications are used to slow the progression of the disease. In addition, adjunctive agents may be prescribed to treat associated symptoms of depression, anxiety, or psychosis.

NMDA Receptor Antagonists and Combination Agents

Acetylcholinesterase (AChE) inhibitors have been standard treatment for over a decade. They work by reducing acetylcholine breakdown. Because individuals with Alzheimer disease are gradually losing neurons that communicate by using this substance, the presence of extra acetylcholine increases communication among the remaining neurons. This appears to temporarily stabilize symptoms related to language, memory, and reasoning for an average of 6 to 12 months.

Commonly prescribed acetylcholinesterase inhibitors include donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). Rivastigmine and galantamine are approved for early to moderate stages of AD, while donepezil is approved for all stages. Although these drugs all act similarly, not all individuals respond to them in the same way. In fact, about half of individuals who take these drugs

Clinical Manifestations and Therapies

Alzheimer Disease

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Stage I Mild cognitive impairment	<ul style="list-style-type: none"> Reduced concentration and memory lapses noticeable by others Difficulty learning new information Problems functioning in work or social settings Frequently losing or misplacing important objects Difficulties with planning and organization Forgetting familiar words or the locations of various objects 	<ul style="list-style-type: none"> Patient/caregiver education and training Environmental modifications to promote safety Encourage planning for advanced stages of the disease while patients are still able to participate in decision making Use of cuing devices such as to-do lists, calendars, written schedules, and verbal reminders Cognitive Activity Kits Deliberate establishment of and adherence to daily routines Referral to community resources, support groups, and/or counseling services Nonpharmacologic therapies such as healing touch, reality orientation, and reminiscence therapy Counseling regarding possible retirement or withdrawal from the more challenging aspects of one's job
Stage II Moderate AD	<ul style="list-style-type: none"> Inability to carry out ADLs, such as preparing meals for oneself and choosing appropriate clothing Loss of ability to live independently Difficulty recalling one's address or phone number Increased problems finding words and communicating clearly Inability to recall information from recent memory Increasing difficulty remembering details from remote memory Disorientation to time and place Increased tendency to become lost Changes in ability to control bladder/ bowels Changes in sleep patterns Withdrawal from social situations and challenging mental activity Increased moodiness, flat affect, or signs of depression and/or anxiety, paranoia 	<ul style="list-style-type: none"> Behavioral interventions such as distraction, provision of meaningful activities Continued use of cuing devices and established routines Assistance with ADLs Administration of anti-AD acetylcholinesterase inhibitors, including rivastigmine (Exelon), galantamine (Razadyne), and donepezil (Aricept); NDMA inhibitors may be added Administration of SSRIs and/or anxiolytics to address mood-related symptoms Occupational, physical, and speech therapy Nonpharmacologic therapies such as healing touch, validation, and reminiscence therapy Consultation with a dietitian or nutritionist Respite care for family members and other caregivers May require around-the-clock care or transition to a skilled nursing facility
Stage III Severe AD	<ul style="list-style-type: none"> Gradual inability to perform any ADLs, including bathing and toileting Eventual urinary and fecal incontinence Inability to identify family and caregivers Extreme confusion and lack of awareness of one's surroundings Gradual loss of remote memory and ability to speak Inability to perform simple mental calculations Dramatic personality changes, including extreme suspiciousness and fearfulness Sundowning, delusions, compulsions, agitation, and violent outbursts Gradual loss of ability to walk, sit unaided, and hold one's head up Development of abnormal reflexes Physical rigidity Loss of swallowing ability 	<ul style="list-style-type: none"> Assistance with all ADLs Continuation of earlier behavioral and pharmacologic therapies Addition of atypical antipsychotics, as appropriate Round-the-clock care and/or admittance to a skilled nursing facility Frequent repositioning Liquid nutrition or feeding tubes as appropriate Respite care for family members and other caregivers End-of-life care

Source: Alzheimer's Association. (2016c). *Stages of Alzheimer's*. Retrieved from http://www.alz.org/alzheimers_disease_stages_of_alzheimers.asp; Budson, A. E., & Solomon, P. R. (2012). New diagnostic criteria for Alzheimer's disease and mild cognitive impairment for the practical neurologist. *Practical Neurology*, 12(2), 88–96; National Institutes of Health. (2015). *The changing brain in AD*. Retrieved from <https://www.nia.nih.gov/alzheimers/publication/part-2-what-happensbrain-ad/changing-brain-ad>

see no delay in symptom progression. AChE inhibitors generally produce mild side effects such as decreased appetite, nausea, diarrhea, headaches, and dizziness. Adverse effects include GI bleeding and bradycardia. Teaching should include avoiding other medications that may increase the risk of GI bleeding and monitoring pulse rate. The patient's nutritional status and fluid balance should also be monitored. The dosage is slowly increased to minimize side effects. Patients and family members should be cautioned not to abruptly stop the medication, as this may cause a sudden worsening of symptoms. (Adams, Holland, & Urban, 2017).

NMDA Receptor Antagonists

NMDA receptor antagonists are believed to block the effects of glutamate, a neurotransmitter that is present with neuronal damage and appears to be involved in cognitive decline. NMDA receptor antagonists do not reverse existing damage, but they do slow the rate at which new damage occurs. Unlike acetylcholinesterase inhibitors, NMDA receptor antagonists generally are not prescribed until an individual is in the moderate to severe stages of AD.

Currently, memantine (Namenda) is the only NMDA receptor antagonist approved by the U.S. Food and Drug Administration (FDA). In 2014, a combination agent of memantine and donepezil (Namzaric) was approved for use in individuals with moderate to severe AD. Side effects of NMDA inhibitors are less common and usually milder than those associated with donepezil, rivastigmine, and galantamine. They include dizziness, constipation, confusion, headache, fatigue, and increased blood pressure. Patients and family members should be cautioned about performing activities requiring mental alertness or coordination until tolerance is established. The medication should be taken with food if stomach upset occurs (Adams et al., 2017; Alzheimer's Association, 2016d).

Other Medications Used to Treat AD Symptoms

Drug classes used to manage the symptoms of AD include antipsychotics (to treat delusions or hallucinations), anxiolytics (to treat anxiety), and SSRI antidepressants (to treat depression). Because there is some evidence that these agents may actually increase the risk of cognitive decline, patients and their families should be encouraged to discuss the risks versus benefits with their providers. For more details on these drugs, please refer to the Medications feature as well as the modules on Stress and Coping and Mood and Affect.

Nonpharmacologic Therapy

Nonpharmacologic interventions that have been demonstrated to be effective in treating AD include exercise, reality orientation therapy, validation therapy, and reminiscence therapy.

Reality Orientation

Reality orientation is a structured approach to orienting individuals to person, time, place, and situations at regular

intervals and as needed through verbal communication and the use of visual cues (pictures, clocks, calendars, orientation boards). Reality orientation therapy is a collaborative intervention that is carried out by all members of the healthcare team. Reality orientation interventions have been demonstrated to improve cognitive function when used in combination with AChE inhibitors (Camargo, Justus, & Retzlaff, 2015). However, reorientation to certain situations or information may be upsetting in some cases and should be used judiciously.

Validation Therapy

Validation therapy involves searching for emotion or intended meaning in verbal expressions and behaviors. The basic premise is that seemingly purposeless behaviors and incoherent speech have significance to the patient and can be related to current needs (Feil, 2014). For example, if an individual is wandering and crying out for her mother, instead of reminding the patient that the mother is dead or unavailable, the nurse may say something like "You are looking for Mother. Is there something you need from her?" The goal is to elicit a response that identifies an unmet need, such as, "Yes, I need her to give me my dinner." The nurse can then address the wandering and associated anxiety by offering the patient something to eat or reassuring her that dinner will be available soon. Unlike reality orientation, validation therapy does not unnecessarily challenge the patient's perception of reality.

Reminiscence Therapy

Reminiscence therapy uses the process of purposely reflecting on past events. The nurse or other healthcare provider may encourage the patient to talk about events that occurred in the past, often by using scrapbooks, photo albums, music, or other items to facilitate the process. In addition to helping patients to retain long-term memory, reminiscence therapy may be comforting, provides a source of self-esteem, identity, and purpose, and can help to prevent isolation and withdrawal (Potter & Moller, 2016).

Complementary Health Approaches

The National Center for Complementary and Integrative Health (NCCIH) publishes findings derived from research about the safety and efficacy of alternative and complementary health practices for AD (see Focus on Integrative Health). Integrative therapies that have empirical evidence to support their efficacy in promoting comfort and relief from the symptoms of AD include art therapy, music therapy, healing touch, and reiki (Han et al., 2013; Livingston et al., 2014). Studies on the use of dietary supplements such as antioxidant vitamins, ginkgo biloba, resveratrol, omega-3 fatty acids, and medical food such as tramiprosate (Vivimind) and caprylic acid for the management of AD are inconclusive at best and associated with risks such as interaction with other drugs and toxicity. There is no convincing evidence to date that dietary supplements such as ginkgo, omega-3, vitamins B and E, ginseng, grape seed extract, or curcumin are beneficial in preventing or mitigating dementia or Alzheimer disease.

NURSING PROCESS

The application of the nursing process should be guided by clinical guidelines that are current and informed by the best available evidence. The primary goal of care is to provide a safe, supportive environment that meets patients' changing abilities and needs. The nurse must also take steps to support patients' family members as they cope with the emotional and physical demands of caring for a loved one with AD. Various tools and techniques for providing nursing care for patients and families with AD can be accessed from reliable sources such as The Hartford Institute for Geriatric Nursing, the Alzheimer's Association, and the Agency for Healthcare Research and Quality (AHRQ). Highlights of standards of current practice are provided in this section.

Assessment

Current clinical guidelines for the nursing assessment of individuals with AD include completion of a health history and assessment of physical status, cognitive function, functional status, behavioral presentation, and caregiver/environment (Fletcher, 2012). Serial assessments allow the nurse to monitor changes indicative of disease progression and the ability of the patient to manage safely in the current living environment.

Observation and Patient Interview

The nurse should start the assessment by observing the patient along with the caregivers. Patients with mild dementia may not present any signs or symptoms notable on appearance. At this stage, family members' reports of noticeable changes in memory or cognitive abilities in certain areas may be the first clue that there is a problem. As dementia progresses, patients exhibit signs of difficulty maintaining self-care, such as dressing inappropriately for the weather or an unkempt appearance; difficulty focusing on simple tasks or paying attention during the patient interview; and variable gait or changes in gait speed. The patient interview should address family history of AD and other dementias; medical history; current medications and use of any supplements; changes in cognition, communication, memory, and behavior; alterations in mood; sleep patterns; ability to perform ADLs; drug and alcohol use; and risk for or history of exposure to environmental toxins.

Cognitive Mental Status

For patients with AD, a thorough mental status examination is critical. Nurses can choose from a variety of assessment instruments, as described in the Assessment section. The MMSE is the test most commonly used to assess cognitive status.

Physical Examination

During the physical assessment, evaluate the patient's height, weight, vital signs, and overall physical condition. Throughout the exam, remain alert for possible signs of abuse, neglect, depression, malnutrition, elimination difficulties, and alterations in skin integrity, as AD increases the risk for all of these.

A number of other conditions can mimic the symptoms of dementia and AD. A useful mnemonic for remembering to assess for these conditions is **DEMENTIA**:

- D**rugs and alcohol
- E**yes and ears
- M**etabolic and endocrine disorders
- E**mootional disorders
- N**eurologic disorders
- T**rauma or tumors
- I**nfection
- A**rteriovascular disease

Functional Status

An assessment of functional status addresses any changes in ability to manage to day-to-day ADLs, such as eating or dressing, and instrumental activities of daily living (IADLs) such as cooking, managing housework, or taking care of finances. This can be addressed through direct questioning of patients or family members (e.g., "Over the past 7 days, have you noticed any changes in your family member's ability to complete getting dressed?"). Screening tools such as the Functional Activities Questionnaire (FAQ) may also be used (Cordell et al., 2013; Fletcher, 2012).

Behavioral Status

The behavioral assessment consists of direct observation of the patient and direct questioning of the patient and caregivers as well as the use of valid assessment tools. Assess for behavior changes associated with AD, including depression, anxiety, irritability, impulsivity, poor judgment, paranoia, delusions, and hallucinations. Inquire about events that precipitate any behavior changes so that potential triggers can be identified and eliminated. The Geriatric Depression Scale (GDS) may be used to detect changes in mood. The BEHAVE-AD is a 25-item assessment tool that nurses can use to elicit caregiver reports about a variety of behaviors. These are then scored to determine the magnitude of the disturbance in terms of patient and caregiver safety (Reisberg et al., 2014).

Caregiver/Living Environment

The final area of assessment addresses the needs of the caregiver and the adequacy of the living environment. Ask the caregiver(s) to share his perspective on the patient's ability to function in light of current support. It is also important to determine the impact that patient behaviors have on the caregiver and to gather data about the quality of the caregiving relationship. Two practical tools for assessing caregiver burden include the Zarit Burden Interview (ZBI) and the Caregiver Role Strain Index (CRI). Also assess current knowledge of effective caregiving interventions and the capacity to employ these interventions in the current living environment. Remember to assess for cultural values, beliefs, practices, and even barriers that may affect provision of care or the patient-family relationship (see Focus on Diversity and Culture: Addressing Cultural Factors That Increase Stigma and Caregiver Burden).

Diagnosis

Appropriate nursing diagnoses for patients with AD vary by stage of the disease and patient and family preferences and needs. Diagnoses should be prioritized to address physiologic

Focus on Diversity and Culture

Addressing Cultural Factors That Increase Stigma and Caregiver Burden

The stigma associated with having a family member with Alzheimer disease is influenced by a variety of cultural factors, and it has been demonstrated to increase caregiver burden by reinforcing negative emotional responses and limiting external sources of support (Parveen et al., 2015; Werner et al., 2012). Negative attitudes and beliefs about dementia and AD are common to many cultures. However, there are varying beliefs regarding the cause of the disease and appropriate management of care. Filial (family) values may reinforce the caregiver's sense that they have primary responsibility for caring for parents or other family members. Across various cultures, education and socioeconomic status are important mediators of the impact of stigma on caregivers. Nurses play a key role in assessing family/caregiver beliefs about AD. Family members may be asked open-ended questions such as "What do you or your family members believe caused this disease?" and "Who do you or your family members believe is responsible for caring for your parent/family member?" Once cultural barriers to care are identified, nurses can initiate teaching to address misperceptions and collaborate with other healthcare professionals to address barriers to care, such as lack of social support (Spector, 2017).

and safety needs first. The following list identifies some common nursing diagnoses:

- *Injury, Risk for*
- *Health Maintenance, Ineffective*
- *Self-care Deficit (specify)*
- *Imbalanced Nutrition: Less Than Body Requirements*
- *Memory: Impaired*
- *Communication: Verbal, Impaired*
- *Fear*
- *Caregiver Role Strain*
- *Swallowing, Impaired*
- *Physical Mobility, Impaired*
- *Wandering*
- *Compromised Human Dignity, Risk for*

(NANDA-I © 2014)

Planning

The planning portion of the nursing process involves identifying desired patient outcomes and formulating steps for achieving them. Appropriate goals and actions will vary depending on a patient's physical and mental status and current living situation, and they may include the following:

- Patient will remain free from injury.
- Patient will utilize lists, calendars, and other memory aids as needed.
- Patient will perform IADLs with caregiver assistance.
- Patient will exhibit reduced anxiety, agitation, and restlessness.
- Patient will take all medications as prescribed.

The nurse should also consider caregiver and family needs during the planning process. Some suggested outcomes are as follows:

- Caregiver will utilize respite care resources as necessary.
- Caregiver will learn effective strategies for coping with the stresses of supporting a loved one with AD.
- Caregiver will obtain the sleep and nutrition necessary to preserve personal health.

Implementation

Implementation of nursing interventions depends on patient and family needs and integrates an understanding of principles of health promotion in relation to the stages of the illness. The Progressively Lowered Stress Threshold (PLST) intervention model is supported by current clinical guidelines and is an approach that should guide nursing care during all stages of the illness (Fletcher, 2012). This model proposes that individuals with dementia and Alzheimer disease require a trajectory of environmental modifications in order to cope with progressive cognitive decline. An escalation in anxiety, depression, or behaviors such as wandering is likely to indicate inappropriate or inadequate environmental modifications.

With the advent of genetic testing and biomarker analysis, nurses increasingly provide care to patients who do not currently demonstrate signs of cognitive decline but who have a high likelihood of developing the disease. Changes in the diagnostic criteria for AD and other dementias now include recognition of mild forms of these disorders and provide opportunities for nurses and other healthcare providers to initiate early treatment to slow the progression of AD as well as increase opportunities for patient participation in advance planning.

Promote Safety and Physiologic Integrity

The safety and physiologic integrity of patients and family members, especially those providing care, is priority, even when significant changes in functional capacity have not yet occurred. The nurse should ensure that patients and families understand the role of health behaviors such as exercise and diet in slowing the progression of the disease. Emphasize the importance of adequate sleep, rest, nutrition, elimination, and pain control. Provide information on minimizing exposure to illness and the timely management of comorbid conditions that impact quality of life and may hasten the rate of cognitive decline.

Injury prevention requires a comprehensive approach that incorporates collaboration with other members of the healthcare team, including occupational and speech therapists. Principles of environmental safety are discussed in detail in the modules on Safety and Mobility and include but are not limited to identifying and removing hazards that increase the risk of falls, burns, drowning, skin breakdown, and ingestion or misuse of toxic substances. The risks and benefits of devices such as medic alert systems, patient tracking or alert systems, and locks should be discussed with patients and families. The use of physical and pharmacologic restraints should be avoided.

» **Stay Current:** For more information on strategies that can be employed to avoid the use of restraints, see *Avoiding Restraints in Patients with Dementia* at the Hartford Institute for Geriatric Nursing at <https://consultgeri.org/try-this/dementia/issue-d1>.

Nurses should also address the patient's ability to continue occupational, recreational, and practical activities, such as driving, that may be negatively impacted by impaired cognition. Research shows that the rate of accidents in individuals in the first 2 years following an early diagnosis of AD is comparable to the general population but quickly increases thereafter (Alzheimer's Association, 2016e; Carter et al., 2015). Family members and caregivers should be alert to signs that driving is no longer safe, such as minor fender benders, getting lost, or ignoring stop signs or other traffic signals. Driver Rehabilitation specialists have expertise in evaluating driving abilities and making recommendations for terminating driving privileges.

» **Stay Current:** For more information on assessment and intervention of driving in older adults with dementia and related disorders, visit <http://seniordriving.aaa.com/evaluate-your-driving-ability/professional-assessment> and <http://www.alz.org/care/alzheimers-dementia-and-driving.asp>

SAFETY ALERT The use of physical and pharmacologic restraints in individuals with AD and dementia significantly increases the risk of injury and death and is never considered therapeutic. Although safety is frequently cited as the rationale for using restraints, the risks of use clearly outweigh the benefits. The use of restraints and other measures to restrict movement can be avoided entirely through behavioral strategies such as distraction, consistent caregiving, provision of meaningful activities, and human monitoring.

Promote Adaptive Functioning and Coping

In the early stages of the disease, the nurse supports adaptive functioning by providing patient and family education and training, facilitating advanced planning, and supporting the emotional needs of both the family and the individual as they come to terms with the diagnosis.

» **Stay Current:** For a nursing standard for addressing advance directives with patients, visit The Hartford Institute for Geriatric Nursing <https://consultgeri.org/geriatric-topics/advance-directives>.

Education centers on accessing health and financial resources, medication teaching, interventions to support optimal cognition and safety (e.g., cuing devices, calendars, lists, label, verbal reminders), and environmental modifications that may reduce stress. Communication strategies for individuals with AD include the following:

- Establish eye contact.
- Begin every interaction by introducing yourself and stating the patient's name.
- Talk in a calm reassuring tone.
- Use simple vocabulary and brief, straightforward sentences.
- Ask only one question at a time. Use questions that require yes or no answers, and provide sufficient response time.
- Repeat questions, explanations, and instructions as required.
- Be careful about challenging the patient's interpretation of reality, as this may lead to agitation and noncompliance.

As the disease progresses, the emphasis of nursing care focuses on addressing behavioral manifestations of the disease, including neuropsychiatric symptoms such as agitation,

depression, and anxiety. Caregivers may need guidance in recognizing the unmet needs that behaviors such as wandering and restlessness represent. Prevention of fatigue, consistency in caregiving, using simple and direct communication, providing comforting and meaningful activities (art, music, reminiscence), scheduling quiet time, and reducing stimulation are effective behavioral strategies.

Nurses are often in a key position to counsel family members as they struggle with ambivalence and guilt related to the decision to transition the patient to a skilled nursing facility. It is important for the nurse to address cultural beliefs that may compound the difficulty associated with making such a decision. Nurses can guide caregivers to select services and placements that best meet the unique needs of the patient and the family and that optimize the family's ability to continue to participate in caregiving. Nurses should be cognizant of the phenomenon of **transfer trauma** or **relocation syndrome**—a worsening of symptoms associated with the stress of moving to a new environment. In addition to family participation in care, strategies to address the transition include retaining as many aspects of the home environment and previous routine as possible.

Provide End-of-Life Care

Nursing care for patients in the final stage of AD focuses on promoting quality of life and minimizing discomfort associated with physiologic decline and profound deficits in cognitive function. Principles of palliative care are discussed in detail in the modules on Comfort and on Grief and Loss and encompass a holistic approach to care. Palliative care with individuals with AD is challenged by the patient's inability to communicate needs. Family members and caregivers who have not resolved relationship issues during earlier stages of the illness may have more difficulty with treatment decisions and are at increased risk for complicated grieving.

Evaluation

Evaluation of patient outcomes is based on an understanding that patients may only be able to achieve a series of short-term outcomes based on the stage of disease progression. The focus is on ensuring that the patient and family achieve the optimal level of wellness for the particular stage of the disease. Evaluation also focuses on the caregivers' ability to manage the progression of the disease while meeting their own health and emotional needs. The following are examples of anticipated outcomes of care.

- The patient utilizes strategies to maintain independent functioning.
- The safety of the patient and others is maintained.
- The patient and/or family adheres to the prescribed treatment.
- Caregivers verbalize that self-care needs are met.

The unmet outcomes may indicate that the level of support being provided to the patient and family is no longer sufficient. In addition, it is possible that goals or certain interventions are no longer appropriate for the stage of the disease. In both cases the nurse would modify the plan of care.

Nursing Care Plan

A Patient with Alzheimer Disease

Sixty-one-year-old Loretta Gordon arrives at her general practitioner's office complaining of memory problems and depression that began about a month ago. Ms. Gordon is currently taking sertraline

for her depression. She is afraid her medication is causing her current complaints, so she came to see the doctor.

ASSESSMENT	DIAGNOSES	PLANNING
<p>Gretchen Burchett, RN, obtains a patient history and conducts a physical examination of Ms. Gordon. Nurse Burchett notes that Ms. Gordon retired 2 years ago after 35 years as an elementary school music teacher. Shortly after retirement, Ms. Gordon began to experience depression and was prescribed sertraline; until recently, her symptoms were well controlled by the medication. Ms. Gordon receives a "comfortable pension" from the school and lives alone in a small house. She has never been married and has no children, but she maintains a close relationship with her brother, who is 15 years younger. Her primary social outlet is a group of women friends she's known since college, although she says she hasn't been attending their weekly get-togethers because she "has a hard time following the conversation." Ms. Gordon is an avid piano player but admits to recent frustration over her inability to follow sheet music.</p> <p>Ms. Gordon is clean and well groomed, and her weight is healthy for someone her age and height. She struggles to find the right words when answering Nurse Burchett's questions. Nurse Burchett also notes a family history of AD and that Ms. Gordon sustained a serious head injury in a car accident 8 years ago. Ms. Gordon's vital signs include temperature 99.0°F oral; pulse 67 bpm; respirations 18/min; and blood pressure 116/72 mmHg.</p> <p>Suspecting mild or early-stage AD, Nurse Burchett administers the MMSE. Ms. Gordon scores 23, indicating mild cognitive impairment. The physician orders blood tests to check for metabolic and endocrine problems and an MRI to assess for impaired blood flow and fluid accumulation in the brain. All of Ms. Gordon's test results are negative, and a diagnosis of probable mild or early-stage familial AD is made. The physician prescribes donepezil, 5 mg orally, increasing to 10 mg after 6 weeks. He also increases her sertraline from 150 mg orally to 175 mg and instructs her to return in 6 months.</p>	<ul style="list-style-type: none"> ■ <i>Risk for Injury</i> related to impaired cognitive function ■ <i>Impaired Memory</i> related to diminished neurologic function ■ <i>Chronic Confusion</i> related to deterioration of cognitive function ■ <i>Impaired Verbal Communication</i> related to intellectual changes ■ <i>Anxiety</i> related to awareness of physiologic and cognitive changes <p>(NANDA-I © 2014)</p>	<p>Goals for Ms. Gordon's care include:</p> <ul style="list-style-type: none"> ■ The patient will remain free from injury. ■ The patient will verbalize an understanding of her disease and its stages. ■ The patient will utilize lists, calendars, and other memory aids as needed. ■ The patient will participate in speech and language therapy. ■ The patient will exhibit decreased signs and symptoms of anxiety and depression. ■ The patient will take all medications as prescribed. ■ The patient will remain in the home environment as long as possible.

IMPLEMENTATION

- Teach about AD, and provide informational materials and recommendations for community resources.
- Collaborate with other members of the healthcare team to ensure advance planning and decision making, including advance directives, financial planning, and legal concerns related to guardianship and estate planning.
- Collaborate with the primary care provider and other members of the healthcare team about home visits to regularly assess the patient's functional capabilities and identify any safety concerns.
- Emphasize the use of calendars and electronic devices to record appointments and alert to important activities, such as medication administration.
- Instruct about the prescribed medications, potential side effects, and dietary changes that can minimize negative side effects.
- Refer to speech and occupational therapy.
- Teach about strategies to address behavioral changes and anxiety associated with AD, including decreasing environmental stress, regular sleep and meal schedules, redirection and distraction, minimizing unexpected changes, and counseling, relaxation, and music therapy for both patients and families.
- Promote therapeutic environments and activities that encourage physical, social, emotional, and cognitive well-being, including physical activity, diet, prevention and management of health problems, cognitive exercises, games, puzzles, and social engagement.

EVALUATION

Nurse Burchett refers Ms. Gordon to a speech therapist, and therapy sessions are scheduled for twice weekly. During therapy, Ms. Gordon engages in a series of exercises designed to slow her decline in communication skills. She has also mastered the electronic calendar and alarm on her cell phone, programming reminders for even basic daily functions. She enjoys an hour of music in the evenings, although she listens to recordings rather than playing her piano. After 6 months of pharmacologic treatment and speech

therapy, Ms. Gordon's cognitive condition is stable and she once again scores 23 on her MMSE.

Ms. Gordon continues to display symptoms of depression, primarily stemming from the realization that there is no cure for her condition. She attends a local AD support group, which helps her verbalize and cope with her anxiety. With the help of her brother, who has invited Ms. Gordon to move into his home, she has created a long-term care plan.

Nursing Care Plan *(continued)*

CRITICAL THINKING

1. Ms. Gordon is fortunate that her brother is willing to be involved in her care. How would you adapt the care plan if Ms. Gordon had no family or her family was unwilling to be involved?
2. Ms. Gordon finds comfort in a support group for AD patients. Identify resources in your area that provide these kinds of services to AD patients and caregivers.
3. Develop a care plan for the nursing diagnosis of Self-Care Deficit related to cognitive decline and physical limitations.

REVIEW Alzheimer Disease

RELATE Link the Concepts and Exemplars

Linking the exemplar of Alzheimer disease with the concept of tissue integrity:

1. Why might patients with AD be at a heightened risk for impaired tissue integrity? What types of impairments would you most expect to see, and during which stages of AD would they most likely occur?
2. When caring for the patient with AD, what nursing interventions are appropriate when seeking to limit the risk of impaired tissue integrity?

Linking the exemplar of Alzheimer disease with the concept of spirituality:

3. How might a patient's spirituality be affected by a diagnosis of AD? How might a patient's diagnosis of AD affect her family and loved ones?
4. What nursing interventions might be appropriate for patients and families who are experiencing spiritual distress related to the cognitive and physical alterations associated with AD?

Linking the exemplar of Alzheimer disease with the concept of legal issues:

5. Why are issues of informed consent often problematic for individuals with AD?
6. What actions might nurses recommend to prevent such issues from arising?

REFLECT Apply Your Knowledge

Robert Moser, a 75-year-old man, is brought to the emergency department by State Trooper Kelly just before midnight. Law enforcement had received reports of a car driving erratically along the highway and pulled Mr. Moser over. Trooper Kelly tells you that when he stopped Mr. Moser, Mr. Moser was able to get out his wallet but unable to tell Trooper Kelly his name. Mr. Moser stated he was trying to find the hospital where his wife is located, but he could not name the hospital or say where it is. Trooper Kelly pulled up the list of contacts in Mr. Moser's cell phone. When Mr. Moser confirmed one of the contacts was his son, Trooper Kelly contacted the son and asked him to meet them at the hospital. The son, who informs Trooper Kelly that Mr. Moser recently was diagnosed with Alzheimer disease, lives out of town and will arrive in about an hour. Mr. Moser is polite and compliant, but he keeps asking "Is this a hospital?" over and over again. As you begin your assessment, Mr. Moser has difficulty finding the words he needs to respond.

1. What additional assessment information do you need?
2. Identify three other conditions that may produce symptoms that mimic dementia.
3. How will you go about the assessment given that Mr. Moser is unable to participate fully?
4. What are Mr. Moser's priorities for care *at this time*?
5. What stage of Alzheimer disease is Mr. Moser likely experiencing?

Exemplar 23.B Delirium

Exemplar Learning Objectives

23.B Analyze delirium as it relates to cognition.

- Describe the pathophysiology of delirium.
- Describe the etiology of delirium.
- Compare the risk factors and prevention of delirium.
- Identify the clinical manifestations of delirium.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with a congenital heart defect.

- Differentiate care of patients with delirium across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with delirium.

Exemplar Key Terms

Confusion, 1740

Confusion Assessment Method (CAM), 1743

Delirium, 1740

Sundowning, 1741

Overview

Delirium is an abrupt, generally transient, and often fluctuating change in mental state and consciousness characterized by disorganized thinking, disorientation, perceptual disturbances, restlessness, agitation, and lability. **Confusion** is a closely related term, broadly used to describe increased difficulty in thinking clearly, making judgments, focusing attention, and maintaining orientation. The terms *acute confusion* and *delirium* have been used interchangeably; however, delirium is recognized as a distinct disorder and is classified by the DSM-5 according to the etiology.

The most important thing to remember about delirium is that it generally signals the presence of a reversible but potentially life-threatening condition. Delirium is associated with a number of adverse outcomes, including increased mortality, institutionalization, and dementia (Davis et al., 2013). The best patient outcomes are associated with the prevention of delirium; however, early detection and management may mitigate the consequences of the condition. It is believed that at least 1 of 10 hospitalized patients will experience delirium in the hospital setting, but the likelihood increases significantly according to age and variables such as diagnosis and treatment. Older adults experience delirium at rates up to 6 times that of the general hospital population. The incidence of delirium in long-term care settings is believed to be comparable, although the condition is often unrecognized. The incidence of delirium in community health settings is more elusive and possibly underestimated because of a lack of reliable measurement methods (Kalish, Gillham, & Unwin, 2014; Davis et al., 2013; Rooney et al., 2014).

Pathophysiology and Etiology

Pathophysiology

The exact pathophysiology of delirium is unknown. It is theorized that the conditions that lead to delirium increase cerebral oxidative stress and impair neurotransmitter action through a variety of structural, inflammatory, metabolic, and neurochemical pathways. For example, psychologic and physiologic stress both activate the sympathetic nervous system, impairing cholinergic transmission. The net result of these changes is diminished cerebral function and alterations in arousal mechanisms of the reticular activating system (RAS) and thalamus (Huang, 2013).

Etiology

A wide variety of conditions can result in delirium, including infections, metabolic imbalances, trauma, nutritional deficiencies, central nervous system disease, hypoxia, hypothermia, hyperthermia, circulatory problems, low blood glucose, toxin exposure, sleep deprivation, and drug and alcohol use and withdrawal (Rosen et al., 2015).

Iatrogenic (treatment-related) factors may also precipitate delirium and include the use of interventions such as medication, surgery and anesthesia, and electroconvulsive therapy (ECT). Hospitalized patients are much more likely to experience delirium because of the presence of predisposing illnesses, exposure to multiple medical interventions that may contribute to cognitive changes, and being in an

environment that is unfamiliar, stimulating, and not conducive to maintaining normal diurnal rhythms. *Transfer trauma* or *relocation syndrome* is a major cause of stress in individuals of all ages and accounts, and a contributing factor to the high incidence of delirium in hospitalized patients. It should be noted that delirium occurs in 10–30% of the general hospital population, 15–50% of postoperative patients, and 70–80% of patients in the intensive care unit. Among hospitalized individuals over age 65, approximately 15–60% experience delirium, as do 20–90% of older patients with documented dementia (Fleet & Ernst, 2013; Solomon, Thilakan, & Jayakar, 2016).

Risk Factors

Although anyone can develop delirium, certain traits increase the likelihood of this condition. Age is a major risk factor. Older adults are at higher risk due to normal age-related cognitive decline. Age-related vision and hearing loss can contribute to delirium by impairing individuals' ability to accurately and effectively interpret their surroundings. Older patients are also more likely to experience many of the underlying physical causes of delirium, such as central nervous system and circulatory disease. Children are more prone to delirium than are adolescents and younger adults. Again, physiology is a primary factor, as children's bodies are less equipped to cope with insults such as fever, infection, and toxin exposure.

Other factors that can contribute to delirium include the presence of a chronic illness, onset of a new illness, or exacerbation of a current condition. The use of drugs, alcohol, or prescription medications such as hypnotics/sedatives, anxiolytics, antidepressants, anti-Parkinson drugs, anticonvulsants, or antispasmodics also increase the risk of delirium (Alagiakrishnan, 2015; Huang, 2013). Individuals with depression and other emotional disorders are at increased susceptibility as well, especially when faced with the added strain of illness, loss, or a change in environment such as hospitalization.

Prevention

Prevention focuses on reducing the incidence or presence of physiologic and psychosocial factors that lead to delirium, early detection of delirium, and a holistic approach to managing delirium in affected individuals. For individuals with predisposing conditions, proper medical management can reduce the likelihood of delirium. Standardized protocols should be implemented in healthcare settings to address the prevention, detection, and management of delirium (Tullman, Fletcher, & Foreman, 2012b).

Clinical Manifestations

Typical manifestations of delirium include reduced awareness, impaired thinking skills, and/or changes in activity level and behavior. See **Table 23-10** » for an overview of common signs and symptoms from each of these categories. The intensity of manifestations varies, with some patients having only subtle symptoms and others experiencing acute loss of most or all cognitive function. Note that diagnostic markers of delirium may vary somewhat depending on the patient's cultural background (see Focus on Diversity and Culture: Delirium).

TABLE 23–10 Manifestations of Delirium

Category	Common Signs and Symptoms
Reduced awareness	<ul style="list-style-type: none"> ■ Difficulty shifting attention from one topic to another ■ Limited or absent span of attention ■ High distractibility ■ Difficulty keeping track of what has been said ■ Inability to answer questions or engage in conversation ■ Little activity or response to the environment
Impaired thinking skills	<ul style="list-style-type: none"> ■ Impaired memory (especially recent memory) ■ Disorganized thought ■ Disorientation to place, time, date, and/or person ■ Rambling, incoherent, illogical, or absent speech ■ Poor word-finding ability ■ Difficulty reading, writing, or understanding speech ■ Hallucinations and/or illusions
Changes in behavior	<ul style="list-style-type: none"> ■ Agitation, irritability, restlessness, or combative behavior ■ Altered sleep patterns ■ Mood swings and extreme emotions ■ Fear, anxiety, and/or depression ■ Withdrawal

D. (2012). Delirium: Prevention, early recognition, and treatment. In M. Boltz, E. Capezuti, T. T. Fulmer, D. Zwicker, & A. O'Meara (Eds.), *Evidence-based geriatric nursing protocols for best practice* (4th ed.). New York, NY: Springer; Osborn, K. S., Wraa, C. E., Watson, A., & Holleran, R. S. (2013). *Medical-surgical nursing: Preparation for practice* (2nd ed.). Upper Saddle River, NJ: Pearson.

Focus on Diversity and Culture Delirium

Culture may also affect the diagnostic process. When working with patients from Hispanic, Asian, African American, and other cultural groups, the nurse must remember that these cultures may promote different conceptions of time, place, and person in comparison to Caucasian-American culture (Spector, 2017). Therefore, what the nurse might perceive as a lack of orientation to time might be perfectly normal, acceptable behavior to a patient and his family. Cultural beliefs may also impact the interpretation of manifestations such as hallucinations and incoherent speech. Patients and their families may view these experiences as spiritual or religious events rather than signs of illness (Spector, 2017). In such cases, the nurse must be careful not to discount or disparage the patient's cultural preferences and beliefs. Promotion of trust and acceptance is necessary for building an effective nurse–patient relationship.

Delirium is marked by vacillating symptoms. An individual may be largely unresponsive at one point in the day but hypervigilant just a few hours later, with a period of normal behavior in between. In addition, the individual's psychomotor activity may be hyperactive, hypoactive, or a mixture of both at various times throughout the day. Confusion that intensifies in the evening or at bedtime is referred to as **sundowning**. Sundowning is not a disorder in and of itself; rather, it is a feature of dementia that affects some individuals.

Clinical Manifestations and Therapies Delirium

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
<p>Variable etiologies; may include the following:</p> <ul style="list-style-type: none"> ■ Hospitalization or transfer to a new environment ■ Infection ■ Metabolic imbalance ■ Trauma ■ Nutritional deficiency ■ Central nervous system disease ■ Hypoxia ■ Hypothermia ■ Hyperthermia ■ Acute circulatory alteration ■ Hypoglycemia (decreased serum glucose) ■ Toxin exposure ■ Sleep deprivation ■ Drug and alcohol use or withdrawal 	<ul style="list-style-type: none"> ■ Reduced awareness, as evidenced by: <ul style="list-style-type: none"> ● Limited span of attention ● Difficulty focusing or logically shifting from one topic to another ● Inability to answer questions or engage in conversation ● Limited response to the environment ■ Impaired thinking skills, as evidenced by: <ul style="list-style-type: none"> ● Impaired memory ● Disorganized thought ● Disorientation to place, time, date, and/or person ● Impaired speaking, reading, and comprehension ability ■ Behavioral changes, such as: <ul style="list-style-type: none"> ● Hyperactivity, hypoactivity, or a combination thereof ● Hallucinations ● Agitation and/or restlessness ● Fear, anxiety, and/or depression ● Altered sleep patterns ● Mood swings ● Withdrawal ■ Acute onset and fluctuation of symptoms ■ Appearance of symptoms at specific times of day (e.g., sundowning) 	<ul style="list-style-type: none"> ■ Physical interventions aimed at correcting biological causes of delirium: <ul style="list-style-type: none"> ● Supplemental oxygen ● IV fluids and/or electrolytes ● Supplemental nutrition ■ Environmental interventions: <ul style="list-style-type: none"> ● Preventing under- or overstimulation ● Instituting safety measures ● Promoting consistency ■ Cognitive interventions: <ul style="list-style-type: none"> ● Orienting patient to place, time, date, and/or person ● Providing reassurance that delirium is temporary ■ Pharmacologic therapies aimed at the underlying cause of delirium (as appropriate) ■ Surgical treatment of the underlying cause of delirium (as appropriate)

Collaboration

Nurses must be familiar with a range of collaborative interventions related to delirium. These include diagnostic tests, medications, and nonpharmacologic therapies. Psychosocial considerations are directed toward both patients and their family members.

Diagnostic Tests

Medical professionals use any number of diagnostic procedures to determine the underlying source of a patient's delirium. The first steps usually include conducting a physical exam and obtaining a detailed medical history. Cognitive testing, such as the CAM test (described later in this exemplar), can also be useful for determining whether a patient is experiencing reversible confusion or another form of impairment.

Based on assessment data, the primary care provider will choose appropriate diagnostic procedures. Examples of tests that may be appropriate for identifying underlying causes of confusion include a detailed neurologic examination; drug and alcohol screening; laboratory tests for signs of infection and metabolic, nutritional, and other imbalances; and screening for depression and other psychiatric conditions.

Pharmacologic Therapy

No one drug or class of drugs is appropriate for all patients with delirium, but some medications may effectively treat the causative condition. For example, antipsychotics may be appropriate for patients with delirium related to an underlying psychotic disorder, and SSRIs and other antidepressants can help minimize delirium in some individuals with mood disorders. In other cases, discontinuation of medications may be the best course of action, especially for individuals who are experiencing drug-related delirium.

Nonpharmacologic Therapy and Integrative Care

Numerous nonpharmacologic interventions may benefit individuals with delirium, depending on their pathology. These interventions fall into three categories: physical, environmental, and cognitive.

- **Physical interventions** target anatomic or biological factors that may be contributing to delirium. Common physical interventions that promote enhanced cognition include oxygen administration, IV delivery of fluids and/or electrolytes, and provision of appropriate nutrition.
- **Environmental interventions** involve enhancing patients' level of comfort within their surroundings, as this helps minimize the likelihood of confusion. Often, these interventions focus on preventing under- or overstimulation, maintaining safety, and promoting consistency. (See the Nursing Process section.)
- **Cognitive interventions** involve orienting patients to person, place, and time, as well as providing reassurance that they are safe and that their delirium will be resolved. Validation therapy may also be an effective way of meeting patient needs (see exemplar on Alzheimer disease and the Nursing Process section below.)

There is some evidence to suggest that sensory interventions such as music therapy may assist in orienting patients experiencing delirium and/or reducing associated anxiety (Dzierba et al., 2015; American Geriatrics Society Expert Panel on Postoperative Delirium in Older Adults, 2015; Zhang et al., 2013). Given the complex nature of delirium and the ranges of patient variables impacting it, collaboration with a qualified music therapist is likely to result in the best outcomes. In addition, a recent meta-analysis of randomized controlled studies suggests that the use of exogenous melatonin may have a preventative effect on delirium (Chen et al., 2016).

SAFETY ALERT Older adults and individuals with dementia or other cognitive disorders and mental illnesses are at increased risk for a misdiagnosis related to the perception that changes in mental status are related to age or a psychiatric condition. In addition, it is easy to confuse diurnal changes in cognition (such as sundowning) with delirium caused by an underlying medical condition. Nurses should never assume that cognitive changes are related to age, mental health issues, or the time of day. A thorough assessment is essential to rule out underlying medical causes of any changes in mental status.

Lifespan Considerations

Although individuals of all ages are susceptible to delirium under certain conditions, risk factors and common etiologies of the condition are associated with different stages of the lifespan. Manifestations of delirium may also vary with different age groups.

Delirium in Children

Like older adults, children lack the functional reserves necessary to cope with both environmental and physiologic stressors and are at increased risk for delirium. In general, children with intellectual and developmental disabilities are at increased risk for delirium. The prevalence of delirium in hospitalized children ranges from 10 to 30% and is more common in younger and critically ill children or those emerging from anesthesia. Any febrile illness may cause symptoms of delirium, even in children being cared for at home. Manifestations of delirium may be confused with willful or oppositional behavior or be extremely frightening for parents. The Cornell Assessment of Pediatric Delirium can be used to detect delirium in children. Besides the prevention and management of the underlying medical condition, the presence of parents and family members has been found to reduce the incidence of delirium. Overall, the prognosis for children with delirium is better than that for older individuals (Schieveld et al., 2015).

Delirium in Adolescents

By adolescence, the ability to compensate for physiologic alterations that may precipitate delirium has improved; however, some of the common causes of delirium in adolescents are different. Adolescents may be at increased risk for head trauma as a result of participation in contact sports or a tendency toward impulsive, risk-taking behaviors. Drug and substance abuse and withdrawal are another common cause of delirium in this age group.

Delirium in Pregnant and Postpartum Women

Delirium during pregnancy or in the postpartum period is a serious sign and may indicate the presence of a life-threatening condition such as preeclampsia and HELLP syndrome, sepsis, hypo- or hyperglycemia, or fluid and electrolyte imbalance (possibly as a result of hyperemesis gravidarum). Delirium may also be associated with the stress of labor or the use of anesthetic agents. Symptoms of delirium may be difficult to distinguish from postpartum psychosis. Priority care focuses on the patient and determining the underlying cause. This includes monitoring fetal well-being as well as ensuring the safety of the newborn.

Delirium in Older Adults

In older patients, delirium may be confused with normal forgetfulness or dementia, especially when presenting in healthcare settings where staff are unfamiliar with the patient's history and prior cognitive status. Individuals with dementia are at increased risk of acute mental status changes associated with delirium, and therefore any change from baseline should be considered significant (Cole et al., 2015). Delirium is often the most prominent manifestation of conditions such as dehydration, respiratory tract infections, urinary tract infections, and urinary retention, and adverse drug events may occur in the absence of symptoms such as fever or discomfort. The possibility of intracranial events (stroke, bleeding) and acute pulmonary and myocardial events should also be considered. Prompt recognition and management of delirium is essential because the risk of long-term disability and death also increases exponentially in older adults (Ahmed, Leurent, & Sampson, 2014; Fick et al., 2013).

NURSING PROCESS

One of the nurse's primary duties in caring for a patient with delirium is to promote resolution of whatever condition is causing the patient's cognitive impairment. The nurse must also take steps to keep the patient safe, support cognitive functioning and comfort, and minimize the likelihood of further episodes of confusion. When assessing an individual's cognitive skills and orientation the nurse accounts for variables such as age and development, level of education, and culture.

Assessment

Nursing assessment for the patient with delirium typically involves three main elements: a health history, a physical examination, and a mental status examination.

Observation and Patient Interview

Observe the patient for behavioral manifestation of delirium, including extreme distractibility, disorganized thinking, rambling, irrelevant and incoherent speech, and purposeless motor activity. Fluctuations in psychomotor activity may also be observed with periods of restlessness and agitation to stupor, catatonia, and somnolence. Mood instability may be manifested by episodes of alternating distress or euphoria. The patient may also appear flushed and diaphoretic.

The history is critical to identifying potential causes of the patient's confusion and highlighting areas that require further assessment. Because the patient may not be able to provide a reliable history, a family member or caregiver may need to be interviewed. For the patient with delirium, basic components of the health history include the following:

- Age
- History of other disease processes
- Recent history of infection and/or fever
- Vision and/or hearing impairments
- Alcohol and drug use (including medications)
- Possible toxin exposure (e.g., in the workplace)
- Dietary patterns
- Untreated or undertreated pain
- History of depression or other mood disorders
- Recent life changes that may be contributing to cognitive and/or emotional upset

Physical Examination

During the physical examination, evaluate the patient's height, weight, vital signs, and overall condition. In addition to a focused assessment of perfusion, oxygenation, intracranial regulation, infection, and inflammation, assess for physical findings associated with any concerns brought up during the health history. For example, for a patient who reports that he is hard of hearing, attempt to determine the degree of impairment and explore the possibility that this impairment may be contributing to the patient's confusion.

To differentiate between delirium and dementia, the **Confusion Assessment Method (CAM)** may be used. The nurse should also screen the patient for depression, because this condition is often linked to confusion in older adults. For discussion of testing instruments designed for this purpose, refer to the Nursing Assessment section in this module.

» **Stay Current:** A current version of the CAM can be accessed online at <https://consultgeri.org/try-this/general-assessment/issue-13>

Because delirium has a fluctuating course, ongoing assessment is important. The nurse should reassess patients with delirium frequently. Some patients may require one-on-one monitoring.

Diagnosis

Appropriate nursing diagnoses for patients with delirium vary, depending on the cause and severity of their condition. Still, some diagnoses are likely to apply to many, if not most, patients with acute confusion. These include:

- *Injury, Risk for*
 - *Self-Care Deficit (Bathing, Dressing, Feeding, and/or Toileting)*
 - *Disturbed Sleep Pattern*
 - *Acute Confusion*
 - *Verbal Communication, Impaired*
 - *Social Interaction, Impaired*
 - *Compromised Human Dignity, Risk for*
- (NANDA-I © 2014)

Planning

The planning portion of the nursing process involves identifying desired outcomes and choosing evidence-based interventions that facilitate their achievement. Again, goals and interventions will vary depending on the cause and severity of a patient's delirium. Appropriate outcomes may include the following:

- Patient will remain free from injury.
- Patient will be oriented to time, place, date, and person.
- Patient will return to baseline cognitive status (i.e., status prior to onset of confusion).
- Patient will demonstrate the ability to communicate in a clear and logical manner.
- Patient will obtain adequate sleep and rest.
- Patient will exhibit reduced anxiety, agitation, and restlessness.
- Patient will be able to perform ADLs.

Implementation

Provide a Safe Environment for the Hospitalized Patient

Typically, nursing interventions for the patient with confusion revolve around providing of a safe, therapeutic environment that prevents further cognitive impairment and promotes resolution of the condition causing the patient's delirium. The following measures may be useful for most patients:

- Maintaining appropriate levels of noise and lighting in an attempt to prevent under- or overstimulation
- Preventing access to potential hazards (e.g., knives, guns, medications, lighters, and chemicals)
- Using behavioral interventions and monitoring systems to address wandering
- Promoting consistency by assigning the same caregivers and scheduling activities at the same time each day
- Providing an environment that supports normal sleep-wake cycles
- Ensuring access to assistive devices, including glasses and hearing aids
- Providing adequate pain management
- Keeping familiar items in the patient's environment without allowing the environment to become disorganized or cluttered
- Using calendars, clocks, and signs to help orient the patient to time, date, and place
- Encouraging loved ones to visit the patient

The nurse can also employ various communication strategies to limit confusion. The nurse should always wear a name tag and introduce himself during patient interactions. The nurse should then verbally orient the patient to date, time, and place. When talking with the patient, the nurse should speak clearly and allow time for response. All explanations of treatments or procedures should be brief and as

easy to understand as possible. The nurse should reinforce reality by helping patients interpret confusing or unfamiliar stimuli. Any misconceptions of events or situations should be gently corrected. The nurse should also reassure patients that their delirium is temporary.

» **Stay Current:** The Hospital Elder Life Program (HELP) is a comprehensive, evidence-based patient-care program that provides optimal care for older persons in the hospital and has extensive resources for healthcare professionals on the prevention, identification and management of delirium in hospitalized patients. For more information visit: <http://www.hospitalelderlifeprogram.org/for-clinicians/about-delirium/>

SAFETY ALERT Challenging a patient who is delusional or misinterpreting reality has the potential to make a patient anxious and lead to agitation or aggressive behavior. Using validation techniques, the nurse can often determine the underlying need without unnecessarily upsetting the patient. Validating data are explained in detail in the module on Assessment.

Promote Safety in the Home

Teaching is especially important when patients have an ongoing health issue that predisposes them to delirium. For example, if patients are taking medications that increase their risk of cognitive changes, they and their loved ones should be informed of common symptoms of delirium and what to do when these symptoms arise. Similarly, patients with diabetes should be taught about signs of confusion related to abnormal blood glucose. In addition, family members and caregivers should be assisted with developing an action plan for assisting the patient during hyperglycemic or hypoglycemic episodes.

Evaluation

Ongoing evaluation is critical for all patients with delirium, as it allows nurses to monitor their condition and adjust the nursing plan of care as needed. Some examples of potential achieved outcomes include the following:

- Patient sustains no injuries.
- Patient is oriented to time, place, date, and person.
- Patient demonstrates an absence of manifestations of delirium.
- Patient communicates clearly and transitions logically between topics.
- Patient is able to perform ADLs.

Individuals with delirium may demonstrate permanent changes in neurocognitive function, especially when conditions such as dementia were already present. Family members and caregivers may be more aware of subtle differences indicating that the patient has not returned to her previous level of function. Even when cognitive status has improved, the nurse recognizes that individuals who have experienced delirium are at increased risk for future episodes. The resolution of delirium may allow the nurse to modify the plan of care and provide teaching that emphasizes the prevention, detection, and treatment of precipitating health issues.

REVIEW Delirium

RELATE Link the Concepts and Exemplars

Linking the exemplar of confusion with the concept of infection:

1. How might delirium increase the patient's risk for infection?
2. Why are patients with infection at a heightened risk for delirium? What types of infections do you think would most increase a patient's likelihood of delirium?

Linking the exemplar of confusion with the concept of stress and coping:

3. Why are patients more likely to experience delirium during periods of increased stress? What sorts of events are likely to be most stressful and thus result in confusion?
4. For the patient experiencing delirium, what nursing interventions could be implemented to help reduce stress and promote effective coping?

Linking the exemplar of delirium with the concept of safety:

5. How might caring for patients with delirium put a nurse's safety in jeopardy?
6. What interventions could a nurse implement to protect her own safety when caring for a patient with delirium? What legal or ethical issues are associated with these measures?

REFLECT Apply Your Knowledge

Clifford Allen is a 64-year-old man who has been married to his wife, Pam, for 40 years. Their only child, 24-year-old Gary, has Down syndrome and lives with them. Mr. Allen is a middle manager for a small manufacturing company where he has worked for the past 20 years.

Overall, Mr. Allen is in good health, although he has recently been undergoing conservative treatment for benign prostatic hyperplasia. He has a history of depression, including a brief episode during college for which he did not seek treatment. Mr. Allen had another episode shortly after his son was born, and at the encouragement of his wife, he sought treatment, which consisted of counseling and antidepressant medications. He quit taking the medications after 6 months and decided he would just learn to deal with depression on his own. Although he has had several mild episodes of depression since that

time, Mr. Allen has been unwilling to seek treatment because he fears the social stigma of being labeled medically depressed and is concerned that his employer will discover it through his use of his medical benefits. It is Mr. Allen's opinion that his employer would perceive depression as a sign of weakness. Overall, Mr. Allen has done well without the medications.

Mr. Allen has been thinking about retiring in the next few years. He and his wife have always planned to do some traveling, but mostly he looks forward to escaping his busy, stressful work environment. Mr. Allen and his son are involved in church activities; they also enjoy a walk each evening after supper. Mr. Allen belongs to a bowling league and is at the bowling alley a couple of evenings a week.

Mr. Allen is admitted to the acute care hospital for a transurethral resection of the prostate (TURP). He has been very anxious about the procedure because of the risk of impotence. The surgery goes smoothly, and he experiences no complications. In the immediate postoperative period, Mr. Allen has a three-way Foley catheter inserted, with continuous bladder irrigation. He experiences pain and occasional bladder spasms because of blood clots. The day after surgery, the nurse enters Mr. Allen's room, and he asks why the hospital bed was brought to his room and calls the nurse by his wife's name. He appears restless and agitated. The nurse assesses Mr. Allen and determines that he is experiencing delirium.

1. What factors may increase the risk of delirium in this patient?
2. What interventions would the nurse initiate for Mr. Allen?
3. What nursing diagnosis would be appropriate for Mr. Allen?
4. What assessment tools would the nurse use to assess Mr. Allen?

Exemplar 23.C Schizophrenia

Exemplar Learning Objectives

23.C Analyze schizophrenia as it relates to cognition.

- Describe the pathophysiology of schizophrenia.
- Describe the etiology of schizophrenia.
- Compare the risk factors and prevention of schizophrenia.
- Identify the clinical manifestations of schizophrenia.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with schizophrenia.

- Differentiate care of patients with schizophrenia across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with schizophrenia.

Overview

Schizophrenia is a profound neurobiological disorder that is characterized by psychotic symptoms, diminished capacity to relate to others, and behaviors that appear odd or bizarre. Approximately 1% of persons living in the United States experience schizophrenia (National Institute of Mental Health, 2016). Although many people associate the disorder with perceptual alterations such as hallucinations, the most chronic and disabling aspects of the disease relate to functional deficits caused by alterations in communication, cognition, attention, memory, emotional regulation, initiative, and social interactions. (These manifestations are frequently classified as positive, negative, and cognitive symptoms and are discussed in more detail in the section on clinical manifestations.) Schizophrenia typically emerges during early adulthood, but it can also occur during childhood and adolescence or first manifest later in life. Schizophrenia is also associated with a 10- to 25-year reduction in life expectancy as a result of comorbid medical conditions and high rates of suicide (Larsen, Munk-Olsen, & Vester-gaard, 2012). Historically, schizophrenia has been poorly understood, and the stigma associated with the disorder is perhaps one of the greatest challenges for individuals impacted by the disease (Gerlinger et al., 2013).

Even though schizophrenia is a single diagnosis, it is one of several disorders included in the DSM-5 within the category of “schizophrenia spectrum and other psychotic disorders” (APA, 2013). Manifestations of schizophrenia range in severity, and this disorder has symptoms and etiologies that overlap with other **psychotic disorders**.

Pathophysiology and Etiology

Pathophysiology

Currently the known pathologic mechanisms associated with schizophrenia include anatomic alterations, neurotransmitter abnormalities, and impairments in immune function. The relationship between these mechanisms is complex, and it is not always clear which alterations are a cause of or a consequence of the disease.

Structural Anatomic Alterations

Brain imaging studies of individuals with schizophrenia consistently reveal a pattern of structural abnormalities that

include decreased volumes of gray matter in the prefrontal cortex, temporal lobes, hippocampus, and thalamus; enlarged ventricles and sulci; and decreased blood flow to the frontal lobe, thalamus, and temporal lobes (see **Table 23-11** »). PET scan studies of individuals with schizophrenia reveal alterations in cerebral blood flow and glucose metabolism (Hayempour et al., 2013). Although brain abnormalities are present prior to the onset of symptoms, they are difficult to detect and become more pronounced with the first and subsequent episodes of psychotic symptoms.

Neurotransmitter Abnormalities

Abnormalities in neurotransmitter function contribute to the manifestations of schizophrenia. Alterations in the dopaminergic system have been implicated, in part because antipsychotic medications block the D₂ receptors norepinephrine and serotonin, and because GABA and acetylcholine neurotransmitter systems are also believed to be involved. Nicotinic acetylcholine receptors (nAChR) appear to be diminished in the hippocampus of individuals with schizophrenia, resulting in disturbances in inhibitory gateways. It has been proposed that nicotine stimulates these receptors, providing temporary relief of symptoms of schizophrenia (Mackowick et al., 2014). Research also implicates dysregulation in the NMDA subclass of glutamate receptors in the disease (Frankenburg, 2015; Hu et al., 2015; Moghaddam & Javitt, 2012). Glutamate is required for the degradation of dopamine and several other neurotransmitters that influence prefrontal information processing. Glutamate receptors also play an important role in migration of neurons during brain development. Individuals with schizophrenia have been shown to have abnormally low levels of glutamate in the CSF.

Immunologic and Inflammatory Pathways

Multiple studies support the involvement of inflammatory/immune pathways with an association with chronic oxidative stress (Okusaga, 2014). Microglia normally serve as a first line of defense against pathogenic invasion in the central nervous system. They are also involved in other essential brain functions, including the pruning and maintenance of synapses and the consumption of fragments of damaged cells. When activated, microglia produce inflammatory cytokines, resulting in a cascade of events that alter brain function. One consequence appears to be an interruption of

TABLE 23–11 Typical CNS Abnormalities Observed in Individuals with Schizophrenia

	Increased Size	Decreased Volume	Decreased Blood Flow	Decreased Blood Glucose	Decreased O ₂ Use	Decreased Activity	Decreased Nicotinic Receptors
Ventricles	X						
Sulci	X						
Temporal lobes		X	X				
Hippocampus		X					X
Prefrontal cortex		X				X	
Thalamus		X					
Basal ganglia			X	X	X		
Frontal lobes			X	X	X		

metabolic processes responsible for NMDA receptor activity and dopamine regulation (Frankenburg, 2015; Martínez-Gras et al., 2012). It is known that individuals with schizophrenia have increased levels of cytokines, especially during periods of acute psychosis or relapse (Kirkpatrick & Miller, 2013). It is believed that additional insults such as illness and stress overwhelm an already compromised neuroimmune system, resulting in an exacerbation of cognitive dysfunction (Fineberg & Ellman, 2013; Horváth & Mirnics, 2014; van Venrooij et al., 2012).

Etiology

The exact causes of schizophrenia are not understood. The preponderance of evidence seems to suggest that some individuals have a polygenic predisposition and that a combination of factors, such as prenatal health issues and environmental factors, lead to manifestations of the disorder (Walder et al., 2014). Recent research also highlights an overlap in the genetic influences of schizophrenia and other neurodevelopmental disorders such as autism (De Lacy & King, 2013; Hommer & Swedo, 2015). The myelination of and reorganization of neuronal structures that typically occurs during adolescence seems to have an activating effect, possibly because the process depends on microglia that may have undergone pathologic changes earlier in development (Ahmed, Buckley, & Hanna, 2013; Catts et al., 2013; Fineberg & Ellman, 2013; Rapoport, Giedd, & Gogtay, 2012).

Previously, it was theorized that specific patterns of interaction in families played a key role in the development of schizophrenia. These **communication deviance** theories postulated that patterns of disorganized communication arose from repeated exposure to contradictory and conflicted messages. It is now believed that, in susceptible individuals, exposure to any overwhelming adversity stimulates a human stress of the hypothalamic–pituitary–adrenal (HPA) axis. This results in suppression of immune dysfunction and ultimately further decompensation of neuronal networks (Akdeniz, Tost, & Meyer-Lindenberg, 2014). It is important to remember that alterations in communication in family members of the individual with schizophrenia or any other psychiatric illness may be the result of the *bidirectional* nature of such conditions. That is, while family members may have a negative impact of the emotional health of the individual, the stress of coping with a family member

with a major mental illness can also lead to a breakdown in family interactions.

SAFETY ALERT Among individuals diagnosed with schizophrenia, an estimated 20 to 40% attempt suicide. Factors associated with this risk include (but are not limited to) greater awareness of the illness, younger age, recent loss, limited support, recent discharge, and treatment failure. Regardless of the treatment phase or the presence of additional risk factors, all individuals with schizophrenia should be closely monitored for suicide.

Risk Factors

Schizophrenia is a multifactorial disease influenced by a confluence of genetic, epigenetic, environmental, and developmental factors. One of the challenges of the disorder is that many of the associated risk factors lack the specificity or strength to guide preventative health measures.

Genetic Factors

Genetic factors significantly impact susceptibility and the risk for schizophrenia. Whereas members of the general population have a 1% risk of schizophrenia, individuals with an affected third-degree relative, such as a cousin, have a risk of 2%, and individuals with an affected second-degree relative (such as an aunt, uncle, half-sibling, or grandparent) have a risk of 2–6%. An individual who has a first-degree relative with schizophrenia (such as a parent or sibling) has a risk of schizophrenia of almost 50% (Light et al., 2014; Ripke et al., 2014). However, no single gene or set of genes has been implicated as a marker for the disorder, and approximately 60% of all individuals with schizophrenia have no known family history of the disease. The risk of schizophrenia increases incrementally with advancing paternal age as a result of cumulative mutations in sperm. Children born to fathers 60 years old and older have an almost twofold risk of developing the disorder (Ek et al., 2015; Frans, MacCabe, & Reichenberg, 2015; Hui et al., 2015; Jaffe et al., 2014; Smith, R., et al., 2013).

Epigenetic Factors

Most researchers now agree that external modifications to genes (**epigenetic** factors) must occur in order for schizophrenia to manifest. Many studies have focused on the impact of external events such as birth complications, in

utero viral exposure, poor prenatal care, and marijuana use on gene expression in schizophrenia (Giovannoli et al., 2013; Kirkbride et al., 2012; Kundakovic, 2014; Sutterland et al., 2013). Recent research has implicated *Toxoplasma gondii* infection (toxoplasmosis) during pregnancy and early childhood in the development of the disease. *T. gondii* is spread via contact with cat feces, and it is recommended that pregnant women and children do not handle cat litter and that litter boxes be changed daily (Flegr, 2015; Torrey, Simmons, & Yolken, 2015).

Psychosocial Factors

Psychosocial factors such as early life adversity (including exposure to chronic and acute stressors such as poverty, violence, and trauma) have also been implicated in schizophrenia. Psychosocial risk factors are increased in instances where disparities in healthcare exist, such as with recent immigrant populations. Biochemical mechanisms involved in the stress response may have an epigenetic influence or exacerbate preexisting neuronal pathology (Kirkbride et al., 2012).

Developmental Factors

There is evidence to suggest that children and adolescents who display certain alterations in emotional, cognitive, language, and motor development are at an increased risk for developing schizophrenia. These findings may relate to manifestations of neurodevelopmental problems that precede the prodromal and active phases of the illness (Laurens et al., 2015). Stress that occurs during certain developmental periods such as early childhood or adolescence may confer a greater risk of developing the disorder.

Prevention

Primary prevention of schizophrenia includes comprehensive healthcare during pregnancy and childhood, and measures to reduce or eliminate adversity and environmental insults (e.g., poverty, abuse, trauma, injury, or exposure to environmental toxins). Secondary prevention of schizophrenia focuses on high-risk groups such as individuals who have a family history of the disorder or who demonstrate behaviors associated with progression to **psychosis**, acute periods of disordered thinking that affects the individual's perception of reality. Interventions include augmenting protective factors for the disease (e.g., teaching social skills or improving family interactions) and treating comorbid psychiatric conditions (Tandon et al., 2012). Research demonstrates that early screening and detection of cognitive, developmental, and behavioral alterations associated with schizophrenia and other mental illnesses may result in better outcomes for individuals, especially when nonpharmacologic interventions such as cognitive-behavioral therapy (CBT) are employed (Stafford et al., 2013; Tandon et al., 2012; Valmaggia et al., 2015). Some aspects of secondary prevention of schizophrenia present ethical challenges, such as the practice of initiating antipsychotic treatment when prodromal symptoms are apparent. The risks associated with labeling and treating individuals who may or may not go on to develop the disorder need to be considered (Appelbaum, 2015).

Tertiary prevention focuses on reducing the impact of the disease in individuals diagnosed with schizophrenia. A diagnosis of schizophrenia is devastating to both patients

and families. Holistic care aims to help patients to manage the disorder in the community, to provide support for family members and caregivers, and to prevent or manage comorbidities commonly associated with the disorder. Two critical components of health promotion for schizophrenia are an emphasis on **recovery** and **rehabilitation**. In the recovery phase, the symptoms of the disorder are present but under control. The emphasis for healthcare is on learning strategies to maintain health, such as adhering to treatment, reducing stress, and using effective coping strategies. The goal is the prevention of **relapse** (or a return to the acute phase of the illness). *Rehabilitation* refers to a level wellness in which symptoms of the condition are under control to the extent that the affected individual can engage in goal-directed activities (e.g., maintaining a job, carrying out self-care) (Potter & Moller, 2016).

Clinical Manifestations

The clinical manifestations of schizophrenia may be classified according to the stage of illness as well as the types of symptoms that are observed. Presenting symptoms may vary from person to person, with periods of exacerbation and remission. The trajectory of the illness must be recognized and understood in order to address the unique needs of individuals with the disorder. Many, but not all, individuals with schizophrenia experience sufficiently severe clinical manifestations that they have difficulty engaging in ADLs and functioning independently. These patients may benefit from in-home services, day treatment programs, group homes or residential care, or psychiatric rehabilitation through community services.

Symptom Types

The symptoms of schizophrenia are generally divided into positive, negative, and cognitive types, as depicted in **Figure 23-7**. There is some overlap in the classification of symptoms, and the presence of these manifestations does not necessarily indicate that an individual has schizophrenia. Affective symptoms are normally not included in these classifications but are common in schizophrenia and are also discussed in this section. The manifestation of symptoms varies according to the phase of the illness.

Positive Symptoms

Positive symptoms are characterized by the psychotic features of the disorder that generally do not occur in healthy people and are outside of the range of normal experiences. Hallucinations, delusions, abnormal movements, and problems with speech or disordered thinking are all classified as positive symptoms.

Hallucinations are abnormal perceptual experiences that usually occur in the absence of external stimuli. Types of hallucinations are discussed in more detail in the Alterations section of this module. In individuals with schizophrenia, auditory hallucinations are generally most prevalent and often have threatening or accusatory content (Docherty et al., 2015).

Delusions are false beliefs that are based on faulty perceptions and inferences. The most common delusions seen in patients with schizophrenia are those of *reference*, which incorporate the belief that certain events occur for the benefit

Figure 23–7 » The symptoms of schizophrenia have been categorized as positive, negative, and cognitive.

of the individual. Nihilistic delusions encompass beliefs that the individual is nonexistent or dead. Religious delusions involve the belief that the individual is a religious figure. Grandiose delusions involve beliefs that the individual has special power or significance. Persecutory delusions involve the belief that others wish to harm the individual. Delusions may take on bizarre or implausible features such as thought broadcasting (belief that others can hear thoughts), withdrawal (belief that others can remove thoughts), control (belief that others can control thoughts), and insertion (belief that others can insert thoughts into the person's mind).

Motor symptoms are common in individuals with schizophrenia and range from motor retardation or slowing to posturing and catatonic states. **Catatonia** is a state of unresponsiveness in an individual who is conscious. It may incorporate features such as *mutism* (lack of speech), *echopraxia* (repeating the movements of others), *echolalia* (repeating the words of others), *waxy flexibility* (maintaining whatever position the individual is placed in), and *automatic obedience* (automatic, robotic cooperation with requests). Catatonia can also manifest as an excited state that includes combativeness and impulsivity. Other motor symptoms may be the result of associated neurologic abnormalities and include oculomotor abnormalities, grimacing, and problems with motor sequencing and coordination (Damilou et al., 2016; Varambally, Venkatasubramanian, & Gangadhar, 2012).

Disorganized thinking is generally manifested in disruption of the form and organization of speech and is also referred to as a formal thought disorder (FTD). Individuals with an FTD lack appropriate, goal-directed thought processes and demonstrate a pattern of abnormal speech, including **loose associations**, tangentiality, incoherence, circumstantiality, and pressured speech. Table 23–1 provides definitions for these indicators of disorganized thinking.

Negative Symptoms

Negative symptoms refer to affects and behaviors that are diminished or absent in individuals with schizophrenia. These include having a flat or blunted affect, thought blocking (a sudden interruption in speech without explanation), **alogia** (poverty of thought and speech), **anhedonia** (inability to experience pleasure), **avolition** (lack of motivation or initiative), and social withdrawal. Negative symptoms tend to persist during all phases of the illness, are difficult to treat, and account for the some of the most disabling manifestations of the illness.

Cognitive Symptoms

Cognitive symptoms of schizophrenia include deficits in memory, attention, language, visual-spatial awareness, social and emotional perception, and intellectual and executive function. Memory deficits impact verbal processing, and individuals with schizophrenia may have difficulty with verbal fluency, pragmatics, and other aspects of spontaneous language. Visual memory deficits and impaired spatial processing also contribute to impaired social interactions. Individuals with schizophrenia often demonstrate poor facial recognition (facial agnosia) and may have difficulty with proxemics and nonverbal processing (e.g., modulating how close to stand to someone, interpreting nonverbal gestures). Individuals with schizophrenia demonstrate difficulty with attention and vigilance and may have difficulty concentrating on tasks that require a sustained focus. They are prone to sensory overload due to difficulty filtering out extraneous information. Studies have demonstrated an association between diminished global intellectual functioning and schizophrenia, with many affected individuals having difficulty with measures of both verbal and perceptual reasoning. Patients with schizophrenia frequently demonstrate **concrete thinking**, focusing on literal aspects of facts and details. They also typically exhibit limited insight due to deficits in theory of mind (Bora & Pantelis, 2013). Problems with executive functioning may manifest as difficulty with planning and organization, problem solving, and modulating impulses. Studies have shown that higher levels of cognitive impairment in individuals with schizophrenia are associated with poorer overall outcomes (Keefe & Harvey, 2012).

Affective Symptoms

In addition to positive, negative, and cognitive symptoms, patients with schizophrenia may also exhibit a number of affective symptoms, especially depression. Affective symptoms such as depression significantly increase the risk of suicide in patients with schizophrenia, especially in combination with other variables such as younger or older age, high IQ, higher levels of premorbid function, proximity to onset, male sex, and recent discharge from the hospital (Popovic et al., 2014).

Phases of the Illness

The classic course of schizophrenia consists of premorbid, prodromal, acute and residual phases. Research demonstrates that acute symptoms of the disorder appear to diminish as individuals grow older, with negative and cognitive

symptoms becoming more pronounced and disabling. Some individuals may actually achieve complete remission of psychotic symptoms (Jeste & Maglione, 2013). Possible explanations for this include age-related dopaminergic activity changes.

Premorbid

Although 75% of patients with schizophrenia are diagnosed during adolescence or early adulthood, a number of alterations may be evident during childhood and the period immediately preceding the onset of the illness. **Premorbid** manifestations occurring in childhood include a number of nonspecific emotional, cognitive, and motor delays that have been identified in individuals who went on to develop schizophrenia (Stafford et al., 2013).

Prodromal Phase

The prodromal phase is a symptomatic period that signals a definite shift from premorbid functioning and continues until psychotic symptoms emerge. Manifestations include sleep disturbance, poor concentration, social withdrawal, perceptual abnormalities, and other attenuated or weakened symptoms of psychosis. A dramatic drop in functional or adaptive capabilities may occur with academic and vocational failure. The length of the prodromal period varies considerably, but for most individuals it lasts for 2 to 5 years (Fusar-Poli et al., 2014; Tandon et al., 2013).

Acute Phase

The acute phase of the illness is marked by the onset of florid psychotic/positive symptoms. It generally follows the prodromal period but in some instances appears suddenly. This period causes significant distress for the individual and is often the first time that help is sought. If the behavior represents a danger to the individual or others, short-term hospitalization may be required. The number of acute phases experienced by individuals is highly variable and depends, in part, on the ability to access high-quality treatment. In general, longer durations of untreated acute psychosis are associated with poorer long- and short-term patient outcomes (Chou et al., 2014).

Residual Phase

The **residual phase** of schizophrenia can be further broken down into the stabilization phase (6–18 months after the resolution of the acute phase) and the maintenance phase. The **stabilization phase** involves the immediate period of *recovery*, in which symptoms are under control but the individual is struggling to overcome exhaustion and cope with the impact of the illness. The **maintenance phase** corresponds with *rehabilitation* and a return to goal-directed activities and some level of functional status, such as holding down a job. It is important to remember that disabling cognitive and negative symptoms may persist during the residual phase. In addition, the patient may continue to demonstrate odd patterns of thinking and behavior. The level of dysfunction often increases with each subsequent episode of relapse. Patients often struggle with **side effects** of their medication and may lack the insight and/or motivation required to adhere to treatment. Comprehensive treatment may reduce the risk of relapse, but it not always

possible to prevent it altogether. Careful monitoring of symptoms can often detect a shift toward the active state of the illness (Stahl et al., 2013).

Comorbid Disorders

Schizophrenia is associated with a number of psychiatric and medical comorbidities described in this section. The presence of these conditions adds to the overall burden of the illness and accounts for the significant reduction in lifespan for affected individuals. Contributing factors to comorbid illness include self-care deficits, sedentary lifestyles, social isolation, lack of access to quality healthcare, and poor dietary habits.

Individuals with schizophrenia are at increased risk for cardiovascular disease, diabetes, COPD, and many infectious diseases. Women with schizophrenia may have a higher incidence of medical problems and are more likely to experience more than one condition (Smith, D., et al., 2013). Approximately 80% of individuals with schizophrenia smoke cigarettes, possibly because of the short-term relief of symptoms associated with nicotine and its effect on nicotinic receptors (Brunzell & McIntosh, 2012). Some studies suggest that cardiovascular problems in patients with schizophrenia are frequently undertreated by healthcare providers (Crump et al., 2013; Smith, D., et al., 2013). Treatment with antipsychotic medications contributes to the overall risk of both cardiovascular disease and diabetes, as common effects include sedation, increased food intake, hyperlipidemia, and alterations in glucose regulation (Crump et al., 2013).

Comorbid substance abuse is found in almost 50% of all individuals with schizophrenia, a condition identified as **dual diagnosis**. Apart from caffeine and nicotine, the main substances of abuse used by individuals with schizophrenia are alcohol (20% over a lifetime), cannabis (lifetime prevalence 30%), and cocaine (lifetime prevalence 15–50%). As mentioned previously, the majority of individuals with schizophrenia smoke cigarettes and are far more likely to consume excess amounts of caffeine (>200 mg/day) than the general public (Thoma & Daum, 2013).

An estimated 25 to 60% of individuals with schizophrenia experience comorbid depression. Interestingly, multiple studies indicate that individuals with higher levels of premorbid function and greater awareness of the implications of their disorder are more likely to experience depression. Anxiety disorders also occur with greater frequency in schizophrenia, with approximately 10–15% of the population experiencing panic attacks and up to 20% having obsessive-compulsive disorder. Posttraumatic stress disorder may be seen in 12–19%. (Tsai & Rosenheck, 2013).

Collaboration

The management of schizophrenia is challenging for both patient and healthcare providers. A number of factors complicate treatment. These include characteristic clinical manifestations such as avolition and disordered thought processes and a fractured healthcare system. Although schizophrenia is a biological illness, many insurance policies continue to place restrictions on the types of services that can be accessed. State and federal funding for prevention and treatment of mental illness is not always a priority, as our society still retains many biases and misconceptions about mental illness.

Another factor complicating the diagnosis and treatment of schizophrenia relates to cultural biases and influences. Providers often misinterpret cultural differences in behaviors and perceptions (see Focus on Diversity and Culture: Schizophrenia). In this section, collaborative care options are discussed, but nurses must recognize that vast improvements in our healthcare system, including cultural competency of providers, are needed to ensure that all patients have access to quality care.

Diagnostic Tests

Qualified mental health providers diagnose schizophrenia on the basis of findings obtained during a psychiatric evaluation of the patient. The evaluation generally includes a history and examination and may incorporate the use of screening tools and psychometric tests. Medical tests such as laboratory values and imaging studies are used to rule out other conditions. The patient must meet the criteria identified in the DSM-5, as exemplified by clinical manifestations described earlier. Diagnostic criteria specify that the individual must have experienced significant impairment of functioning for six or more months in one or more areas, such as home, work,

Focus on Diversity and Culture Schizophrenia

Numerous studies have demonstrated that African and Latino Americans are up to three times more likely to be diagnosed with schizophrenia than are Caucasian Americans. Researchers have concluded that this phenomenon occurs even in the absence of a genetic predisposition to the disorder within these populations, leading the researchers to suggest that cultural biases play a significant role (Schwartz & Blankenship, 2014). Psychiatric diagnoses rely, in part, on clinician judgment about whether or not certain behaviors deviate from the norm. In many instances, providers do not account for cultural variances or the context in which the behaviors occur (Spector, 2017). It is possible that individuals from communities of color may be more reluctant to report affective symptoms that suggest other disorders. In addition, some perceptual experiences may be influenced by cultural beliefs. Nurses and other healthcare providers need to assess individual variables that may lead to misdiagnosis. Nursing care should not be dependent on diagnostic labels that may not consider patient-centered needs.

Figure 23-8 » These PET scans show the difference between the brains of a normal patient and a patient with schizophrenia during a verbal fluency task—that is, the patients were asked to speak words. The red and yellow areas were activated when the subjects spoke the words. In the normal subject (top row), the brain shows much activity in the prefrontal and motor areas, and less activity in the parietal area on the left side. In the subject with schizophrenia (bottom row), there is also activity in the middle temporal gyrus (lower center of brain), which is not seen in the normal subject.

and self-care. Other mental disorders, such as bipolar disorder, and substance use also must be ruled out for a diagnosis of schizophrenia to be made (APA, 2013; Weickert et al., 2013).

Like other neurocognitive disorders discussed in this module, a number of biomarkers have been identified for schizophrenia, including the brain-imaging findings depicted in **Figure 23-8** ». Presently biomarker analysis is used for research purposes, but in the future it may be used to confirm preclinical findings or to validate a diagnosis of schizophrenia.

Pharmacologic Therapy

The first line of intervention for schizophrenia is pharmacologic treatment with antipsychotic medications. The primary goal of pharmacotherapy is to decrease the positive symptoms of the disorder to a level that enables the individual to maintain social relationships and complete ADLs with minimal assistance. Antipsychotics do not cure schizophrenia, and complete remission is achieved in only about two thirds of patients taking these medications (Dold & Leucht, 2014). The relapse rate for individuals who discontinue the drugs is approximately 60–80% (Adams et al., 2017). Adherence to pharmacologic treatment is challenged by factors such as denial or poor insight into the illness, self-care deficits, and the incidence of common and serious adverse effects.

Antipsychotic medications include older, conventional agents called typical antipsychotics (first generation), atypical

antipsychotics (second generation), and dopamine system stabilizers (third generation) outlined in the Medications table in the section on Collaborative Therapies at the beginning of this module. Within each classification, different agents have properties that may make them more or less suitable for treating certain target symptoms. In addition, the profile of side effects and adverse effects may differ. When selecting an agent to treat psychotic symptoms clinicians, consider factors such as the severity of symptoms, prior degree of symptom response, adherence factors (e.g., dosing convenience, cost), side effect profile, and patient needs (Stahl et al., 2013). Long-acting injectable formulations may increase adherence. The efficacy of all classes of antipsychotics in treating the acute symptoms of the disease is about the same. An adequate treatment trial, with the full response to the medication being demonstrated, may take anywhere from 3 to 10 weeks and is necessary to evaluate efficacy, although symptoms such as hallucinations and delusions may diminish in days.

Typical or conventional antipsychotics consist of phenothiazine type (such as chlorpromazine) and nonphenothiazine (haloperidol). This is the “first generation” of drugs introduced to treat schizophrenia. The mechanism of action for both phenothiazine and nonphenothiazine antipsychotics is believed to be the blocking of postsynaptic D_2 receptors. Unfortunately, there are numerous adverse effects associated with typical antipsychotics that range from uncomfortable to

disabling and life threatening. Anticholinergic effects occur, such as dry mouth, sedation, constipation, postural hypotension, and urinary retention. These effects are uncomfortable and place patients at increased risk of injury and infections. Sexual side effects such as ejaculation disorders and delay in achieving orgasm may be troubling for patients. Endocrine effects such as hyperprolactinemia can lead to osteoporosis, menstrual irregularities, decreased libido, gynecomastia, lactation, and erectile dysfunction.

Extrapyramidal symptoms (EPS) frequently occur with first-generation antipsychotics and include *acute dystonia*, *akathisia*, secondary *parkinsonism*, and *TD*. The most common EPS is **akathisia**, a feeling of uncomfortable restlessness that is often not recognized and managed appropriately. **Dystonia** often results in sudden and severe muscle spasms in the face, neck, and torso that can be frightening for patients and have the potential to lead to airway obstruction if not identified and reversed. Secondary parkinsonism is manifested by tremors, muscle rigidity, masked facies (lack of expression), stooped posture, and shuffling gait. **Tardive dyskinesia (TD)** is a potentially irreversible condition characterized by unusual facial movements, lip smacking, and wormlike movements of the tongue. **Neuroleptic malignant syndrome (NMS)** is a potentially fatal condition characterized by severe autonomic instability. Manifestations include high fever, confusion and changes in level of consciousness, muscle rigidity, and hyperthermia. Management of adverse effects such as anticholinergic symptoms and EPS often includes the use of anticholinergic medications such as benztropine (Cogentin). Antiparkinsonian/antimuscarinic drugs such as trihexyphenidyl (Artane) may be used to decrease stiffness and rigidity. Parenteral benztropine and diphenhydramine (Benadryl) can quickly reverse dystonia. Beta-adrenergic blockers and benzodiazepines may reduce the symptoms associated with akathisia. TD is usually managed with a reduction in dose or a switch to another agent. If NMS is suspected, antipsychotic agents are immediately discontinued and the patient is admitted to the intensive care unit (ICU) for supportive care.

Atypical antipsychotics (also called second-generation antipsychotics) are believed to also block D₂ receptors, although they have a weaker affinity that may account for the lower profile of certain side effects. In addition, atypical antipsychotics also block serotonin and alpha-adrenergic receptors. It is believed that these agents also treat some of the negative symptoms of the illness, although the clinical significance of this has recently come under question (Fusar-Poli et al., 2015). Examples include risperidone (Risperdal) and olanzapine (Zyprexa). One advantage of atypical antipsychotics seems to be a lower incidence of EPS and TD at therapeutic doses. However, adverse effects can still be quite severe, with an increased risk of medical problems such as metabolic syndrome, cardiovascular and cerebrovascular events, type 2 diabetes mellitus, blood dyscrasias, seizures, and sudden death. Anticholinergic effects, endocrine effects, TD, and NMS can also occur with these medications.

Dopamine-serotonin system stabilizers (DSSs—also called dopamine partial agonists or third-generation antipsychotics) have therapeutic benefits similar to those of atypical antipsychotics and an even lower profile of adverse effects. These agents are generally well tolerated, with very few anticholinergic side effects and a lower incidence of

weight gain. They also seem to target affective symptoms and are often used to treat bipolar disorder and depression. Aripiprazole (Abilify) was the first drug approved from this class, and a new drug, brexpiprazole (Rexulti), was recently approved. Because of its similar therapeutic action, aripiprazole is included in the Medications feature with the atypical antipsychotics.

In addition to antipsychotics, individuals may be treated with adjunctive medications such as antianxiety agents, antidepressants, and mood stabilizers. These medications are discussed in the Collaborative Therapies section in the introduction to this module and in the modules on Stress and Coping and on Mood and Affect.

Nonpharmacologic Therapy

As mentioned previously, the recovery and rehabilitation model is the overarching approach to caring for individuals with schizophrenia outside of hospital and institutional settings. This model does not represent any single distinct pathway to care, but instead recognizes that each individual maintains their own life goals and should be provided with a variety of resources that will empower them to make informed decisions and build on their own strengths in order to regain control of their lives. Pharmacologic interventions alone are insufficient to address the complex needs of individuals with schizophrenia. Nurses providing care to patients with schizophrenia across all settings can anticipate interfacing with a variety of team members, including psychiatrists, social workers, occupational therapists, psychologists, psychiatric rehabilitation specialists, and mental health workers.

Family Intervention and Psychoeducation

Research demonstrates that the provision of family interventions, such as psychoeducation and counseling, can reduce the relapse rate for schizophrenia by up to 20% (Pitschel-Walz et al., 2015). Studies indicate that the best results are achieved when family interventions continue over several months and are combined with pharmacologic interventions and other treatment modalities. Some studies indicate that family psychoeducation in particular reduces the subjective burden of schizophrenia and leads to a more positive family atmosphere (Gühne et al., 2015).

Social Skills Training

Schizophrenia is characterized by deficits in social cognition that have a profound effect on the individual's ability to accurately read social cues and respond appropriately. Social skills training employs a systematic approach to teaching individuals with schizophrenia how to interact with others. One particularly effective approach is Social Cognition and Interaction Training (SCIT). SCIT is a group intervention delivered over a 6-month period. Participants work with trained therapists on three phases that consist of learning about emotions, figuring out situations, and practicing what was learned. Computerized exercises, videos, and other tools may be used to enhance learning. The overall effectiveness of such programs is still under investigation; however, early studies suggest that the best results are achieved when SCIT is combined with cognitive remediation (Bowie et al., 2012; Gühne et al., 2015; Kurtz & Richardson, 2012; Roberts et al., 2014).

Cognitive–Behavioral Therapy

CBT is a psychosocial treatment that may be helpful in assisting patients with schizophrenia to cope with their symptoms by using distraction, positive self-talk, or behavioral processes such as exercising. In CBT, patients are encouraged to reframe symptoms of psychosis as attempts to cope. Problem-solving techniques are used to identify and make use of new coping strategies. Although earlier studies supported the efficacy of CBT for schizophrenia, a systematic review and meta-analysis conducted in 2014 indicates that CBT results in modest therapeutic effects (Jauhar et al., 2014). Some researchers argue that these findings are too restrictive, underestimating the benefits of more focused techniques and failing to consider benefits outside improvement in positive and negative symptoms (Mueser & Glynn, 2014; Thase, Kingdon, & Turkinton, 2014; Turner et al., 2014).

Cognitive Remediation

Cognitive remediation or rehabilitation includes strategies aimed to address cognitive deficits associated with schizophrenia. Techniques are similar to educational interventions employed in special education and focus on compensatory strategies as well as drill and practice techniques aimed at strengthening specific cognitive functions, such as working memory. Compensatory techniques include organizing and modifying the home environment to support adaptive function (labeling items, making lists, posting emergency numbers) and assisting patients to break down new skills into smaller steps that are then overlearned. Rehabilitation techniques include the use of computer programs that “exercise” certain cognitive functions through engaging games and activities. Because many models are used, the efficacy of these programs is difficult to measure; however, studies suggest that the most effective models address beliefs and motivation and incorporate opportunities for real-world practice (Bowie et al., 2012; Medalia & Saperstein, 2013).

Vocational Training

Vocational rehabilitation or training encompasses a variety of services aimed at increasing functional capacity and reducing unemployment for individuals with schizophrenia. Prevocational programs aim to increase employability by providing skills training. Supported employment programs assist patients to find and maintain employment. Vocational training may be incorporated into one of the community service models discussed in this section.

Community Service Models

A variety of community service models are available to address the needs of individuals with schizophrenia. Some of the most common models include crisis intervention teams, case management, and ACT.

Crisis intervention refers to short-term, intensive measures to address symptoms or behaviors that impact the safety and equilibrium of the patient and others. The portal of entry into crisis intervention may be the emergency department or through a mobile crisis intervention or outreach team. After an assessment is made, interventions such as medication adjustment, 24-hour monitoring, ECT, or a change in services are implemented in the least restrictive environment possible. For some patients, this may mean a

short inpatient stay; for others, services may be provided in the community in the patient’s home, in a residential treatment center, or through a combination of partial day treatment and home care. **Mobile crisis outreach teams** consist of interprofessional team members who are deployed to the site of the crisis for assessment and intervention. They have special training that may be used to effectively de-escalate the situation and usually work in collaboration with law enforcement.

» **Stay Current:** For more information on mobile outreach teams and other crisis interventions services visit the National Alliance for the Mentally Ill (NAMI) “Getting Treatment During a Crisis” At <https://www.nami.org/Learn-More/Treatment/Getting-Treatment-During-a-Crisis>

Case management is a method of coordinating care by assigning each individual to a case manager or a qualified person who completes an assessment of patient needs, develops a plan, coordinates appropriate services, monitors the quality of care being provided, and maintains a collaborative relationship with the affected individual (see the module on Managing Care). Many variables impact the efficacy of this model, including availability of community resources, caseload, and clinician experience and training. These variables make it difficult to support or refute the overall effectiveness of these programs (Dadich, Fisher, & Muir, 2013).

Assertive community treatment (ACT) aims to meet many of the same goals as case management, but ACT is a service delivery model in which interprofessional team members share accountability for meeting patient needs in a collaborative and often intensive manner. Most individuals involved in ACT can expect to meet with more than one team member on a weekly basis. Services are available 24 hours a day and 7 days a week. ACT models follow a specific high-fidelity framework for meeting patient needs (such as medical care, housing, social support, and employment) by limiting team-member caseloads to no more than 10 individuals and by providing services directly rather than relying on referrals to agencies. The usefulness of ACT has been validated by research, which shows that ACT decreases patient hospitalization time and severity of symptoms while improving stability and quality of life (Bond & Drake, 2015; Schöttle et al., 2014).

» **Stay Current:** For more information on ACT programs and free evidence-based tool kits, visit the Substance Abuse and Mental Health Services Administration at <http://store.samhsa.gov/product/Assertive-Community-Treatment-ACT-Evidence-Based-Practices-EBP-KIT/SMA08-4345>

Individual, Family, and Group Therapy

The benefits of group, individual, and family therapies for other alterations in psychosocial function are discussed in the modules on Self, Stress and Coping, and Mood and Affect. Group interventions vary from self-help groups to those that have more focused on specific goals such as psychoeducation or social skills. The individual needs of the patient and family are used to determine which groups are most likely to provide the greatest benefits. Comprehensive care should include individual counseling for the patient with schizophrenia as well as counseling to address the unique burdens and challenges of the patient’s family.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is a procedure that delivers electronic impulses into the brain under general anesthesia. The goal of treatment is to induce seizure activity that, for the most part, is effective in treating affective disorders such as depression. ECT is not typically used to treat schizophrenia but appears to demonstrate some efficacy in treating certain symptoms of schizophrenia such as depression, paranoia, and catatonia (Zervas, Theleritis, & Soldatos, 2012). ECT is most effective when used in conjunction with medication. For more information on this procedure, refer to the module on Mood and Affect.

Repetitive Transcranial Magnetic Stimulation

Repetitive transcranial magnetic stimulation (rTMS) is a type of therapy that uses an electromagnet placed on the scalp to deliver pulses roughly equivalent to the strength of an MRI. The FDA approved rTMS for the treatment of depression in 2008. The efficacy of rTMS in treating auditory hallucinations and other symptoms of schizophrenia has been the subject of research for several years. A recent Cochrane review conducted by Dougall and colleagues (2015) concluded that, while some studies have suggested improvements in patients, there is currently insufficient robust evidence to conclude that rTMS is an effective standardized treatment for schizophrenia.

» **Stay Current:** For more information on collaborative treatments used to treat schizophrenia, visit <http://www.nami.org/Learn-More/Mental-Health-Conditions/Schizophrenia/Treatment>

Complementary Health Approaches

Integrative and complementary treatments for schizophrenia include the use of nutritional interventions and supplements and the use of mind-body practices. There is no evidence to suggest that any of these treatments are effective alternatives to the collaborative interventions just discussed.

Research on nutritional interventions has focused on potential risks and benefits of supplementation with B vitamins, vitamin D, and omega-3 fatty acids. Currently the most positive and conclusive findings support the use of omega-3 fatty acids in the prodromal and residual phases of the disease (Arroll, Wilder & Neil, 2014; Chia et al., 2015). However, at least one randomized controlled study suggested that the use of omega fatty acids in the acute phase of the illness may actually exacerbate symptoms (Emsley et al., 2014). Safety and practical considerations should guide the use of nutritional interventions. The use of supplements should be discussed with providers so that an individual assessment of the risks versus potential benefits can be made.

Data regarding the effectiveness of mind-body interventions to manage the symptoms of schizophrenia is mixed. A systematic review conducted by Helgason and Sarris (2013) found mainly supportive evidence for music therapy, meditation, and other mindfulness techniques. Relaxation techniques, yoga, and mind-body groups had some supportive evidence. Evidence on the use of art therapy, drama, dance therapy, hypnosis, and biofeedback techniques was inconclusive at best.

Lifespan Considerations

As previously stated, the majority of individuals with schizophrenia experience an emergence of symptoms in

early adulthood with a classic course preceded by prodromal symptoms and a lessening of positive symptoms with aging. The remainder of individuals with schizophrenia may be grouped into those with an early-onset schizophrenia (EOS) of the disorder (before the age of 18) or a pattern of later onset (after the age of 40), sometimes referred to as late-onset schizophrenia (LOS).

Early-Onset Schizophrenia

EOS generally refers to the emergence of symptoms of schizophrenia before 17 to 18 years of age. EOS accounts for approximately 4–5% of all individuals with schizophrenia. Onset prior to puberty is extremely rare, occurring in less than 0.04% of the population and is further classified as childhood-onset schizophrenia (COS). In general, childhood schizophrenia may be more difficult to diagnose. Hallucinations are less complex and may focus on childhood themes such as monsters and toys, making them difficult to distinguish from fantasy play. Symptoms such as disordered speech, motor deficits, cognitive deficits, and social withdrawal may overlap with manifestations of developmental disorders such as autism spectrum disorders (ASD) (Clemmensen, Vernal, & Steinhausen, 2012).

Adolescents who experience EOS demonstrate symptoms similar to the adult variants of the disorder. Onset in adolescence seems to be at least slightly more prevalent in boys and is associated with an increased risk of suicide (Clemmensen et al., 2012; Kelleher et al., 2012). The overall prognosis for both children and adolescents with EOS is poor and is associated with greater chronicity and higher levels of disability (Bartlett, 2014; Driver, Gogtay, & Rapoport, 2013). Management of EOS includes many of the same treatments and therapies that are used with adults with appropriate developmental modifications. Children are at increased risk of adverse effects from psychotropic medications, and many agents do not demonstrate the same efficacy as is observed in adults (Driver et al., 2013).

Late-Onset Schizophrenia

About 20–30% of all patients do not experience symptoms of schizophrenia until after age 40. The incidence of LOS seems to be greater in women, but other risk factors for the disease are comparable to those associated with an earlier onset. Typically, positive symptoms of the disease are more predominant, with paranoia, elaborate delusions, and hallucinations (Hansen et al., 2015). Both cognitive and negative manifestations of the disease are higher than in the general population but lower than what is commonly observed in adult-onset schizophrenia. Patients with LOS often respond to lower doses of antipsychotic medication. These findings have led some scientists to suggest that late-onset schizophrenia may even represent a distinct disorder (Maglione, Thomas, & Jeste, 2014).

When symptoms of schizophrenia do not emerge until after age 60, the condition is often referred to as very-late-onset schizophrenia (VLOS). VLOS can be distinguished from other variants by a lower genetic load and a higher level of premorbid function. The etiology of VLOS is believed to be neurodegenerative and organic factors. The incidence is higher in immigrant populations, suggesting that sociocultural factors also play a role (Nebhinani, Pareek, & Grover, 2014). Management may include lower-dose antipsychotics and psychosocial interventions.

NURSING PROCESS

The application of the nursing process depends on many factors, including the phase of the illness the patient is experiencing. Primarily, nursing goals for patients with schizophrenia include promoting symptom control and facilitating effective coping to help the patient achieve optimal mental, physical, and social functioning. Ideally, the patient will avoid further episodes of psychosis and be able to function successfully in the community to the greatest degree possible.

Assessment

Nursing assessment of a patient with schizophrenia typically involves three main elements: a patient interview, a physical examination, and a mental status examination.

Observation and Patient Interview

Nurses and others may notice the following in patients with schizophrenia: deteriorating personal appearance and neglect of personal hygiene; weight loss; unusual gestures; pacing; or incoherence characterized by making up words or speaking in sentences that make no sense (word salad). Many individuals with schizophrenia smoke, so a noticeable odor of smoke or tobacco may be present. A lack of insight is characteristic of schizophrenia, so patients may be unaware of these changes or actions.

The patient interview can reveal risk factors for schizophrenia, as well as help identify early signs of psychosis in patients who have not yet been diagnosed. For the patient with known or suspected schizophrenia, elements of the health history should include age; family history and paternal age; history of perinatal health problems or exposures, developmental delays, or exposure to trauma or adversity; history of behaviors such as substance abuse; history of positive, negative, cognitive, and affective manifestations; family coping; history of commonly comorbid mental illness (e.g., addiction, anxiety disorders, or mood disorders); and presence or emergence of major life stressors.

For the patient diagnosed with schizophrenia, ask about possible risk factors for exacerbations or signs of relapse, such as:

- Poor adherence to the prescribed treatment regimen (especially pharmacologic therapy)
- Possible development of resistance to antipsychotic medications
- Presence of mild to full-blown symptoms of psychosis
- Recent life events that may increase the likelihood of relapse

Physical Examination

Next, during the physical examination, evaluate the patient's overall physical condition. Throughout the physical exam, remain alert for possible signs of metabolic problems, cardiovascular problems, drug/alcohol abuse, and poor self-care, as schizophrenia increases the risk for all of these. Note any evidence of side effects from medications, such as movement problems, weight gain, or changes in vital signs.

Mental Status Examination

Finally, individuals with known or suspected schizophrenia should receive a thorough mental status examination. Nurses can choose from a variety of assessment instruments, as

described in the Mental Assessment feature. Regardless of which tool is used, closely monitor for possible manifestations of schizophrenia throughout the mental status exam. Also keep in mind the patient's cultural and religious background, as this can affect an individual's description and interpretation of symptoms such as auditory and visual hallucinations.

Following the health history, physical exam, and mental status examination, several steps may be appropriate. For an individual suspected of having (but not yet diagnosed with) schizophrenia, referral to a psychologist or to a psychiatrist or other physician may be warranted. Laboratory testing and imaging studies may also be necessary to rule out other potential health problems. When working with a patient who has already been diagnosed with schizophrenia, note any significant changes in the patient's signs, symptoms, and behaviors since the last assessment. In addition, investigate the patient's living situation and adherence to the prescribed treatment regimen.

Diagnosis

Appropriate nursing diagnoses for patients with schizophrenia vary depending on symptoms and level of functioning. Still, some diagnoses are likely to apply to many, if not most, patients. Examples of these diagnoses include:

- *Suicide, Risk for*
- *Other-Directed Violence, Risk for*
- *Injury, Risk for*
- *Health Maintenance, Ineffective*
- *Self-Care Deficit (Bathing and/or Dressing)*
- *Verbal Communication, Impaired*
- *Social Interaction, Impaired*
- *Coping, Ineffective*
- *Noncompliance.*

(NANDA-I © 2014)

Planning

The planning portion of the nursing process involves identifying desired patient outcomes and formulating steps for achieving those outcomes. For patients with schizophrenia, appropriate nursing outcomes typically fall into one of three broad categories: symptom reduction, improved quality of life, and helping patients achieve life goals.

Outcomes Related to Symptom Reduction

- Patient will no longer experience hallucinations and delusions.
- Patient will experience a reduction in disordered thoughts.
- Patient will demonstrate appropriate affect.
- Patient will experience fewer negative symptoms of schizophrenia.
- Patient will take all medications as prescribed.

Outcomes Related to Quality of Life

- Patient will demonstrate appropriate self-care and personal hygiene.
- Patient will obtain adequate sleep.
- Patient will refrain from use of alcohol and/or illicit drugs.

- Patient will demonstrate improved coping skills.
- Patient will make a concerted effort to interact with others and avoid social isolation.

Outcomes Related to Achieving Life Goals

- Patient will cultivate appropriate occupational skills.
- Patient will find a job and maintain gainful employment.
- Patient will retain responsibility for personal finances.
- Patient will live independently in the community.

Implementation

Implementation involves evidence-based nursing interventions that facilitate the patient's achievement of identified goals of care. Although appropriate interventions will vary, the following principles apply to most patients diagnosed with schizophrenia.

Prevent Injury

The nurse's first priority of care should be to provide a safe environment for patients with schizophrenia and prevent them from engaging in violence toward self or others. When hallucinating or interpreting others' actions and statements from the standpoint of delusions, the patient may believe herself to be in danger, regardless of whether there is a factual basis for her fear. Under such circumstances, both the patient and perceived aggressors may be at risk for injury. Nursing interventions directed toward promoting safety and preventing injury may include administering antipsychotic medications as ordered, ensuring that the patient's surroundings are free of potentially harmful objects, minimizing environmental stimuli, and monitoring for suicidal behavior.

Provide Symptomatic Treatment

The nurse's second priority should be promoting control of the patient's current symptoms and minimizing the likelihood that additional symptoms will arise. Applicable nursing interventions may include orienting the patient to person and place; avoiding overwhelming or overstimulating the patient; remaining calm and consistent when speaking with the patient; and always informing the patient before touching him. When the patient appears to be experiencing hallucinations or delusions, the nurse should explain that she is not experiencing or thinking these things, yet she understands that they are real for the patient. Of course, the nurse must also ensure that patients understand and are able to follow all parts of their treatment regimen. Many times, patients will require referral to various community agencies that can assist patients with activities such as finding support groups, remembering to take their medications, and obtaining transportation to and from doctors' appointments and therapy sessions.

Educate Patients and Significant Others

Teaching and encouragement are another vital area of intervention for both patients with schizophrenia and their families. Inform patients and their loved ones about the symptoms and course of the disease, available therapeutic options and how they work, possible medication side effects, and potential signs of relapse. The nurse should also explore patients' and families' current communication and coping skills and encourage the development of new and potentially more

effective strategies (see Patient Teaching: Communication Techniques for Families with a Member with Schizophrenia). Encourage patients to adopt healthier behaviors, such as discontinuing use of nicotine and alcohol, obtaining adequate sleep, and eating a balanced diet. Social skills training is often appropriate, as is encouraging patients to participate in activities that minimize their likelihood of social isolation and withdrawal. In addition, many individuals derive great benefit from training (or perhaps retraining) in how to perform various occupational skills and ADLs. To keep patients on the path toward fuller functioning and possibly even independent living, the nurse should be sure to provide frequent positive reinforcement for desired actions and behaviors.

Advocate for Patients

The nurse must take steps to advocate on behalf of patients with schizophrenia. For example, the nurse should ensure that all interventions and therapies are actually in a patient's best interests and not merely intended to ease the burden on the patient's family and caregivers. The nurse should also make sure patients understand their legal rights to the greatest degree possible. Because individuals with schizophrenia are often unable to understand or independently exercise these rights during periods of acute psychosis, they should be encouraged to develop advance directives and similar documents explaining their wishes for times when the disorder is not controlled.

Evaluation

Ongoing evaluation is critical for patients with schizophrenia, as it allows nurses to monitor their condition and adjust any patient-specific diagnoses, goals, and interventions as

Patient Teaching

Communication Techniques for Families with a Member with Schizophrenia

Families are often overwhelmed by the stress associated with having a member affected by schizophrenia. Without specific tools to cope, ineffective communication patterns can arise and have the potential to contribute to poor patient outcomes. Nurses can teach family members strategies to improve communication. For example, if a family is concerned about a patient's behavior, the nurse can guide them through the use of some of the following techniques:

- Using "I" language to express positive feelings (e.g., "I am happy when you decide to sit down for dinner with us")
- Engaging in active listening (e.g., asking questions and nodding in agreement when another person speaks)
- Making positive, specific requests for change that are linked to emotions (e.g., "I would really like it if you could play a game with us tonight")
- Expressing negative feelings with "I" rather than "you" language (e.g., saying "I'm worried that you may not be getting enough sleep" instead of "You never get enough sleep at night")

After teaching these skills, the nurse should have family members schedule a time for practice. It is also important for the nurse to emphasize that the more often family members use these skills, the more natural they will become.

necessary. Some general examples of potential achieved outcomes for patients with schizophrenia include the following:

- The patient adheres to the medication regimen.
- The patient demonstrates utilization of available community resources.
- The patient communicates clearly and transitions logically between topics.

- The patient reports an absence of hallucinations and/or delusions.
- The patient is able to perform ADLs.
- The patient refrains from use of nicotine, alcohol, and illicit drugs.
- The patient is able to work in a structured setting.

Nursing Care Plan

A Patient with Schizophrenia

Lauren Hildebrand, age 22, is brought to a private mental health center by her father, Peter, who is concerned about recent changes in her behavior. He reports that she is demonstrating increasing difficulty expressing her thoughts and that she often stops talking midsentence,

as though she's forgotten what she was saying. He also states that Ms. Hildebrand dropped out of her graduate program in engineering 4 months ago because she suddenly was unable to maintain her grades. Mr. Hildebrand believes these problems are tied to cocaine use.

ASSESSMENT

Angel Sanchez, the RN at the health center, obtains a patient history and physical examination of Ms. Hildebrand. Mr. Sanchez notes that Ms. Hildebrand was adopted as an infant and little is known about her birth mother beyond the fact that she was homeless at the time Ms. Hildebrand was born. Until 10 months ago, Ms. Hildebrand was an A student at the local university and was awarded a position as a graduate assistant in the engineering department. Shortly after beginning her assistantship, she began having problems expressing herself. At first, she simply seemed distracted, rapidly switching from one topic to another in conversation; this eventually segued into problems logically connecting thoughts and completing sentences. Within 6 months, Ms. Hildebrand was no longer able to maintain her grades and job responsibilities and was forced to drop out of the graduate program. Around this time, her friends became aware of her drug problem. Out of concern, they contacted her parents.

Ms. Hildebrand's clothes are relatively new and fashionable, but they are rumpled and smell strongly of body odor. It appears that Ms. Hildebrand hasn't bathed or combed her hair in several days. Her affect is flat. Mr. Sanchez detects redness in and around Ms. Hildebrand's nostrils and notices that she frequently rubs her nose, both of which suggest insufflation of cocaine. Ms. Hildebrand admits that she uses cocaine but states that she hasn't used it in 3 days. She has difficulty answering Mr. Sanchez's other questions; her speech is garbled and relies heavily on rhyming words that do not make sense when strung together. Ms. Hildebrand is very thin, and the shape of her arm, hand, and clavicle bones stands out clearly under her skin. Her vital signs include T 100.1°F oral; P 95 bpm; R 22/min; and BP 131/88 mmHg.

Based on his mental status assessment of Ms. Hildebrand, Mr. Sanchez suspects schizophrenia. The psychiatrist orders an MRI to rule out abnormalities such as brain tumors. Aside from slightly enlarged ventricles, Ms. Hildebrand's MRI does not reveal any unusual findings. After speaking with Ms. Hildebrand's father, the psychiatrist interviews Ms. Hildebrand, after which he diagnoses her with probable acute schizophrenia. Based on her mental state and substance abuse, the psychiatrist recommends Ms. Hildebrand complete a 28-day inpatient stay at the mental health center, where she will receive treatment for her psychiatric condition and substance abuse. He also prescribes olanzapine, 5 mg/day for 1 week, to be followed by 2.5 mg/day increases each week until Ms. Hildebrand exhibits improvement, not to exceed 20 mg/day.

DIAGNOSES

- *Risk for Injury* related to disorganized thinking patterns and substance abuse
- *Impaired Social Interaction* related to altered cognitive function
- *Impaired Verbal Communication* related to perceptual and cognitive impairment
- *Ineffective Health Maintenance* related to perceptual and cognitive impairment
- *Self-Care Deficit (Bathing)* related to cognitive impairment and substance abuse
- *Imbalanced Nutrition: Less Than Body Requirements* related to cognitive impairment and substance abuse

(NANDA-I © 2014)

PLANNING

Goals for Ms. Hildebrand's care include:

- The patient will remain free from injury.
- The patient will demonstrate clear communication patterns.
- The patient will verbalize logical thought processes.
- The patient will exercise appropriate self-care and hygiene measures, including bathing or showering daily and completing oral hygiene care twice daily.
- The patient will discontinue cocaine use.
- The patient will gain 1 to 2 lb per week.
- The patient will engage in appropriate rehabilitation and group therapy activities while hospitalized and after release.

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Monitor the patient for indicators that suggest the potential for injury to self or others.
- Ensure the patient receives care that promotes physical and psychologic safety.
- Administer all medications as ordered.
- Monitor for signs and symptoms of cocaine withdrawal and address the need for substance abuse treatment.
- Assist the patient with establishing a pattern of self-care that includes adequate nutritional intake and hygiene.
- Teach patient and family members how to cope with schizophrenia and how to respond to signs of relapse.
- Encourage the patient to attend and engage in group therapy sessions.
- Ensure appropriate post-discharge services such as ACT.

EVALUATION

Mr. Sanchez works closely with Ms. Hildebrand during her stay at the mental health center. While at the center, Ms. Hildebrand receives education about her disorder, its causes and symptoms, and complications commonly associated with it. She also receives substance abuse counseling, CBT, and vocational counseling to prepare her to find a job after she is released. Her medication is gradually increased over the course of her stay until she reaches an

effective dose of 12.5 mg/day. By the end of her inpatient stay, Ms. Hildebrand is able to demonstrate appropriate self-care skills related to hygiene, nutrition, and medication administration. She can also clearly and logically describe the symptoms of her condition and verbalize strategies for coping with them. She is scheduled to return to the center twice each week for group therapy and has an appointment to meet with an ACT provider.

CRITICAL THINKING

1. Based on the little we know of Ms. Hildebrand's birth mother, can we draw any conclusions about either Ms. Hildebrand's genetic predisposition to schizophrenia or environmental factors prior to her birth that may have predisposed her to this disorder? Why is it reasonable to draw these conclusions?
2. Research community services for individuals with schizophrenia in your geographical area. What types of services are offered, and which of these services would you recommend to Ms. Hildebrand if she were your patient? Why would you recommend them?
3. Develop a care plan for the nursing diagnosis Risk for Self-Directed Violence related to disruptions in cognitive processes.

REVIEW Schizophrenia

RELATE Link the Concepts and Exemplars

Linking the exemplar of schizophrenia with the concept of immunity:

1. Why might patients with schizophrenia be at a heightened risk of HIV infection and AIDS?
2. What measures might you implement when caring for a patient with schizophrenia to limit the risk of HIV exposure?

Linking the exemplar of schizophrenia with the concept of addiction:

3. Why are patients with schizophrenia more likely to abuse nicotine, alcohol, and illicit drugs? Be sure to explore physical, social, and psychologic factors in your response.
4. What special challenges might arise when addressing addiction behaviors in patients with schizophrenia (as opposed to other patients)? Why? How might the nurse attempt to overcome these challenges?

Linking the exemplar of schizophrenia with the concept of managing care:

5. Why are care coordination and case management especially important for patients with schizophrenia?
6. What sort of professionals might be involved in the overall plan of care for a patient with schizophrenia? How could the nurse promote better collaboration and communication among these providers?

REFLECT Apply Your Knowledge

Dwight Gibson, a 46-year-old man, is brought to the emergency department by his landlord, Ms. Alder. Ms. Alder is concerned about Mr. Gibson's current mental state. She reports that his behavior has always been eccentric for the 5 years she's known him. For example, he perpetually seems worried that someone is "out to get him" and has installed extra locks on his doors and windows.

Lately, however, Ms. Alder has felt that Mr. Gibson's behavior is progressing from merely unusual to severely disturbed. Ms. Alder explains that she lives in the apartment below Mr. Gibson's, and several times over the past month, she's heard him yelling. When Ms. Alder goes to check on him, he tells her he's arguing with the "voices," yet there's never anyone else in the apartment with him. Ms. Alder also mentions that Mr. Gibson seems to be letting garbage accumulate in his apartment, as it smells quite bad. Upon observation, Mr. Gibson's hair is dirty and his clothes are stained and torn. As the nurse conducting Mr. Gibson's initial assessment, you introduce yourself to him and ask how he is feeling. He replies that he is feeling fine. Next, you ask Mr. Gibson if you may check

his blood pressure. He appears agitated and states, “They told you to do that, didn’t they? They’re trying to steal my spirit. They’re afraid my spirit will tell me the truth. I will not let you do that.”

1. What additional assessment information do you need?
2. How should you respond to Mr. Gibson’s refusal to allow you to assess his blood pressure?

3. What are Mr. Gibson’s priorities of care at this time?
4. Should Mr. Gibson be determined to be experiencing schizophrenia, what nursing diagnoses would be appropriate for inclusion in his plan of care?

Module 24

Culture and Diversity

Module Outline and Learning Outcomes

The Concept of Culture and Diversity

Cultural Diversity

24.1 Describe the language used to describe cultural diversity.

Values and Beliefs

24.2 Analyze how values and beliefs are components of cultural diversity.

Disparities and Differences

24.3 Describe how cultural disparities and differences affect healthcare.

Concepts Related to Culture and Diversity

24.4 Outline the relationship between culture and diversity and other concepts.

Developing Cultural Competence

24.5 Analyze the need for developing cultural competence.

Nursing Process

24.6 Summarize the nursing process in the context of cultural competence.

>> The Concept of Culture and Diversity

Complementary therapies, 1780	Diversity, 1765	Minority, 1765	Sexual orientation, 1771	

Culture refers to the patterns of behavior and thinking that people living in social groups learn, develop, and share. The term **diversity** refers to the array of differences among individuals, groups, and communities. Today's nurses must be able to work with diverse populations of patients—patients of varying socioeconomic, cultural, and spiritual backgrounds and patients with varying values and belief systems. To be able to provide culturally aware nursing, nurses must examine their own cultural values and beliefs.

Cultural Diversity

Any discussion of culture and diversity must be informed by the terms and language that are part of that discussion. **Discrimination**, or the restriction of justice, rights, and privileges of individuals or minority groups, may occur when dominant

groups reinforce their rules and regulations in a way that limits opportunities for others. A dominant group may be one that is dominant by reason of its numbers or as a result of having influence, power, money, and position to remain dominant while reinforcing rules and norms that benefit its own interests. The term **minority** usually refers to an individual or group of individuals who are outside the dominant group. Although demographics can vary from one area to another, in the United States, African Americans, Hispanics, and Native Americans are among those generally considered minority groups. **Subculture** is a term that refers to a group of people within a culture whose practices or beliefs are distinct or separate from the dominant or parent culture. Subculture is a term often defined more broadly and has been used to describe certain religious sects, ethnic groups, and even devotees of some genres of music or philosophy.

Multiculturalism is defined as many cultures and sub-cultures coexisting within a given society in which no one culture dominates. In a multicultural society, human differences are accepted and respected. Classrooms in an academic setting may be considered multicultural when all students are socialized to succeed and all learning styles are valued and understood.

In the United States, one driver of multiculturalism has been immigration. People from nearly every country in the world have come to the United States in search of a new way of life. Each year, approximately 1 million individuals obtain legal permanent resident status in the United States. The majority of those who immigrate are from Asian countries, primarily India (U.S. Department of Homeland Security, 2016).

Many individuals coming to America have sought freedom from an oppressive government. Others coming to our country have sought religious freedom, and still others freedom from poverty (**Figure 24-1** >>). In 2014, more than 1 million people came into the United States under legal status; of those, 96,066 claimed refugee status and 38,176 claimed asylum from political oppression (U.S. Department of Homeland Security, 2016). Many others come to the United States as refugees and claim family sponsorship. Nurses should take into consideration that some immigrants have fled such horrors as civil unrest, war, and oppression. Their psychological scars may run deeper than the physical ones.

Each family or group of immigrants brings its own culture, adding to what has been described as the “melting pot” that is the United States. The image of a melting pot implies the assimilation of multiple ethnic groups and their cultural practices into a single national identity with national allegiance and values. However, as these groups become established in the American culture, part or all of their ethnic identity remains. Instead of a melting pot, the United States should be considered a salad bowl of different flavors or a mosaic of the unique qualities of the cultural groups, coming together to make one America.

Source: sx70/iStock Editorial/Getty Images.

Figure 24-1 >> A crowded street in the Chinatown area of Flushing, Queens, New York. More than half a million Chinese-Americans live in New York City.

Members of each of these **ethnic groups** have common characteristics, including nationality, language, values, and customs, and they share a cultural heritage. Examples of ethnic groups are the large Cuban American population living in and around Miami, Florida; the Lakota Sioux, one of three major ethnic groups that make up the Great Sioux Nation; and the Hmong populations living in western North Carolina and in the Minneapolis-Saint Paul area in Minnesota.

In addition to different cultural and ethnic groups, individuals in the United States belong to one or more races. The U.S. Census Bureau (2013) identifies the following races:

- White
- Black or African American
- American Indian or Alaska Native
- Asian
- Native Hawaiian or Other Pacific Islander

Individuals of Hispanic, Latino, or Spanish origin may identify as members of any race.

Cultural, ethnic, racial, and other differences make nursing care both a privilege and a challenge. Nurses who are able to develop cultural competence and practice evidence-based care that is relevant to all of their patients will gain confidence in their abilities and greater personal benefit from their work with individual patients. A culturally competent practice begins with gaining a greater understanding of the differing values and beliefs of others (**Box 24-1** >>) and recognizing how these differing values and beliefs affect patients in all aspects of providing care.

Box 24-1

Nurses' Self-Awareness and Cultural Humility

Professional nurses must possess self-awareness. Self-awareness is critical to developing sensitivity to differences while supporting a sense of cultural humility rather than superiority over others. **Cultural humility** is the “ability to maintain an interpersonal stance that is other-oriented (or open to the other) in relation to aspects of cultural identity that are most important to the [person]” (Hook et al., 2013, p. 2)

As a nursing student, you may find your personal values to be in conflict with professional values. For example, you may find yourself uncomfortable with a certain ethnic group or religious faith. Yet a nurse, or any healthcare provider, cannot refuse to care for a person on the basis of cultural identity. Instead, your profession calls you to practice cultural humility, realizing that the person needs care, not judgment.

Following the June 2016 Orlando club shooting in which 49 people died and 53 others were wounded, one of the surgeons who was on duty the night of the shooting noted that he treated dozens of wounded people that night. He didn't know if any given patient was gay or straight, Hispanic or Black. He just knew that they needed care (Itkowitz, 2016). Similarly, military nurses have to care for wounded enemy combatants. Both nursing and military ethical codes require that enemy detainees are cared for without bias (Thompson et al., 2014). These examples illustrate the essence of cultural humility.

Values and Beliefs

Culture includes a society's values, beliefs, assumptions, principles, myths, legends, and norms. People living within a culture typically share many of the prevailing society's values and beliefs. People use these values and beliefs to help them define meaning, identify acceptable behaviors, choose emotional reactions, and determine appropriate actions in given situations. Values and belief systems are part of a culture, as are family relationships and roles. To understand patient behaviors in more depth, a nurse must identify which cultures are prevalent demographically in a given area, learn more about those cultures by reading or attending a class about them, and apply that knowledge and experience when providing patient care.

Values reflect an underlying system of beliefs. **Cultural values** describe preferred ways of behaving or thinking that are sustained over time and used to govern or guide a cultural group's actions and decisions. When people live together in a society, cultural values often determine the rules people live by each and every day. These rules may be variously stated, but they basically address similar values. Examples of some rules in Western culture (which usually refers to North America and parts of Europe) may include the following:

- Don't steal from others.
- Respect other people's property.
- Don't hurt others.
- Don't cheat on spouse or significant other.
- Share your food and clothing with those who are in need.
- Speak truthfully based on what you see.
- Respect your elders for their wisdom and experience.
- Respect God or a higher power.
- Respect nature and your environment.

Cultural characteristics include observable behaviors as well as the unseen values that influence those behaviors. Cultural practices have meanings that give the group its worldview and that reflects the social organization of the culture as a whole. The organization of a culture or society includes the following elements:

- **A physical element.** The geographic area in which a society is located
- **An infrastructure element.** The framework of the systems and processes that keep a society functioning
- **A behavioral element.** The way people in a society act and react to each other
- **A cultural element.** All the values, beliefs, assumptions, and norms that make up a code of conduct for acceptable behaviors within a society.

Each culture has its own worldview or understanding of the world. A **worldview** refers to how the people in a culture perceive ideas and attitudes about the world, other people, and life in general. A culture's worldview supports its overall **belief system**, which is developed to explain the

mysteries of the universe and of life that each society tries to understand:

- What is the meaning of life?
- How do individuals know their purpose in life?
- What is reality?
- How much can be known about values and beliefs?
- Is there a God or power beyond me?
- How was the universe created?
- What happens after death?
- How do we care for the sick?

A cultural belief system influences an individual's decisions and actions in society regarding everything from preparing food and caring for the sick to rituals of death and burial. Scientific and medical advancements may or may not impact a culture's belief systems. Belief systems differ in every culture. The beliefs of a society are passed from generation to generation by word of mouth and by rituals, such as reading certain stories or books on holidays (**Figure 24-2** >>>). In many cases, cultural practices are rooted in the individual's religious faith or practices (see the module on Spirituality). Children learn the belief system of their culture from parents and other family members who teach them any number of values and beliefs, including those about "right or wrong." Differing opinions may originate from religious beliefs or social conditions. People make decisions about "right or wrong," and as things change, people adapt and the culture evolves.

Belief systems are based on people's experiences and exposures to differences found in our world. As people's knowledge and understanding grow, their belief systems expand. Knowing why we believe what we believe builds self-awareness and understanding of differences in our own beliefs compared with the beliefs of others.

Culturally based beliefs and traditions can affect the course and outcome of disease and illness. Healthcare

Source: 3bugsmom/iStock/Getty Images.

Figure 24-2 >>> Cultures try to understand and give meaning to life through spiritual beliefs, social values, and acceptable behaviors. In this picture, a 12-year-old girl is seen reading the Torah with her parents as she is acknowledged as a Bat Mitzvah, a Jewish adult.

TABLE 24-1 Examples of Differences in Core Beliefs

North American and Western Cultures	South American and Eastern Cultures
Health is viewed by many as the absence of disease.	Health is a state of harmony that encompasses the mind, body, and spirit.
Use of specialty practitioners (e.g., pediatricians, obstetricians)	Preference for respected healers from the culture of origin (e.g., herbalists, midwives, curanderos)
Recognition that food affects bio-physical processes, functions	Belief that food can restore imbalances
Independence, individualism, freedom are valued	Interdependence with family, community, and group acceptance are valued
Emphasis on use of modern (Western) healthcare practices to maintain or treat health issues	Emphasis on traditional methods of maintaining, protecting, and restoring health

Source: Based on Spector, R. E. (2017). *Cultural diversity in health and illness* (9th ed.). Hoboken, NJ: Pearson Education.

providers and patients bring their respective cultural backgrounds and expectations to each interaction. These differences can impact both the expectations and practices of the patient and the provision of services by nurses and other healthcare professionals. Some of these many differences are listed in **Table 24-1** ».

Cultural differences can present barriers to necessary care. Some areas in which barriers can arise include the following (Spector, 2017):

- The importance, or lack of importance, of family members’ involvement in managing illness and disease
- Lack of trust in the healthcare system and providers
- The belief that illnesses are not linked to scientific pathophysiology
- Refusal of modern healthcare providers to believe the mind–body connection
- Fear or denial of death or life after death
- Cultural assumptions about disease and illness that may influence the presentation of symptoms or the response to treatments.

Many cultures will not continue treatments and medications once they feel well (Carteret, n.d.). This is particularly true when discussing terminal illness and dying (Rollins & Huack, 2015). Although cultural beliefs and behaviors change over the years as a cultural group adapts to new ideas and conditions, some individuals may retain traditional behaviors and thinking and continue to follow the beliefs and practices as always. Tension can arise when different health belief systems conflict with each other. The result may be anxiety, anger, or fear. The healthcare provider may reduce a patient’s discomfort and promote trust by showing a nonjudgmental attitude of respect. A nurse must also recognize the common defense mechanisms such as anger, avoidance, denial, intellectualization, or projection that may be used when an individual feels threatened (Berman & Snyder, 2012). See the module on Stress and Coping for information about defense mechanisms.

Professional nurses work with and care for people who have differing values and beliefs. It is important for nurses to understand how their own cultural beliefs and practices inform who they are as nurses, in part to strengthen their own value systems but also to ensure they are sufficiently self-aware to keep from projecting their own beliefs and values onto their patients.

Cultural Transmission

A society is a group of people who share a common culture, rules of behavior, and basic social organization. Culture is transmitted, or learned and shared, by people living together in a society. Cultural characteristics, such as customs, beliefs, values, language, and socialization patterns, are passed from generation to generation. **Cultural groups** can be categorized around racial, ethnic, religious, or socially common practice patterns. Race, however, does not equate with culture. Cultural groups often share common characteristics such as language, customs, beliefs, and values (Purnell, 2014; Spector, 2017). See **Box 24-2** ».

Culture is transmitted from one generation to the next through language, material objects, rituals, customs, institutions, and art. Through the use of a common language, people learn how to live by the rules governing the society and how to earn money or trade goods or services to meet basic needs, such as food and shelter. Culture can influence everything the members of a society think and do.

Enculturation, or cultural transmission, is exemplified by a process children use to learn cultural characteristics from adults. These characteristics are often normalized, meaning that certain characteristics are used to define acceptable rules and procedures of behaviors. People biologically inherit physical traits and behavioral instincts, but they socially inherit cultural characteristics. An individual learns culture from other people in a society. Enculturation occurs in families until the children are ready to leave and establish their own values, beliefs, and practices through exposure to other cultural or societal practices through work, marriage, or higher education. However, enculturation may continue

Box 24-2

Cultural Characteristics

- History of origin
- Holiday customs
- Styles of dress
- General worldview
- Religious beliefs and practices
- Birth and death rituals and practices
- Food preferences and eating patterns
- Values
- Roles and patterns of relationships
- Leadership structure
- Health and illness beliefs and behaviors
- Social systems
- Concept of time
- Concept of personal space
- Gestures and facial expressions
- Concept of self
- Common language

among family members who live close to each other, celebrate religious holidays together, or otherwise work to maintain the culture within their family and limit their exposure to cultural differences. The great variety of cultural characteristics provides a broader perspective of cultural differences and respect.

People in a society have cultural characteristics that are embedded in art, music, food, religion, and traditions. Because culture is adaptive, these characteristics may be modified over the years as people use culture to adjust to changes in the world around them. Cultural behaviors are learned by:

- Observing others' actions
- Hearing instructions on what behaviors are right or wrong
- Imitating others doing a behavior
- Getting reinforcement (either positive or negative) for enacting a behavior
- Internalizing behaviors
- Spontaneously doing the behaviors without thinking about it

Different societies can come together and share or exchange cultures as well. People may evolve from one cultural group to another. **Assimilation** is the process of adapting to and integrating characteristics of the dominant culture as one's own. People typically benefit by exchanging ideas, natural resources, and goods. **Acculturation** is the process of not only adapting to another culture but also accepting the majority group's culture as one's own. Because culture is complex, members of a cultural group may engage in many behaviors and habits unconsciously, making them difficult to explain to others. Sometimes assimilation and acculturation are implicit and covert, whereas other times assimilation can be overt and coercive.

As individuals go through the process of acculturation, they may choose to discard some practices from their culture of origin in exchange for practices of the dominant culture. Therefore, nurses need to ask appropriate questions to assess individual cultural practices rather than make assumptions. For example, some patients of Chinese background may be practicing Buddhists who prefer traditional Chinese practices such as herbs and acupuncture; others may belong to a different faith and completely embrace Western medicine; while still others may blend practices in ways that make sense to them. Careful assessment of the individual patient is necessary to avoid making assumptions and stereotyping.

Diversity

Cultural differences are not the only hallmarks of diversity. Gender, race, class, sexual orientation, and age are just a few of the differences among individuals living in the United States. In many instances, these factors carry important implications for nursing. For example, African American women are at greater risk for heart disease than any other single population; older adults are at greater risk for injury due to falls; and children are at greater risk for accidental injury. Nurses must be prepared to work with each individual who walks in the door, regardless of that individual's personal background.

The concept of **social justice** recognizes that in society, not all groups are treated equally. Nursing has a long history and current mission to promote social justice by promoting a balance among groups in the sharing of resources, rights, and responsibilities (National League of Nursing, n.d.). Using a lens of social justice enables individuals and organizations to follow a code of ethics that promotes equitable distribution of resources and seeks equitable rights for all individuals, thus providing advocacy for people who lack access to resources. Culturally competent nurses should respect and advocate for human dignity. Stereotyping, prejudice, and discrimination can threaten the delivery of healthcare services and adversely affect patient outcomes. Nurses need to understand and recognize these attitudes in themselves and others in order to reduce their effects on the patients they serve. To overcome barriers to multiculturalism, nurses must have a deep understanding of vulnerable patients who are impacted by racism, sexism, classism, and heterosexism.

Gender

Traditionally gender has been dichotomized into two groups: men and women. However, it is now known that some people do not fit neatly into these categories of gender. **Intersex** is a general term used for a variety of conditions in which an individual is born with a reproductive or sexual anatomy that does not seem to fit the typical definitions of female or male (Intersex Society of North America [ISNA], n.d; Vanderbilt University, 2017). The term **transgender** refers to individuals who do not identify with the gender assigned to their body. *Genderqueer* or *gender nonconforming* are terms adapted by those who don't identify with either male or female; rather, they identify as both (Hein & Levitt, 2014). For example, an individual who identifies as transgender may have typical female anatomy but feel like a male and seek to become male by presenting as male and taking hormones or electing to have gender reassignment surgeries. A genderqueer person might have feelings of being both male and female.

Differences between men and women go beyond anatomy and physiology and cultural or social definitions. Compared to women, men typically are less verbal and more action oriented and have stronger skills in logic, mathematics, and coordination; women tend to be more skilled in languages, perceiving and responding to others' needs, and the arts. However, these are general tendencies and taking them at face value may lead to **stereotyping**. Stereotyping is an overgeneralization of group characteristics that reinforces societal biases and distorts individual characteristics (Grandbois & Sanders, 2012). Even within genders, individual diversity is expected; for example, some women may be highly coordinated, mathematically skilled, and uninterested in the arts. No conclusion about an individual can ever be drawn based on a simple term such as *woman* or *man*.

The genders also differ in access to and control over resources and decision-making power in the family and community. The extent of these differences is often cultural. Gender roles, often in interaction with socioeconomic circumstances, influence exposure to health risks, access to health information and services, health outcomes, and the social and economic consequences of ill health. This can be

demonstrated by viewing the differences in mortality and morbidity between men and women of different cultures as well as their involvement in health prevention and health promotion programs. Therefore, nurses must recognize the root causes of gender inequities when designing a nursing plan of care. To obtain positive outcomes, health promotion and disease prevention and treatment need to address gender differences. For example, millions of women are injured as the result of spousal or significant other abuse, but the magnitude and health consequences of interpersonal violence against women have often been neglected in both research and policy.

Generally, there seems to be an assumption that interventions will be just as effective for men as for women. Many health promotion programs may be gender-blind and based on research that neither accounted for nor controlled for the gender of the study participants. Until the 1990s, many medications were tested only on White men, with no consideration that women or people of other ethnicities respond differently. Only in the mid-1990s did pharmaceutical companies begin to look at pharmacokinetic differences between males and females. Understanding the differences in responses between genders has led to research on how drugs affect women as well as those from different races and cultural backgrounds. As a result, scientists are finding that some drugs are more effective for women while others are more effective for men. In addition to the way in which men and women respond to health promotion, they also display different needs with regard to their response to the same diagnosis. For example, the traditional symptom of crushing chest pain as a primary indicator of myocardial infarction has been found to be primarily a male response. Women with myocardial infarction are more likely to experience extreme fatigue that extends to pain in the jaw, back, or shoulder if not treated early. Biological differences such as genetics, hormones, and metabolic influences combine to play a part in shaping different symptoms as well as morbidity and mortality rates (Casper et al., 2000; Schuiling & Likis, 2013).

By improving their understanding of how gender differences impact patient health, nurses can develop a plan of care that meets the specific and unique healthcare needs of each patient. It is important that nurses not allow their own gender bias or preconceived beliefs to affect their ability to assess and plan appropriate care for the individual patient. Health-promoting interventions aimed at inclusion in a safe and supportive environment promote a trusting nurse-patient relationship. Nurses should promote an environment in which patients can access essential services that address the differences between men and women in an equitable manner. When planning care, nurses who take into consideration the biological differences and social vulnerability of men and women are more likely to see positive outcomes for their patients.

Bias can be defined as favoring a group or individual over another. Gender bias results in **sexism** and occurs when male values, beliefs, or activities are preferred over female. Sexism may be overt or covert. Institutional bias related to gender results in sexist practices within an organization. Nurses need an awareness of cultural variations of gender, as they will be caring for diverse patient needs. What might

be considered sexism by one culture may not be in another. The wearing of a hijab, or head scarf, is an example. In some regions of the world, women are required by Islamic tradition to cover; however, in other areas of the world women have a choice to cover their heads. Some Muslim women find wearing the hijab empowering. Because their bodies are covered, they cannot be sexualized (Yusef, 2015). Because many women view wearing a hijab as an expression of faith, doing so should not necessarily be seen as a sign of sexism.

Another example of perceived sexism is that of the Hmong culture. In this culture, women typically do not make healthcare decisions, even regarding their own bodies. Typically, the woman's husband or father makes the decision, but sometimes, an elder man makes the healthcare decision for the woman. A woman could have an abscessed tooth, but the elder, not the patient, would determine if the tooth should be extracted because having males make medical decisions is preferred by many in this culture.

Race

The concept of race is complex. Historically, **race** has often been defined by physical attributes linked to continents of origin: Asia, Europe, Africa, and the Americas. Variations of skin color and hair texture have traditionally been used as markers of race. The dialogue about race and genetics is ongoing (Social Science Research Council, n.d.). However, the 2010 U.S. census data were collected by racial designation.

» **Stay Current:** To learn more about the U.S. census racial categories, search the U.S. Census Bureau's website: <https://www.census.gov/topics/population/race/about.html>.

The oppression of a group of people based on perceived race is known as **racism**. Although racism is often perceived as overt acts of hostility, racism can also be insidious policies, procedures, traditions, and rules that benefit one group of people over another. For example, not providing translation services or not offering expensive diagnostic or treatment modalities based on race contributes to unequal treatment and injustice.

Class

Socioeconomic variations contribute to a society stratification based on money and access to resources. **Classism** is the oppression of groups of people based on their socioeconomic status. The lack of access to resources is apparent in some of the people at the lowest economic level such as the homeless, those living in poverty, or undocumented immigrants.

Homelessness

Among the most vulnerable patients are those who are homeless. Homeless patients present unique and complex challenges because they often live in dangerous, unsanitary conditions; have diets that are severely lacking in nutrients; and have very few resources for coping with illness. They must find shelter and food every day and cannot predict what the next day will bring. People who are homeless have difficulty obtaining, keeping, and storing medications. A high incidence of substance abuse and mental illness limits their ability to provide self-care. An important nursing

intervention in addition to providing care to those who are homeless is to identify resources to help these patients.

» **Stay Current:** The U.S. Department of Health and Human Services is the primary government agency for providing funds, research, and resources for the homeless. This website provides several resources and links on the subject of homelessness in the United States, including links to local and state agencies: <http://www.hhs.gov/programs/social-services/homelessness/index.html>.

Poverty

Although people who are homeless can be considered impoverished, many families with adequate shelter live in poverty. Children and those living in female-headed households are at greatest risk of living in poverty. Of those households living in poverty, 28.2% are headed by a woman, compared to 5.4% married couples and 14.9% male-headed households (U.S. Census Bureau, 2016).

- U.S. Census Bureau (2016) data indicate that the overall poverty rate is 13.5% with 43.1 million living in poverty. This is a decrease of 1.2% from the previous year, indicating that poverty rates have been improving over the past years.
- Median household income was \$56,516 in 2015, which is a statistically significant 5.2% increase from 2014. This is the greatest change since 2007, the year of the last recession.
- The 2016 Census Bureau data also showed that 19.7% of children live in poverty, a decrease of 1.4%.
- Children of African American identity are more likely to live in poverty than their White counterparts. The poverty rates of Hispanic children continue to rise. Asian poverty statistics remain unchanged.
- The 2015 poverty rate for people age 65 and over was 8.8%, statistically unchanged for several years.
- More individuals are insured than in previous years, with only 9.1% reporting they are uninsured.

Undocumented Immigrants

Undocumented immigrants often do not seek healthcare until their condition becomes critical. This behavior results from a complex combination of factors. Many are uninsured, do not speak English, and have not yet learned the culture of their new homeland. Many believe that accessing healthcare will result in legal consequences, up to and including deportation. For some, the differences between the U.S. healthcare system and the medical practices and beliefs of their culture of origin create an additional barrier. These factors combine to create fear in the undocumented immigrant patient who needs medical attention (Ku & Jewers, 2013).

Special healthcare concerns related to this population include lack of preventive care, inadequate immunization status, and lack of past medical records. Because they enter the country without border screening, risks of diseases such as tuberculosis and HIV are much higher. Many feel more comfortable seeking help from traditional healers. Others receive their health information from television, the internet, community members, or family members, which can lead to misinformation and improper treatment.

States and regional politics vary across the country with regard to whether or not government or healthcare facilities are required to ask for proof of citizenship when providing care. Further, some states require reporting undocumented people, which also impedes those people's willingness to seek care. The nurse needs to be familiar with the laws within the state of nursing practice. When providing care to patients who may be or are known to be undocumented immigrants, the nurse has the ethical and moral imperative to deliver the same high-quality care delivered to any patient. Use of an interpreter or interpreter system will improve the quality of communication if the patient does not speak English or does not speak English well enough to understand the information presented. Thorough screening, nursing history, and assessment contribute to determining both current condition as well as risks, preventive care needs, and understanding of self-care upon discharge. Because access to healthcare for this population is unpredictable, nurses should maximize each opportunity to care for and teach self-care to these patients.

Sexual Orientation

Sexual orientation is a continuum ranging from those who have a strong preference for a partner of the same sex to those who strongly prefer someone of the opposite sex. *Homosexual* individuals prefer a partner of the same sex, with the term *lesbian* used to describe women who prefer to develop intimate relationships with other women. The term *gay* may refer to homosexual women or men, but is more commonly used to describe men who are homosexual. *Heterosexual* individuals prefer to develop an intimate relationship with a partner of the opposite sex. *Bisexual* individuals are physically attracted to both males and females. The most common biases related to sexual orientation are **homophobia** (fear, hatred, or mistrust of gays and lesbians often expressed in overt displays of discrimination) or **heterosexism** (view of heterosexuality as the only correct sexual orientation). In recent years, the American population has had a greater tolerance and acceptance of homosexuality. In a 2013 Pew Research Center survey, 55% of Americans were accepting of homosexuality. In the same survey, 92% of gays and lesbians reported feeling that society has become more accepting (Drake, 2013). Support for homosexuality and same-sex marriage in the United States remained at 55% following the Supreme Court's 2015 ruling that determined a constitutional right for homosexuals to marry (Fingerhut, 2016).

However, LGBTQ individuals (lesbian, gay, bisexual, transgender, and queer/questioning) continue to report discrimination and harassment, despite changing attitudes in society, even in the healthcare setting. A study showed that heterosexual nurses would much rather care for heterosexuals than gay men (Sabin, Riskind, & Nosek, 2015). Members of the LGBTQ community are also at greater risk for healthcare disparities and health issues. This is partially due to sexual practices, but also due to fear of discrimination and stigma. According to the Health Resources and Services Administration (n.d.), LGBTQ individuals are at higher risk for such health problems as obesity, mental health issues, substance abuse, and violence.

Transgender individuals face greater discrimination in healthcare than lesbians and gays. According to the National Transgender Discrimination Survey (Grant et al., 2011), 28% of transgender individuals delayed seeking healthcare for fear of discrimination, a far higher number than lesbians and gays report. The survey also found that 19% experienced refusal of care due to their gender status, and 28% experienced harassment in the healthcare setting (Grant et al., 2011). Sadly, transgender people are more likely to have mental health issues, including depression and anxiety, as well as abuse drugs and alcohol in order to cope with the difficulties involved in being transgender. The study found that 41% of those surveyed had attempted suicide; this is compared to 1.6% of the general public (Grant et al., 2011).

Social determinants affecting the health of LGBTQ individuals largely relate to oppression and discrimination. Examples include:

- Legal discrimination in access to health insurance, employment, housing, marriage, adoption, and retirement benefits
- Lack of laws protecting against bullying in schools
- Lack of social programs targeted to and/or appropriate for LGBTQ youth, adults, and older adults
- Shortage of healthcare providers who are knowledgeable about and culturally competent in providing LGBTQ healthcare.

Nurses must advocate for a physical environment that contributes to healthy LGBTQ individuals, including:

- Safe schools, neighborhoods, and housing
- Access to recreational facilities and activities
- Availability of safe meeting places
- Access to health services.

The Institute of Medicine (IOM) (2011) of the National Academies has published a book addressing LGBTQ health issues throughout the lifespan and found an ongoing need for healthcare professionals to improve culturally competent healthcare and to eliminate healthcare disparities. A follow-up report published in 2013 recognized even greater need for more research and promotion of health-seeking behaviors in the LGBTQ population (National Institutes of Health LGBT Research Coordinating Committee, 2013).

Disability Status

Many patients have physical or cognitive disabilities. During the past 30 years, various terms have been used to describe people with intellectual disabilities. Mental deficiency, mental retardation, mental handicap, developmental disability, and learning disability are examples. Patients with an intellectual disability and their families experience poorer healthcare compared with the general population. Living with an intellectual disability is often challenged by coexisting complex and chronic conditions and can lead to economic hardship and family conflict. Both intellectual and physical disability can impair the individual patient's ability to participate in health promotion and to provide self-care.

The American Association of People with Disabilities (2016) is the nation's largest cross-disability rights organization. It is an important advocacy, resource, and referral organization for individuals with disabilities and their families, friends, and advocates. Nurses working with patients with disabilities must develop trusting relationships so they can successfully assist patients with disabilities and their families and caregivers and enable them to find resources.

Age

Children and older adults are considered vulnerable populations. Both older adults and children often depend on others for nutrition, healthcare, transportation, and personal safety. Many older adults live on limited incomes. In 2014, there was a great disparity between men's and women's income for those over 65: the average income for a man was \$31,169; for women it was \$17,375 (Administration on Aging, 2015). More than 4.5 million (10%) older adults live in poverty, while 2.5 million (5.3%) live close to the poverty line (Administration on Aging, 2015). **Ageism** is defined as discrimination against older adults. U.S. culture places an emphasis on youth, beauty, and productivity, which minimizes respect and access to opportunities for older adults. The increasing use of the internet and technology as a primary means of sharing and retrieving information also has implications. More and more older adults are embracing technology and the internet, particularly in those with higher education and/or spouses (Vroman, Arthanat, & Lysack, 2015). However, those who have less education or do not have access to technology resources are left behind.

Disparities and Differences

In many ways the United States is a nation that celebrates culture and diversity. From Greek festivals to soul food to Tex-Mex, from gay pride parades to Chinese New Year, there is plenty of diverse heritage and society to celebrate. Unfortunately, these differences also give rise to disparities of opportunity, and these include disparities that relate to healthcare. In 2002, the Institute of Medicine released a report on disparities in the United States regarding the types and quality of health services that racial and ethnic groups receive. This historic report explored factors that may contribute to inequities in care and recommended policies and practices to eliminate these inequities. Fifteen years later, despite much progress, inequities still exist, and researchers are attempting to identify and prevent the causes of disparities (**Figure 24-3** »). Nurses should be alert to practices in their work environment that impact the quality of care offered to individuals of any ethnic group. Healthcare practices should be accessible and culturally relevant, and patient preferences should be at the core of decision making. Nurses should work collaboratively to ensure quality care and provision of best-practice methods to all patients.

The recommendations for reducing these disparities in healthcare include increasing awareness of them among the public, healthcare providers, insurance companies, and policy makers. In addition, more diverse healthcare providers are needed in underserved communities, and more interpreters are needed in clinics and hospitals to improve the

Figure 24-3 » Although much has been done to improve the quality of health services received by American cultural and ethnic minorities, these services are still in need of continued reform.

quality of care. The U.S. Department of Health and Human Services offers a free, online course to educate nurses and other healthcare workers on culturally competent care (<https://www.thinkculturalhealth.hhs.gov/education/nurses>) in order to help educate nurses and narrow the healthcare disparities gap and improve overall health in different populations.

» **Stay Current:** To read more on cultural competency, information on health equality, and other topics on minorities, explore <http://minorityhealth.hhs.gov>.

Vulnerable Populations

The concept of multiculturalism assumes that all cultural groups are equally valued and respected by others. Unfortunately, this is rarely the case. Historically, the United States has had norms, values, and even laws based on stratification of gender, race, and class divisions. The term **vulnerable population** refers to groups of people in our culture who are at greater risk for diseases and reduced lifespan due to lack resources and exposure to more risk factors. Poverty is a major culprit in vulnerable populations (World Health Organization, 2016). Persons in poverty are at risk for malnutrition, poor housing, violence, and limited or no access to healthcare. Other conditions associated with vulnerability include age, disability, health/disease state, education status, language spoken, and socioeconomic situation.

Oppression, or the systematic limitation of access to resources, may be covert or subtle and typically is linked to laws, education, or even healthcare norms and regional access to services and transportation. All vulnerable populations are less able than others to safeguard their needs and interests adequately. In conceptual terms, the most vulnerable are those households with the fewest choices and the greatest number of disabling factors.

Patients from vulnerable populations are more likely to develop health problems because they have the greatest number of risk factors and the fewest options for managing those risks. These individuals often have limited access to healthcare and are more dependent on others for helping

them meet their healthcare needs. Those from vulnerable populations are likely to be older, living in poverty, homeless, in abusive relationships, mentally ill, chronically ill, or children. It is not uncommon for vulnerable individuals to belong to more than one of these groups. They face multiple challenges, statistically poorer outcomes and shorter life-spans, and higher mortality and morbidity rates due to cumulative or combinations of risk factors. They may be from any culture, ethnicity, age, or gender, although they are more likely to be women than men. Nurses face many challenges when caring for individuals who are vulnerable. Their physical, social, and emotional needs are complex, and many have multiple chronic conditions that can complicate care still further. Assessing the patient from a vulnerable population requires the nurse to investigate all systems, determine stressors and coping mechanisms, and help the patient identify potential resources.

The welfare of vulnerable populations depends on the nation's willingness to provide the necessary programs to promote health and well-being. Other issues impacting the provision of healthcare to vulnerable populations include accessibility and transportation. Impoverished children living in very rural communities, for example, may not have access to fluoridated water and may be an hour from the nearest dentist who accepts Medicaid.

A primary focus of healthcare, as outlined by *Healthy People 2020*, is to reduce the disparity of access to healthcare among groups. *Healthy People 2020* defines a **health disparity** as "a particular type of health difference that is closely linked with social, economic, and/or environmental disadvantage. Health disparities adversely affect groups of people who have systematically experienced greater obstacles to health based on their racial or ethnic group; religion; socioeconomic status; gender; age; mental health; cognitive, sensory, or physical disability; sexual orientation or gender identity; geographic location; or other characteristics historically linked to discrimination or exclusion" (The Secretary's Advisory Committee on National Health Promotion and Disease Prevention Objectives for 2020, 2008, p. 28). Some examples of vulnerable group affiliations are highlighted in this module.

Social Differences

People learn the social behaviors practiced in their cultures and communities. These behaviors differ from culture to culture, from community to community. They may also be practiced by members of subcultures who decide to maintain traditional cultural practices, whereas others from the same culture living nearby may choose to adapt to the dominant culture (**Figure 24-4** »). The terms **subculture** and **minority** are sometimes used to label groups characterized by specific norms, beliefs, and values that coexist or even oppose those of the dominant culture. Some common social behavioral variations among people of different cultures involve communication, environmental control, hygiene, space, time, and social organization. These ethnic differences exist within smaller cultural groups within a larger society. Within the United States, social differences are evolving as individuals from different cultural groups relocate for college or work and interact with people from other cultures, and as the numbers of individuals of different cultural

Source: gsheldon/iStock Editorial/Getty Images.

Figure 24-4 » Subcultures can maintain heritage and identity through dress, foods eaten, and cultural festivities. This Amish family in Bird-in-Hand, Pennsylvania, wears traditional plain clothing and drives a horse-drawn buggy while sharing the road with the larger community of non-Amish Pennsylvanians who drive cars.

groups change over time. For instance, there has been a silent move of Native Americans from the reservations to the cities. This migration is partially due to violence on the reservations, poverty, and other socioeconomic factors (Williams, 2013). More Native Americans are living in cities than ever before, with roughly 70% living in metropolitan areas. With this, unfortunately, comes an increased poverty rate. Native Americans and Native Alaskans have the highest rate of poverty of all the races. In Minneapolis, Minnesota, the poverty rate for Native Americans is roughly 45%, compared to a national average for Native Americans of 27% (Macartney, Bishaw, & Fontenot, 2013; Williams, 2013). Yet, despite the higher poverty rates, Native leaders report that cities bring more opportunities than the reservations (Williams, 2013).

Communication

Cultural groups may speak a unique language or a variation of another language. The meaning of words can differ among various groups of people, and misunderstandings may result from lack of common communication. Languages vary in terms of references to time, gender, roles, or common concepts and definitions. Translation of concepts from one language to another may miss contextual embedded meanings and lead to misunderstandings. Misinterpretation of nonverbal communication also may lead to problems. Direct eye contact may show disrespect in some cultures and be a sign of interest and active listening in others. An example of a difference in nonverbal communication is when up-and-down head nodding does not reflect agreement, but instead is an attempt to acknowledge respect for authority.

Environmental Control

Relationship to the environment varies among cultures. Different health practices, values, and experiences with illness can be associated with an external or internal locus of control. Rotter (1966) theorized that individuals believe either

that they can control certain aspects of their lives (internal locus of control) or that outside sources control their lives (external locus of control). Those who believe in an internal locus of control over their health will be motivated to eat healthy, exercise, and make use of other wellness measures. For example, an American of European descent would more likely follow an internal locus of control based on the cultural belief of independence and care for self. Those who follow an internal locus of control tend to respond well to preventive medicine. Those with an external locus of control will feel that outside influences will care for their health. For example, some people who are Muslim believe the status of their health is Allah's will. Those who follow an external locus of control are less likely to be as engaged in preventive measures as they do not see themselves as being in control of their health.

Religious Variations

Many religions are practiced, including Protestant Christianity, Catholicism, Judaism, Hinduism, Islam, and Buddhism. **Religion** refers to a set of doctrines accepted by a group of people who gather together regularly to worship that offer a means to relate to God or a higher power, nature, and their spiritual being. Religion plays a greater role in some communities than in others. One town may sponsor a living nativity at Christmas, whereas the next may ban religious observances on government property altogether. See the module on Spirituality for more information.

Space

Culture defines an individual's perception of personal space. Comfort may result from honoring the boundaries of personal space, whereas anxiety can result when these boundaries are not followed. Practices regarding proximity to others, body movements, and touch differ among groups. Variations of intimate zones and social public distance occur among cultural groups, and a healthcare provider needs to be aware that what he perceives as normal or appropriate may produce anxiety for others (Dayer-Berenson, 2011).

Time

The concepts of time, duration of time, and points in time vary among cultures. Past-oriented cultures, for example, value tradition. Individuals from cultures that closely follow tradition may not be receptive to new procedures or treatments. Present-oriented cultures focus on the here and now, and individuals from these cultures may not be receptive to preventive healthcare measures. Different cultures value time differently, and some may not emphasize being on time for appointments (Spector, 2017). Healthcare providers are very regulated by clock hours influencing wake, sleep, work, and mealtimes. Not all cultural groups are regulated by clock hours.

Biological Variations

People differ genetically and physiologically. These biological variations among individuals, families, and groups produce differences in susceptibility and response to various diseases among people of different cultures and all walks of life (**Figure 24-5** »). The field of ethnopharmacology addresses variations in pharmacodynamics and

Source: TAGSTOCK1/iStock/Getty Images.

Figure 24-5 » People from different cultures vary biologically. This couple of Japanese descent is likely to have higher blood glucose levels than people of other ethnic backgrounds.

pharmacokinetics among cultural groups. Nurses are responsible for monitoring patients' responses to the drugs they give and thus must be aware of these differences. In addition, some enzyme deficiencies occur more commonly in some cultural groups. For example, lactose deficiency (the inability to absorb milk by-products) or other malabsorption disorders are seen with increased incidence in Asian and African cultural groups.

Susceptibility to Disease

Certain ethnic groups or races may tend toward developing specific diseases. African Americans, for example, have a higher incidence of hypertension and sickle cell disease. Cystic fibrosis occurs almost exclusively in Caucasians. Native Americans have a higher incidence of diabetes (33%) than any other group (Spanakis & Golden, 2013). Sometimes, however, an individual's susceptibility to disease is not so obvious but may be discerned as a nurse takes a health history, including the health of any parents, grandparents, and siblings.

Skin Color

Historically, skin color has been associated with racial definitions. However, labeling of people based on their skin color should be avoided. Healthcare providers need to explore ethnic variations and not make assumptions based on skin color. As a nurse, when doing skin assessment, it is important to know that darker skin tones require closer inspection and enhanced lighting to observe changes (e.g., when assessing for changes in oxygenation). Skin color changes such as erythema and cyanosis are subtle, and palpation and lighting will need to be used for skin assessment. In addition, skin color does impact some prevalence statistics: African Americans and Native Americans have lower incidences of skin cancer due to higher levels of melanin.

Additional cultural and social differences are outlined in **Table 24-2 »**.

TABLE 24-2 Additional Cultural and Social Differences

Category	Implications
Hygiene	Cleanliness practices can vary among cultural groups. Whether or not body odor is disguised, ignored, or enhanced can vary by culture, as can hairstyles and grooming practices.
Nutrition	Food preferences can be an indicator of or cause of disease. Cooking techniques vary and may increase risk for disease in susceptible populations. Social patterns around eating and food choices also have implications for health promotion and direct nursing care.
Skeletal and growth and development differences	Skeletal variations occur across racial and cultural lines. For example, small-framed American women of European descent are at greater risk for osteoporosis. Pubertal developmental changes occur at different times.
Social organization	Across cultures and communities, the roles of older adults and the respect given them vary. Differences among who is the recognized head of household and gender roles also exist. Work and recreational patterns and norms vary. The role of adult children and caretaking expectations also vary among groups.

Clinical Example A

Susan Moore is a 16-year-old girl who comes to a local family practice clinic for a first-time appointment. She is complaining of painful, irregular, and heavy menstrual periods. Her mother comes with her to the clinic visit. Susan's assessment is notable for her lack of participation in regular medical care. Her parents homeschool Susan and her sisters, and her mother tells you that they hardly ever see a physician. Following a thorough nursing assessment and physical examination, the family nurse practitioner diagnoses Susan with endometriosis and recommends hormonal contraceptives. Susan's mother is adamant that Susan not take any medication, saying they believe in using only "natural" therapies and do not use prescription drugs. Susan begins to cry, complaining of how much pain she is in constantly, and she pleads with her mother to let her try the medication.

Critical Thinking Questions

1. What are the priorities for care for Susan based on the information presented here?
2. How can you show cultural sensitivity to Susan and her mother and promote evidence-based care?
3. Using therapeutic communication, what could you say or do to affect Susan's mother's decision regarding her daughter's treatment?

Concepts Related to Culture and Diversity

Differences among patients that are attributable to culture, ethnicity, race, gender, sexuality, and vulnerability impact the nursing care of patients in a variety of ways. Within the concept of communication, it is important to understand that patients use language differently, speak different languages, and recognize nonverbal cues differently. Therapeutic

Concepts Related to Culture and Diversity

CONCEPT	RELATIONSHIP TO CULTURE AND DIVERSITY	NURSING IMPLICATIONS
Comfort	The verbalization of pain and preferred comfort measures may differ based on cultural expressions, gender norms, or other factors.	<ul style="list-style-type: none"> ■ Patients' reaction to pain may range from stoicism to hysterics. Nurses must assess and accept a variety of patient responses to pain and provide myriad interventions that include opioids, nonopioids, adjunct therapy, and complementary and alternative methods for reducing pain and increasing comfort.
Communication	Listening, clarification, reflection, and all therapeutic communication techniques are important when communicating with people different from you.	<ul style="list-style-type: none"> ■ Use therapeutic communication skills. ■ Identify translation and interpreter resources in your organization. ■ Use language that the patient understands.
Healthcare Systems	Availability of healthcare services for vulnerable populations may be low. Availability of resources varies by community.	<ul style="list-style-type: none"> ■ Unequal distribution of facilities and resources. ■ Recognize cultural and group differences among healthcare providers. Seek to advocate for vulnerable populations. ■ Refer patients in need of additional resources to social services and nonprofit service agencies.
Professional Behaviors	Recognize personal values and professional values.	<ul style="list-style-type: none"> ■ Self-awareness of cultural competence.
Sexuality	Sexual orientation, homophobia, heterosexism.	<ul style="list-style-type: none"> ■ Assist in advocating for LGBTQ healthcare needs and access. ■ Recognize same-sex partners as family and patient support.
Spirituality	Recognize religious beliefs related to dietary regimen or times of fasting.	<ul style="list-style-type: none"> ■ Show respect for religious differences, leaders, and practice. ■ Recognize that your personal spiritual and religious beliefs will not be universally shared with your patients. ■ Be nonjudgmental of differences. ■ Support patient religious practices.

communication, interpreters, shared languages, and awareness of nonverbal cues can help nurses communicate more effectively with patients from diverse backgrounds.

Within healthcare systems, the resources available to the different types of patients depend on a variety of factors, especially whether or not the patients have health insurance and access to resources such as transportation. Patients who live in poverty or who are homeless may need referrals to additional resources. Nurses must advocate for services, such as interpreters or mental health resources, for their patients who do not have the awareness or influence to ask on their own.

The professional behavior of nurses must be built on a moral and ethical code. Nursing as a discipline has a culture of its own. Nurses must understand collegial and regional differences to effectively work collaboratively with interprofessional teams. Self-awareness, emotional intelligence, and lifelong learning should be characteristics of a nurse's professional behavior.

Another concept related to culture and diversity is sexuality. Gender roles and the timing and type of sexual relationships vary among groups of people. Heterosexual and homosexual variations may also be culturally embedded.

Another concept related to culture and diversity is spirituality. Although spirituality may be defined more broadly

than religion, cultural variations exist around religious and church doctrines such as Hinduism, Judaism, Buddhists, Christianity, and Muslim practices. Religious practices commonly influence eating or fasting patterns, types of worship, and family roles and responsibilities. The Concepts Related to Culture and Diversity feature lists some, but not all, of the concepts integral to providing culturally aware nursing.

Developing Cultural Competence

Cultural competence is the ability to apply the knowledge and skills needed to provide high-quality, evidence-based care to patients of diverse backgrounds and beliefs to overcome barriers and access resources promoting health and wellness. Cultural competence has some basic characteristics:

1. Valuing diversity
2. Capacity for cultural self-assessment
3. Awareness of the different dynamics present when cultures interact
4. Knowledge about different cultures
5. Adaptability in providing nursing care that reflects an understanding of cultural diversity.

Cultural competence can be considered a process as well as an outcome, although no one person can be competent in dealing with all types of cultural variations. The American Association of Colleges of Nursing (2008) has identified five competencies considered essential for baccalaureate nursing graduates to provide culturally competent care in partnership with the interprofessional team:

- **Competency 1.** Apply knowledge of social and cultural factors that affect nursing and healthcare across multiple contexts.
- **Competency 2.** Use relevant data sources and best evidence in providing culturally competent care.
- **Competency 3.** Promote achievement of safe and quality outcomes of care for diverse populations.
- **Competency 4.** Advocate for social justice, including commitment to the health of vulnerable populations and the elimination of health disparities.
- **Competency 5.** Participate in continuous cultural competence development.

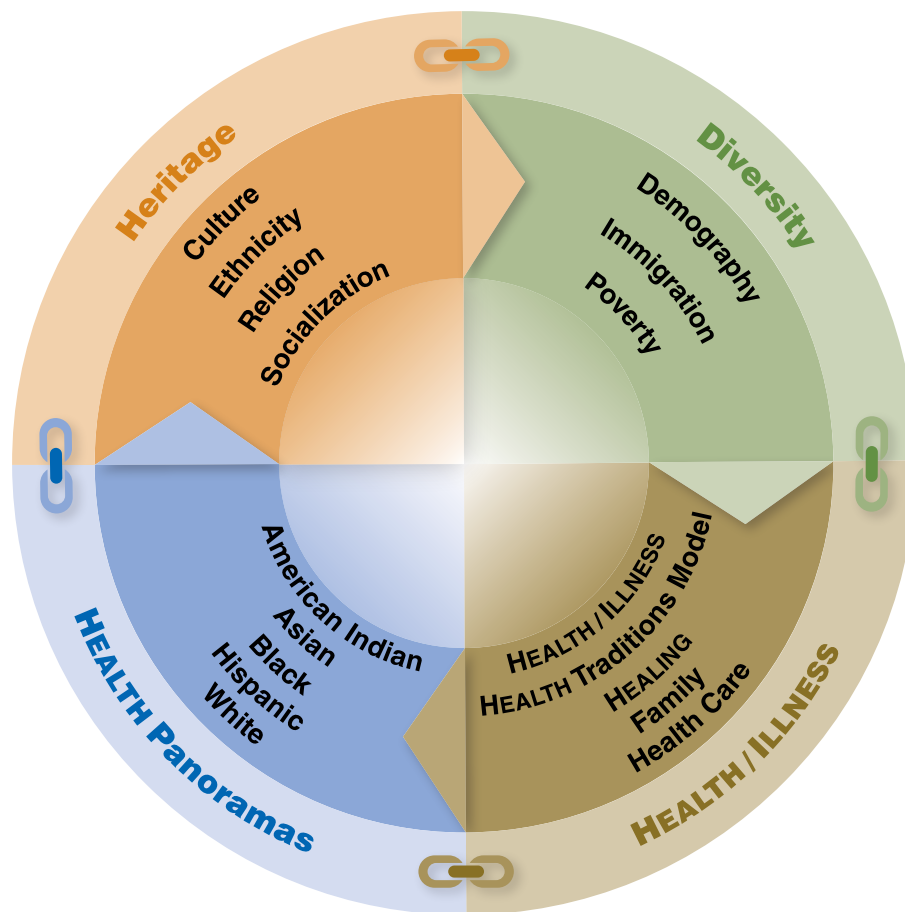

Because the concept of culture is very complex, scholars have identified models of cultural competence to facilitate the continuous process of cultural competence. The purpose of using a model is to help communicate and enhance the understanding of a complex concept. A theoretical model

may provide a nurse or student with a deeper understanding of how concepts are related. Many models have been published. One of the oldest, yet still relevant, nursing theories regarding culture is Madeleine Leininger's (2002) Culture Care Diversity and Universality theory. Leininger developed this theory with a unique emphasis on cultural care and the nurse. See the module on Caring Interventions for more information regarding Leininger's Theory of Culture Care Diversity and Universality.

Another model is Rachel Spector's HeritageChain (2017), which outlines the variables that impact culturally competent care. These include the cultural heritage of the patient and the provider; the diversity of the area in which patient and provider live and work; the health panoramas of traditional cultural groups; and aspects of health and illness, such as traditional healing versus modern healthcare practices and family support and considerations (**Figure 24-6** »).

The nurse's journey toward cultural competency begins with self-awareness, with identifying areas in which the nurse can improve how she relates to and communicates with individuals with values and beliefs different from her own. See the Focus on Diversity and Culture feature for a values clarification checklist to help you begin to cultivate self-awareness.

The LEARN model (Association of American Medical Colleges, 2005; Berlin & Fowkes, 1983) can be used as a tool for developing cultural competency. Below is a modification

Figure 24-6 » The HeritageChain model of cultural competence developed by Rachel Spector (2017).

Focus on Diversity and Culture

How Culturally Competent Are You?

To help you identify areas where you can improve when providing nursing care to culturally different people, answer the following questions by checking “Yes” or “No”:

- | | | |
|------------------------------|-----------------------------|---|
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I accept values of others even when different from my own. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I accept beliefs of others even when different from my own. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I accept that the male and female roles may vary among different cultures. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I accept that religious practices may influence how a patient responds to illness, health problems, and death. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I accept that alternative medicine practices may influence a patient's response to illness and health problems. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I accept cultural diversity in my patients. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I attend educational programs to enhance my knowledge and skills in providing care to diverse cultural groups. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I understand that patients who are unable to speak English may be very proficient in their own languages. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I try to have written materials in the patient's language available when possible. |
| <input type="checkbox"/> Yes | <input type="checkbox"/> No | I use interpreters when available to improve communication. |

If you have more No responses than Yes responses, you may not be as culturally competent as you could be. The purpose of this self-assessment is to increase your awareness of areas where you can improve your cultural competence.

of the **LEARN** model that can help nurses include cultural behaviors in a patient's healthcare:

Listen to the patient's perception of the problem.

Explain your perception of the problem and of the treatments ordered by the physician.

Acknowledge and discuss the differences and similarities between these two perceptions.

Review the ordered treatments while remembering the patient's cultural parameters.

Negotiate agreement. Assist the patient in understanding the medical treatments ordered by the physician, and have the patient help to make decisions about those treatments as appropriate (e.g., choosing cultural foods that are permitted on an ordered diet).

Clinical Example B

Mr. and Mrs. Ali come to a local clinic because Mrs. Ali, who is 6 months pregnant, is not feeling well. Mr. Ali speaks English fluently, but his wife's proficiency in English is more limited. Both are dressed in American-style clothes. During the assessment, the registered nurse, Clea Smith, determines that the couple has a 9-month-old and a 2-year-old at home. Ms. Smith also learns that Mr. Ali is the head of the household, making most of the major decisions for the family, and that Mrs. Ali has sole responsibility for the family's care and daily living needs. Mrs. Ali presents with exhaustion and elevated blood pressure. After obtaining a urine specimen, the provider diagnoses toxemia and orders Mrs. Ali to be on strict bedrest and to return in 2 weeks. While Mr. Ali conveys concern for his wife's health, he is reluctant to have her treatment disrupt the household routine.

Critical Thinking Questions

1. What are the priorities of care for Mrs. Ali?
2. What additional information would you like to collect about this family?
3. Using the LEARN model, describe how the nurse working with this family could understand and address this situation and the physician's recommendations with both the husband and wife.

In addition to the LEARN model, nursing scholars have identified models that illuminate a variety of areas for nurses to explore to deepen their understanding of cultural competence.

Purnell's (2014) model of cultural competence identifies how individuals, families, communities, and the global society all possess 12 domains of culture:

1. Overview, inhabited localities, and topography
2. Communication
3. Family roles and organization
4. Workforce issues
5. Biocultural ecology
6. High-risk behaviors
7. Nutrition
8. Pregnancy and childbearing practices
9. Death rituals
10. Spirituality
11. Healthcare practices
12. Healthcare practitioners.

No one becomes culturally aware or culturally competent overnight. As healthcare providers, it is imperative that we recognize common prejudices. **Prejudices** are prejudgments about cultural groups or vulnerable populations that are unfavorable or false because they have been formed without the background knowledge and context on which to base an accurate opinion. There is a process by which nursing students (and other individuals) learn cultural confidence, with learning taking place in a fairly predictable sequence:

1. Students begin by developing cultural awareness of how culture shapes beliefs, values, and norms.
2. Students develop cultural knowledge about the differences, similarities, and inequalities in experience and practice among various societies.
3. Students develop cultural understanding of problems and issues facing societies and cultures when values, beliefs, and behaviors are compromised by another culture.

4. Students develop cultural sensitivity to the cultural beliefs, values, and behaviors of their patients. This reflects an awareness of their own cultural beliefs, values, and behaviors that may influence their nursing practice.
5. Students and nurses develop cultural competence and provide care that respects the cultural values, beliefs, and behaviors of their patients.
6. Nurses practice lifelong learning through ongoing education and exposure to cultural groups.

Standards of Competence

Maintaining cultural competence is an ongoing process. Nurses continually assess, modify, and evaluate the care provided to culturally diverse patients. In 2011, Douglas et al. addressed current standards for culturally competent nursing care. Their 12 standards are:

1. Social justice
2. Critical reflection
3. Knowledge of cultures
4. Culturally competent practice
5. Cultural competence in healthcare systems and organizations
6. Patient advocacy and empowerment
7. Multicultural workforce
8. Education and training in culturally competent care
9. Cross-cultural communication
10. Cross-cultural leadership
11. Policy development
12. Evidence-based practice and research.

Institutions such as hospitals also need to develop and implement cultural competence to address the cultural and language needs of an increasingly multicultural patient population. Purnell et al. (2011) developed a guide to assessing a culturally competent organization and suggested the following areas be addressed:

- **Administration and governance.** Some areas in which an organization may consider being culturally competent are congruence with a mission statement and implementation of policies and procedure. All administrators must walk the talk and promote organizational practices that promote cultural competence. Organizations should initiate a continuous monitoring process for assessment and evaluation of cultural and language needs. These practices may be hiring protocols, having an ethics or cultural committee to resolve conflicts, having a cafeteria with diverse food choices, and instituting effective communication policies. In addition, monies must be allocated to provide resources and training throughout the organization. Handouts and marketing plans should reflect diverse groups in their narrative, illustrations, and relevant terminology (Byrne et al., 2003).
- **Orientation and education.** The orientation or professional development for *all* employees should address concepts of cultural competency. An organization should have a philosophy of respect for all of its employees and have resources for multicultural and multilingual employees and community partners.

- **Language.** The United States is a country of many cultures, and healthcare professionals need to have a basic understanding of how language impacts healthcare delivery systems. Patients with limited proficiency in English often run into barriers when they try to enter the healthcare system. They may delay making an appointment because of difficulties communicating over the telephone, for example, and during this delay, the health problem may become more severe, requiring more expensive treatment. If the patient does make an appointment, there may be misunderstandings about the scheduled date, time, or location. Nurses need to know that translation services and interpreter access are federal mandates. Note, too, that translation services involve written communication, and interpreters refer to oral communication.

- **Staff competencies.** The last area for organizational cultural competency is providing opportunities for all staff to learn about a variety of cultural groups and become educated as culturally competent providers. Being competent is both an individual and organizational moral imperative for which the organization should provide resources and opportunities for education and multicultural experiences.

Using an Interpreter

Many patients do not speak English, and many who do speak some English are of limited proficiency. Any facility receiving federal funding from the U.S. Department of Health and Human Services is required to communicate effectively with patients or risk the loss of that funding. Having bilingual nurses available is one strategy to address the language barrier. Another strategy is providing access to language banks through electronic or telephone systems that nurses can dial for interpreter services. Unless a patient brings an interpreter with her, however, an interpreter may not have any previous knowledge of the patient. Nurses can ask a patient or family with limited English proficiency if the family works with any area service organizations that provide interpreters. These organizations attempt to provide competent interpreters who build relationships with families over time. However, the nurse should be aware that some cultures find it offensive to discuss medical issues with a member of the opposite gender or a younger person (Chang & Kelly, 2007). The nurse should collaborate with the patient and family regarding specifics for an interpreter.

Guidelines for using an interpreter include the following:

- When possible, use an interpreter to translate and provide meaning behind the words.
- To protect patient confidentiality and to guard against the possibility of the interpreter misunderstanding medical information, avoid using a family member as an interpreter.
- If possible, use an interpreter of the same gender as the patient.
- Address your questions to the patient, not the interpreter, but maintain eye contact with both the patient and the interpreter.

- Avoid using metaphors, medical jargon, similes, and idiomatic phrases.
- Observe the patient's nonverbal communication.
- Plan what to say, and avoid rephrasing or hesitating.
- Use short questions and comments. Ask one question at a time.
- Speak slowly and distinctly, but not loudly.
- Provide written materials in the patient's language as available.

Clinical Example C

Henry Lee is approximately 55 years old. Born in China, he has been living in the United States for the past 10 years, working as a professor at a local university. Following surgery for a broken arm, he refuses pain medication, explaining that his discomfort is bearable and he can survive without medication.

When you next check on him, you find him restless and uncomfortable. You have a standing order to administer medication as needed, and again offer to administer medication. Mr. Lee again refuses, saying that your other responsibilities are more important than his discomfort and he does not want to impose.

Critical Thinking Questions

1. What do you think is behind Mr. Lee's refusal to accept medication?
2. What can you do or say to change Mr. Lee's perception of the situation?
3. What additional information might influence your nursing care?

NURSING PROCESS

The nursing process is interwoven in providing culturally competent care. In each step, the nurse should be considerate of the patient's cultural background and practices. This holistic approach will help both the patient and the nurse create a therapeutic plan of care.

Assessment

The provision of culturally competent care begins with incorporating culture into the initial nursing assessment. Areas for assessment include the use of traditional healing practices such as herbal supplements or mind-body practices (e.g., cupping, acupuncture); cultural practices related to food preparation and preferences; religious or cultural practices at specific times of day or during the week; health beliefs; and preferences for care, such as whether or not women prefer to be examined by a female nurse.

When patients speak languages other than English or are not proficient in English, minimal assessment information from patients can be obtained with the following questions:

- What language do you speak? Do you speak any English?
- How long have you lived here?

- Describe the illness or problem that brings you here today.
- What do you think caused your problem?
- When did it start?
- Why do you think it started when it did?
- What does your sickness do to you?
- How severe is your sickness?
- What do you fear about your sickness?
- What helps make it better? Worse?
- What kind of treatment do you think you need?
- Are there any religious practices we need to know about?
- Who is your family?
- Who makes decisions most of the time?
- Who can you go to for help when you need it?

Assessment of cultural influences and practices is imperative because differences in cultural behaviors, beliefs, and values may result in barriers to patients achieving positive outcomes. Cultural misunderstandings or miscommunications also may result from different perceptions of health and of the illness diagnosed.

Nursing assessment of the patient's values and beliefs includes assessing for the use of complementary and alternative therapies. The term **complementary therapies** refers to any of a diverse array of practices, therapies, and supplements that are not considered part of conventional or traditional medicine and that are used *in addition to* conventional treatments. **Alternative therapies** is a term used to describe use of these diverse therapies *instead of* conventional therapies (see the Focus on Integrative Health feature). Assessing the patient for use of these therapies is important to determine patient preferences for care and if there are any therapies the patient is currently using that are contraindicated.

Diagnosis

Once the assessment is complete, nurses can begin to form diagnoses appropriate to the individual or family seeking care. Examples of NANDA International (NANDA-I) nursing diagnoses that may be appropriate for patients of different cultures include:

- *Powerlessness*
- *Spiritual Distress*
- *Religiosity, Risk for Impaired*
- *Fear*
- *Decisional Conflict*
- *Resilience, Risk for Impaired*
- *Anxiety*
- *Health Maintenance, Ineffective*
- *Coping, Ineffective*
- *Social Interaction, Impaired.*

(NANDA-I © 2014)

- *Disturbed Thought Processes*

Planning

Planning care in collaboration with the patient increases the likelihood that the patient will follow the care plan, particularly if the plan is culturally sensitive. At times it can be challenging to incorporate a patient's cultural preferences and practices into the care plan, especially in the hospital setting. For example, those patients whose origins are from India tend to have strong family ties. When a person becomes ill, several family members may come to the hospital and gather in the room, causing crowding. Typically, the mother will provide care for the patient. This can cause conflict, as many from India believe in self-medication and herbal medicines. The nurse, therefore, should collaborate with the patient and family to provide safe, effective care. Appropriate goals for patients will include the following:

- The patient will remain safe through the use of interpreters, educational materials written in the patient's primary language, and other cultural bridges of communication between the healthcare team and the patient.
- The patient will meet nutritional needs during hospitalization through meal accommodation, nutritional counseling, and incorporation of preferred foods in the meal plan.
- The patient will perform ADLs and increase mobility when appropriate.
- Both patient and family members will verbalize understanding of necessity of early mobility and independence with ADLs.

Implementation

Implementation should involve a care plan that incorporates the patient's cultural beliefs and practices.

Promote Safety

There is great potential for harm due to cultural and language issues. Patients who do not understand the language of the nurse may not adhere to safety instructions, including using a call light before getting out of bed. Family members may bring comfort foods from home that might interfere with fluid or diet restrictions. Some might want to complement the patient's care with traditional healing remedies that may interact with medications. The nurse must create an open channel of communication with family members and the patient in order to provide safe and culturally sensitive care. Additional assessment and patient teaching regarding safety procedures, medication side effects and interactions, and other areas of care may be necessary.

Provide Adequate Nutrition

In the hospital setting, ethnic foods are often not available. Many cultures see food as a way to provide healing and comfort. Some patients may not eat hospital food because it is foreign or taboo. For instance, those of Jewish heritage may not eat the food provided in a hospital if it is not prepared and served correctly in a kosher manner. Vietnamese

patients may ignore Western food or diet recommendations if they follow traditional cultural practices regarding eating certain foods during illness. Regardless of the patient's background, carefully assess patient and family expectations and practices regarding foods and beverages and incorporate these into the plan of care when it is safe to do so.

Promote Physical Mobility

Many cultures believe that the sick must remain in bed with little physical activity until deemed well. The belief is that the sick person must gain strength. For example, some Filipinos believe that even showering is too strenuous for the patient and will bathe the family member in bed. The cultural belief of restricted activity may cause conflict with nurses who wish to promote activity to prevent skin integrity breakdown, clots, and other complications with immobility. The nurse can take this opportunity to educate as well as collaborate. The nurse should collaborate with the family to implement a plan that does include mobility, but also appreciates the cultural need for rest.

Evaluation

The evaluation of the nurse's plan of care will involve the underlying goals that include a culture component. Goals may include:

- The patient expresses that cultural needs were met.
- The patient is able to verbalize understanding of medical diagnosis and treatment plan.
- The patient is able to collaborate with the care team when using complementary therapies.
- The patient is able to meet nutritional needs.

Evaluating how successfully the patient is able to follow the treatment regimen while observing cultural practices and rituals is essential to determining patient outcomes but also provides a way for nurses to evaluate whether or not they provided culturally competent care that promoted improved patient outcomes.

Focus on Integrative Health Overview of Complementary Health Approaches

The National Center for Complementary and Integrative Health (NCCIH) reports that approximately 33.2% of Americans use complementary and integrative health approaches (sometimes referred to as complementary and alternative medicine, or CAM) (Clarke et al., 2015). Types and examples of these approaches include:

- **Natural products.** Dietary supplements, including fish oil and herbal supplements such as turmeric
- **Mind and body practices.** Meditation, yoga, acupuncture, chiropractic medicine, massage therapy

» **Stay Current:** For more information on complementary and alternative therapies, go to the NCCIH website: <https://nccih.nih.gov>.

REVIEW The Concept of Culture and Diversity

RELATE Link the Concepts

Linking the concept of culture and diversity with the concept of development:

1. How might a pediatric patient's development be impacted if his or her mother is homeless?
2. How might an adolescent's development be impacted by the realization that he or she is homosexual?

You are a nurse working in a children's rehabilitation center. A 6-year-old girl who is recovering from a motor vehicle accident comes to your center for an extended stay. She speaks a little English. Her family has recently moved here from China, and her parents likewise have limited English. Although they are grateful for the help they are receiving, they are very stressed about their daughter's situation.

Linking the concept of culture and diversity with the concept of communication:

3. How might the nurse assess this family's values and beliefs in light of the family's inability to speak English?
4. How might involvement of an interpreter to facilitate communication impact the patient and her family's values and beliefs? How can you overcome this problem?

Linking the concept of culture and diversity with the concept of advocacy:

5. How can you advocate for this patient's values and beliefs while she is in the rehabilitation center?
6. The patient's family wishes to pray at the child's bedside using candles, which are not allowed because of the risk for fire related

to oxygen use. How can you advocate for this family while maintaining safety?

REFLECT Apply Your Knowledge

Elam Avromovitch, a 76-year-old man, is visiting his son's family in the United States when he develops chest pain. A native of Israel and a follower of ultra-Orthodox Judaism, Mr. Avromovitch speaks Yiddish as his first language. Tests reveal he is having an acute myocardial infarction and needs intervention in a cardiac catheterization lab. The nurses on the cardiac floor are attempting to prepare him for the procedure while his son translates. The nurse attempts to call for a translator for the consent, but the son declines a translator, stating that he will serve instead. When attempting to undress Mr. Avromovitch for a required admission skin assessment before the procedure, the patient starts to "shoo" away the female nurses and tries to cover up. The son explains that women are not permitted to see him undressed, particularly women who are not of his faith.

1. Is the use of the son for interpretation valid for a legal consent for treatment?
2. How can the nurse respect Mr. Avromovitch's diversity requirements while maintaining facility policy and meeting the patient's healthcare needs?
3. What nursing diagnoses and interventions would be appropriate for Mr. Avromovitch's plan of care?

Module 25

Development

Module Outline and Learning Outcomes

The Concept of Development

Normal Development

25.1 Analyze the components and theories of normal development.

Growth and Development Through the Lifespan

25.2 Summarize the developmental milestones of individuals across the lifespan.

Alterations to Development

25.3 Differentiate alterations in development.

Concepts Related to Development

25.4 Outline the relationship between development and other concepts.

Health Promotion

25.5 Explain the promotion of healthy development.

Nursing Assessment

25.6 Differentiate common assessment procedures and tests used to examine development.

Independent Interventions

25.7 Analyze independent interventions nurses can implement for patients with alterations in development.

Collaborative Therapies

25.8 Summarize collaborative therapies used by interprofessional teams for patients with alterations in development.

Lifespan Considerations

25.9 Differentiate considerations related to the assessment and care of patients with alterations in development throughout the lifespan.

Development Exemplars

Exemplar 25.A Attention-Deficit/Hyperactivity Disorder

25.A Analyze ADHD as it relates to development.

Exemplar 25.B Autism Spectrum Disorder

25.B Analyze ASD as it relates to development.

Exemplar 25.C Cerebral Palsy

25.C Analyze CP as it relates to development.

Exemplar 25.D Failure to Thrive

25.D Analyze failure to thrive as it relates to development.

Cephalocaudal, 1786		Moral behavior, 1792	Proximodistal, 1786	Transductive reasoning, 1798
Cognitive development, 1789		Moral development, 1792		

Jean Piaget (1970) wrote: “It is with children that we have the best chance of studying the development of logical knowledge, mathematical knowledge, physical knowledge, and so forth” (p. 14). Understanding lifespan development and applying that knowledge can provide the nurse with valuable tools to provide a holistic approach to caring for patients of all ages.

The terms *growth* and *development* both refer to dynamic processes. Often used interchangeably, these terms have different meanings. **Growth** refers to physical change and increase in size. Indicators of growth include height, weight, bone size, and dentition. The pattern of physiologic growth is similar for all people. However, growth rates vary during different stages of growth and development. The growth rate is rapid during the prenatal, neonatal, infancy, and adolescent stages and slows during childhood. Physical growth is minimal during adulthood.

Development is an increase in the complexity of function and skill progression, the capacity and skill of an individual to adapt to the environment. Development is the behavioral aspect of growth (e.g., an individual develops the ability to walk, to talk, and to run).

Normal Development

Growth and development are independent, yet interrelated, processes. For example, an infant’s muscles, bones, and nervous system must grow to a certain point before the infant is able to sit up or walk. Growth generally takes place during the first 20 years of life; development takes place throughout the lifespan. Principles of growth and development include:

- Growth and development are continuous, orderly, sequential processes influenced by maturational, environmental, and genetic factors.
- All humans follow the same pattern of growth and development.
- The sequence of each stage is predictable, although the time of onset, the length of the stage, and the effects of each stage vary with each individual.
- Each **developmental stage** (level of achievement) has its own characteristics. For example, Piaget suggested that in the sensorimotor stage (birth to 2 years) children learn to coordinate simple motor tasks.
- Growth and development occur in a **cephalocaudal** direction, that is, starting at the head and moving toward the trunk, legs, and feet (**Figure 25–1** »). This pattern is particularly obvious at birth, when the head of the infant is disproportionately large.
- Growth and development occur in a **proximodistal** direction, that is, from the center of the body outward (see **Figure 25–1**). For example, infants can roll over before they can grasp an object with the thumb and second finger.
- Development proceeds from simple to complex, or from single acts to integrated acts. To accomplish the integrated act of drinking and swallowing from a cup, for example, the child must first learn a series of single acts: eye–hand coordination; grasping; hand–mouth coordination; controlled tipping of the cup; and then mouth, lip, and tongue movements to drink and swallow.

Figure 25–1 » In normal cephalocaudal growth, the child gains control of the head and neck before the trunk and limbs. In normal proximodistal growth, the child controls arm movements before hand movements. For example, the child reaches for objects before being able to grasp them. Children gain control of their hands before their fingers; that is, they can hold things with the entire hand before they can pick something up with just their fingers.

- Development becomes increasingly differentiated. Differentiated development begins with a generalized response and progresses to a specific skilled response. For example, an infant’s initial response to a stimulus involves the total body, but a 5-year-old child can respond more specifically with laughter or fear.
- The pace of growth and development is uneven. It is known that growth is greater during infancy than during childhood. Asynchronous development is demonstrated by rapid growth of the head during infancy and the extremities at puberty.
- The rate of growth and development is highly individual; however, the sequence of growth and development is predictable. Stages of growth usually correspond to certain developmental changes (**Table 25–1** »).

Theories of Growth and Development

Theories help to explain one or more aspects of an individual’s growth and development. Typically, theorists examine only one aspect of development, such as the cognitive, moral, or physical aspect. The area chosen for examination usually reflects the researcher’s academic discipline and personal interest. The theorists may also limit the population that is studied to a particular part of the lifespan, such as infancy, childhood, or adulthood.

Although such theories can be useful, they have limitations. First, although a given theory may explain one aspect of the growth and development process, an individual does not develop in fragmented sections but rather as a whole human being. Thus, application of several theories may be

TABLE 25–1 Stages of Growth and Development

Stage	Age	Significant Characteristics	Nursing Implications
Neonatal	Birth–28 days	Behavior is largely reflexive and develops to more purposeful behavior.	Assist parents to identify and meet unmet needs.
Infancy	1 month–1 year	Physical growth is rapid.	Control the infant's environment so that physical and psychologic needs are met.
Toddlerhood	1–3 years	Motor development permits increased physical autonomy. Psychosocial skills increase.	Safety and risk-taking strategies must be balanced to permit growth.
Preschool	3–6 years	The preschooler's world is expanding. New experiences and the preschooler's social role are tried during play. Physical growth is slower.	Provide opportunities for play and social activity.
School age	6–12 years	This stage includes the preadolescent period (10–12 years). Peer group increasingly influences behavior. Physical growth is slower.	Allow time and energy for the school-age child to pursue hobbies and school activities. Recognize and support child's achievement.
Adolescence	12–18 years	Self-concept changes with biological development. Values are tested. Physical growth accelerates. Stress increases.	Assist adolescents to develop coping behaviors. Help adolescents develop strategies for resolving conflicts.
Young adulthood	18–40 years	A personal lifestyle develops. Individual establishes a relationship with a significant other and a commitment to something; many become parents. Physical growth slows and then stops (except for weight gain). Metabolism begins to slow down.	Accept adult's chosen lifestyle and assist with necessary adjustments relating to health. Recognize the individual's commitments. Support change as necessary for health.
Middle adulthood	40–65 years	Lifestyle changes because of other changes; for example, children leave home, occupational goals change. Physical changes may include weight gain, diminished vision and hearing, onset of wrinkles, hair loss in men. Risk for onset of chronic illness greatest during this time.	Assist patients to plan for anticipated changes in life, to recognize the risk factors related to health, and to focus on strengths rather than weaknesses.
Older adulthood			
<i>Young-old</i>	65–74 years	Adaptation to retirement and changing physical abilities is often necessary. Chronic illness may develop/continue.	Assist patients to keep mentally, physically, and socially active and to maintain peer group interactions.
<i>Middle-old</i>	75–84 years	Adaptation to decline in speed of movement, reaction time, and balance issues. Increasing dependence on others may be necessary.	Assist patients to cope with loss (e.g., hearing, sensory abilities, eyesight, death of loved one). Provide necessary safety measures.
<i>Old-old</i>	85 years and older	Increasing physical problems may develop. Many need help with self-care.	Assist patients with self-care as required, and with maintaining as much independence as possible.

necessary to gain insight about an individual's growth and development.

Another limitation of some theories is the suggestion that certain tasks are performed at a specific age. In most cases, the child or adult does accomplish the task at the time specified by the guidelines. In other cases, however, the nurse may find that an individual does not accomplish the task or meet the milestone at the exact time the theory suggests. Such individual differences are not easily defined or categorized by a single theory.

Growth and development are commonly thought of as having five major components: psychosocial, cognitive, moral, spiritual, and biophysical. Theorists have attempted to study and explain development through these lenses as well as others, including social learning, temperament and personality, and ecology. Researchers have advanced several theories about the various stages and aspects of growth and development, particularly with regard to infant and child development. A discussion of some of the major theories follows.

Psychosocial Theories

Psychosocial development refers to the development of personality. **Personality** can be considered an outward expression

of the inner (intrapersonal) self; the enduring characteristic patterns of thinking, feeling, and behavior that make an individual unique. It encompasses an individual's temperament, feelings, character traits, independence, self-esteem, self-concept, behavior, ability to interact with others, and ability to adapt to life changes. Although personality is enduring over time, it may be influenced by or adapt to changes or differences in education, environments, and experiences.

Sigmund Freud (1856–1939) proposed many of the earliest theories regarding the development of personality. For nurses, the most relevant part of his work centers around the development of ego defense mechanisms, which are described in the module on Stress and Coping.

Erikson (1902–1994)

Erik H. Erikson (1963, 1968) proposed a theory of development that includes the entire lifespan, as he believed that people continue to develop throughout life. He described eight stages of development (**Table 25–2** »).

Erikson's theory proposes that life is a sequence of developmental stages or levels of achievement. Each stage signals a task that must be accomplished. The resolution of the task can be complete, partial, or unsuccessful. Erikson believed

TABLE 25-2 Erikson's Eight Stages of Development

Stage	Age	Primary Task	Outcomes of Successful Task Accomplishment	Outcomes of Failed Task Accomplishment
Infancy	Birth–18 months	Trust versus mistrust	Development of basic trust and sense of security	Lack of trust, sense of fear
Early childhood	18 months–3 years	Autonomy versus shame and doubt	Basic awareness of independence; sense of autonomy and self-control	Self-doubt, sense of helplessness, heightened dependence on caregivers
Late childhood	3–5 years	Initiative versus guilt	Emergence of basic sense of self-guidance and self-discipline	Impaired self-initiative, insecurity regarding leadership ability
School age	6–12 years	Industry versus inferiority	Confidence in ability to attain goals, initial formation of identity apart from nuclear family, successful peer group integration	Sense of incompetence, low self-esteem, difficulty integrating into peer groups
Adolescence	12–20 years	Identity versus role confusion	Formation of strong sense of identity as an individual and as a member of society, identification of personal and occupational goals	Role confusion, social alienation, potential substance abuse, potential development of antisocial personality disorder
Young adulthood	18–25 years	Intimacy versus isolation	Development of healthy romantic relationships without compromising personal identity	Avoidance of intimacy, fear of commitment, isolation
Adulthood	25–65 years	Generativity versus stagnation	Productivity and creativity, desire to care for and guide offspring (or, if childfree, to guide the next generation)	Self-preoccupation, primary attainment of pleasure through self-indulgence, stagnation
Maturity	65 years–death	Integrity versus despair	Sense of peace concerning life experiences, life choices framed within a meaningful context, development of wisdom	Life experiences framed by bitterness and/or regret; may progress to hopelessness and depression

Source: Based on Erikson, E. (1963). *Childhood and society*. New York, NY: W.W. Norton; Weber, J. R., & Kelley, J. H. (2010). *Health assessment in nursing* (4th ed.). Philadelphia, PA: Lippincott Williams & Wilkins; Watts, J., Cockcroft, K., & Duncan, N. (Eds.). (2010). *Developmental psychology* (2nd ed.). Cape Town, South Africa: UCT Press.

that the more successful an individual is at each developmental stage, the healthier the personality of the individual will be. Failure to complete any developmental stage interferes with the individual's ability to progress to the next level. These developmental stages can be viewed as a series of crises. Successful resolution of these crises supports healthy ego development. Failure to resolve the crises damages the ego.

Erikson's eight stages reflect both positive and negative aspects of the critical life periods. The resolution of the conflicts at each stage enables the individual to function effectively in society. Each phase has its own **developmental tasks** (skills or behavior patterns, such as walking or toiletting independently, that are characteristic of that phase). At each stage, the individual must find a balance between, for example, trust and mistrust (stage 1) or integrity and despair (stage 8). See **Figures 25-2** » and **25-3** ».

According to Erikson, the environment is highly influential to development. Nurses can enhance a patient's development by being aware of the individual's developmental stage and assisting with the development of coping skills related to stressors experienced at that specific level. Nurses can strengthen a patient's positive resolution of a developmental task by providing the individual with appropriate opportunities and encouragement. For example, the nurse can encourage a 10-year-old child (industry versus inferiority) to be creative, to finish schoolwork, and to learn how to accomplish these tasks within the limitations imposed by health status. The nurse can encourage the older adult to maintain generativity (care for and connection with others) to avoid a sense of stagnation, or a feeling of disconnectedness that increases self-absorption and loneliness.

Erikson emphasized that people must change and adapt their behavior to maintain control over their lives. In his

view, no stage in personality development can be bypassed, and people can become fixated at one stage or regress to a previous stage under anxious or stressful conditions. For example, a middle-aged woman who has never satisfactorily resolved the identity versus role confusion task might

Source: Purestock/Getty Images.

Figure 25-2 » This infant is clearly on his way to accomplishing a sense of basic trust in and security with his mother.

Figure 25-3 >> Regular visits from a home health nurse can help older adults maintain their health and independence, contributing to the achievement of integrity versus despair.

regress to an earlier stage when stressed by an illness with which she cannot cope.

Gould (1935–)

Roger Gould is another theorist who has studied adult development. He believes that transformation is a central theme during adulthood: “Adults continue to change over the period of time considered to be adulthood and developmental phases may be found during the adult span of life” (Gould, 1972, p. 33). According to Gould, in his 20s the individual assumes new roles, in the 30s role confusion often occurs, in the 40s the individual becomes aware of time limitations in relation to accomplishing life’s goals, and in the 50s the acceptance of each stage as a natural progression of life marks the path to adult maturity.

- **Stage 1 (ages 16–18).** Individuals consider themselves part of the family rather than individuals; they begin to want to separate from their parents.
- **Stage 2 (ages 18–22).** Although individuals have established autonomy, they feel it is in jeopardy; they feel they could be pulled back into their families.
- **Stage 3 (ages 22–28).** Individuals feel established as adults and autonomous from their families. They see themselves as well defined but still feel the need to prove themselves to their parents. They see this as the time for growing and building for the future.
- **Stage 4 (ages 28–34).** Marriage and careers are well established. Individuals question what life is all about and wish to be accepted as they are, no longer finding it necessary to prove themselves.
- **Stage 5 (ages 34–43).** This is a period of self-reflection. Individuals question long-held values as well as life itself. They see time as finite, with little time left to shape the lives of adolescent children.
- **Stage 6 (ages 43–50).** Personalities are seen as set. Time is accepted as finite. Individuals are interested in social activities with friends and spouse and desire both sympathy and affection from spouse.

- **Stage 7 (ages 50–60).** This is a period of transformation, with a realization of mortality and a concern for health. There is an increase in warmth and a decrease in negativism. The spouse is seen as a valuable companion (Gould, 1972, pp. 525–527).

Peck (1919–2002)

Theories and models about adult development are relatively recent compared with theories of infant and child development. Research into adult development has been stimulated by a number of factors, including increased longevity and healthier old age. In the past, development was viewed as complete by the time of physical maturity, and aging was considered a decline following maturity. The emphasis was on the negative rather than positive aspects of aging. However, Robert Peck (1968) believed that, although physical capabilities and functions decrease with old age, mental and social capacities tend to increase in the latter part of life.

Peck (1968) proposed three developmental tasks during old age, in contrast to Erikson’s one (integrity versus despair):

1. **Ego differentiation versus work-role preoccupation.** An adult’s identity and feelings of worth are highly dependent on that individual’s work role. On retirement, people may experience feelings of worthlessness unless they derive their sense of identity from a sufficient number of roles that one such role can replace the work role or occupation as a source of self-esteem. For example, a man who likes to garden or golf can obtain ego rewards from those activities, replacing rewards formerly obtained from his occupation.
2. **Body transcendence versus body preoccupation.** This task calls for the individual to adjust to decreasing physical capacities and at the same time maintain feelings of well-being. Preoccupation with declining body functions reduces happiness and satisfaction with life.
3. **Ego transcendence versus ego preoccupation.** Ego transcendence is the acceptance without fear of one’s death as inevitable. This acceptance includes being actively involved in one’s own future beyond death. Ego preoccupation, by contrast, results in holding onto life and a preoccupation with self-gratification.

Cognitive Theory

Cognitive development refers to the manner in which people learn to think, reason, and use language. It involves a person’s intelligence, perceptual ability, and ability to process information. Cognitive development represents a progression of mental abilities from illogical to logical thinking, from simple to complex problem solving, and from understanding concrete ideas to understanding abstract concepts. The most widely known cognitive theorist is Jean Piaget (1896–1980). His theory of cognitive development has contributed to other theories.

According to Piaget (1966), cognitive development is an orderly, sequential process in which a variety of new experiences (stimuli) must exist before intellectual abilities can develop. Piaget divides cognitive development into four major phases: the sensorimotor phase, the preoperational phase, the concrete operational phase, and the formal

TABLE 25–3 Piaget’s Phases of Cognitive Development

Phases and Stages	Age	Significant Behavior
Sensorimotor phase	Birth–2 years	
Stage 1: Use of reflexes	Birth–1 month	Uses reflexes: sucking, rooting, grasping.
Stage 2: Primary circular reaction	1–4 months	Infant responds reflexively. Objects are extension of self.
Stage 3: Secondary circular reaction	4–8 months	Awareness of environment grows. Changes in the environment are actively made as infant recognizes cause and effect.
Stage 4: Coordination of secondary schemata	8–12 months	Intentional behavior occurs. Object permanence begins.
Stage 5: Tertiary circular reaction	12–18 months	Toddlers discover new goals and ways to attain goals. Rituals are important.
Stage 6: Mental combinations	18–24 months	Language gives toddlers a new tool to use.
Preoperational phase	2–7 years	Young children think by using words as symbols. Everything is significant and relates to “me.” They explore the environment. Language development is rapid. Words are associated with objects. As children get older, egocentric thinking diminishes. They think of one idea at a time. Words express thoughts.
Concrete operational phase	7–11 years	Children solve concrete problems, begin to understand relationships such as size, understand right and left, and recognize various viewpoints.
Formal operational phase	11 years and up	Children use rational thinking. Reasoning is deductive and futuristic.

Source: Data from Piaget, J. (1966). *Origins of intelligence in children*. New York, NY: W.W. Norton. Copyright © 1966 International Universities Press, Inc.

operational phase. A detailed discussion of these phases, and how the nurse can incorporate his or her knowledge of them into nursing plans and interventions, can be found in the module on Cognition.

An individual develops through each of these phases; each phase has its own unique characteristics (**Table 25–3** »). In each phase, the individual uses three primary abilities: assimilation, accommodation, and adaptation. **Assimilation** is the process through which humans encounter and react to new situations by using mechanisms they already possess. In this way, people acquire knowledge and skills as well as insights into the world around them. **Accommodation** is a process of change whereby cognitive processes mature sufficiently to allow the individual to solve problems that were unsolvable before. This adjustment is possible chiefly because new knowledge has been assimilated. **Adaptation**, or coping behavior, is the ability to handle the demands made by the environment.

Nurses can use Piaget’s theory of cognitive development when developing teaching strategies. For example, a nurse can expect a toddler to be egocentric and literal; therefore, explanations to the toddler should focus on the needs of the toddler rather than on the needs of others. A 13-year-old can be expected to use rational thinking and to reason; therefore, when explaining the need for a medication, a nurse can outline the consequences of taking and not taking the medication, enabling the adolescent to make a rational decision. Nurses must remember, however, that the range of normal cognitive development is broad, despite the ages arbitrarily associated with each level. When teaching adults, nurses may become aware that some adults are more comfortable with concrete thought and are slower to acquire and apply new information than are other adults.

Behaviorism

Behaviorist theory states that learning takes place when an individual’s reaction to a stimulus is either positively or

negatively reinforced. The more rapid, consistent, and positive the reinforcement, the more likely a behavior is to be learned and retained.

B. F. Skinner (1904–1990) believed that organisms learn as they respond to or “operate on” their environment. His research led to the concept of *operant conditioning*, in which he maintained that rewarded or reinforced behavior will be repeated; behavior that is punished will be suppressed.

Social Learning Theory

Albert Bandura (1925–), a contemporary psychologist, believes that children learn attitudes, beliefs, customs, and values through their social contacts with adults and other children. Children imitate (or model) the behavior they see; if the behavior is positively reinforced, they tend to repeat it. However, Bandura also believes that people can consciously choose how to act, such as deciding to handle problems by talking rather than using violence. The external environment (the behavior of others) and the child’s internal processes are both key elements in the behaviors the child manifests (Bandura, 1986, 1997a).

Bandura believes that an important determinant of behavior is **self-efficacy**, or the expectation that someone can produce a desired outcome. For example, if adolescents believe they can avoid use of drugs or alcohol, they are more likely to do so. A child who has confidence in his or her ability to exercise regularly or lose weight has a greater chance of success with these behavior changes. Parents who have confidence in their ability to care adequately for their infants are more likely to do so (Bandura, 1997b).

Temperament Theory

In contrast to personality, **temperament** refers to innate characteristics, such as nervousness or sensitivity, that do not change over time. Chess and Thomas (1995, 1996) recognize the innate qualities of personality that each individual brings to the events of daily life. They view the child as an

individual who both influences and is influenced by the environment. However, Chess and Thomas focus on one specific aspect of development: the wide spectrum of behaviors possible in children and how they respond to daily events. Infants generally display clusters of responses, which Chess and Thomas have classified into three major personality types (**Box 25–1** >>). Although most children do not demonstrate all behaviors described for a particular type, they usually show a grouping indicative of one personality type (Chess & Thomas, 1995, 1996).

Longitudinal research has demonstrated that personality characteristics displayed during infancy are often consistent with those seen later in life. The ability to predict future characteristics is not possible, however, because of the complex and dynamic interaction of personality traits and environmental reactions.

Resiliency Theory

The concept of resilience first appeared in the literature in the early 1970s. Werner, Bierman, and French (1971) studied a cohort of children from Kauai, Hawaii, in efforts to understand why some children who grow up in poverty and other challenging situations did not follow in the footsteps of their parents, many of whom were alcoholics and/or had mental illness. The researchers felt those children grew up “resilient” to challenging situations (Werner et al., 1971). Resiliency theory examines the individual’s characteristics as well as the interaction of those characteristics with the environment. **Resilience** is the ability to function with healthy responses, even when experiencing significant stress and adversity (Benard, 2014). In this model, the individual or family members experience a crisis that provides a source of stress, and the family interprets or deals with the crisis based on resources

Box 25–1

Patterns of Temperament—Chess and Thomas

- **“Easy” child.** The “easy” child is generally moderately active; shows regularity in patterns of eating, sleeping, and elimination; and is usually positive in mood and when subjected to new stimuli. The easy child adapts to new situations and is able to accept rules and work well with others. About 40% of children in the New York Longitudinal Study displayed this personality type.
- **“Difficult” child.** The “difficult” child displays irregular schedules for eating, sleeping, and elimination; adapts slowly to new situations and persons; and displays a predominantly negative mood. Intense reactions to the environment are common. The New York Longitudinal Study found that approximately 10% of children display this personality type.
- **“Slow-to-warm-up” child.** The “slow-to-warm-up” child has reactions of mild intensity and is slow to adapt to new situations. The child displays initial withdrawal followed by gradual, quiet, and slow interactions with the environment. About 15% of children in the New York Longitudinal Study displayed this personality type.

The remaining 35% of children studied showed some characteristics of each personality type.

available. Families and individuals have **protective factors** that provide strength and assistance in dealing with crises and **risk factors** that promote or contribute to their challenges (Cairns et al., 2014). Protective and risk factors can be identified in children, in their families, and in their communities. A

Evidence-Based Practice

Resiliency

Problem

Staff retention is an ever-present issue for intensive care units (ICUs). Nurses are faced with constant stress from many different sources, including but not limited to patient acuity, family dynamics, and ethical challenges. Those nurses who choose to work in critical care areas tend to have a higher incident of depression, anxiety, and posttraumatic stress disorder (PTSD).

Evidence

Mealer et al. (2014) conducted a small study of 27 nurses who worked in a variety of critical care settings. Prior to the study, the test subjects showed evidence of stress-related mental health conditions, including anxiety and depression. Of the 27 subjects, 11 scored positive for PTSD symptoms.

The group was divided into an intervention group (13 subjects) and control group (14 subjects). Those in the intervention group participated in a 2-day, multi-module resilience training that included writing therapy, mindfulness therapy, and self-care techniques. After 12 weeks, those who participated in the resilience training showed improvement in several mental health screening tools, including a significant decrease in depression, and reported greater skills in coping with the stresses of ICU nursing.

Implications

Providing resilience training, as well as prompting resilience and self-care techniques, is a worthy investment for nurse managers and healthcare facilities to make, as the outcomes of improved mental health and improved coping skills are likely to lower burnout and error rates and improve retention rates. Likewise, nurses, particularly those in critical care situations, should be aware that working in this specialty area calls for great resilience. Nurses can nurture their own personal resilience through different techniques, such as journaling and peer counseling. Nurses can apply this concept of resilience in several different ways.

Critical Thinking Application

1. You are working as the staff educator on an oncology unit. In what ways is this evidence-based resilience training applicable to your unit? Give a rationale for your answer.
2. You are working as a nurse manager of a 28-bed ICU. You want to incorporate resilience training for your staff. Should the training be part of the new hire orientation? Should the training be delayed until the new staff member is off probation and has been working on the unit for 6 or more months? Should resilience training be part of the yearly staff education? Give rationales for your answers.

typical crisis for a young child might be a transfer to a new child care provider. Protective factors for a child transferring to a new provider could involve past positive experiences with new people and an “easy” temperament. An additional protective factor might be the level of understanding the new child care provider has about the adaptation needs of young children to new experiences. Risk factors for a child experiencing this type of transition might include repeated moves to new care providers, limited close relationships with adults, and a “slow-to-warm-up” temperament.

Once confronted by a crisis, the child and family first experience the **adjustment phase**. This phase is characterized by disorganization and unsuccessful attempts at meeting the crisis. In the **adaptation phase**, the child and family meet the challenge and use resources to deal with the crisis (Walsh, 2011). Adaptation may lead to increasing resilience, as the child and family learn about new resources and inner strengths and develop the ability to deal more effectively with future crises.

Ecologic Theory

The relative importance in human development of heredity versus environment—or nature versus nurture—is controversial among theorists. **Nature** refers to the genetic or hereditary capability of an individual. **Nurture** refers to the effects of the environment on a person’s performance. Contemporary developmental theories increasingly recognize the interaction of nature and nurture in determining the individual’s development.

The ecologic theory of development was formulated by Urie Bronfenbrenner to explain the individual’s unique relationship in all of life’s settings, from close to remote (Bronfenbrenner, 1986, 2005; Bronfenbrenner et al., 1996). **Ecologic theory** emphasizes the presence of mutual interactions between the individual and these various settings. Neither nature nor nurture is considered more important. Bronfenbrenner believes each individual brings a unique set of genes—and specific attributes such as age, gender, health, and other characteristics—to his or her interactions with the environment. The individual then interacts in many settings at different levels or systems, such as family, school or work, and sports team or interest club. The systems the individual encounters affect both the individual and the other systems. For example, communication between the parent, the pediatrician’s office, and the school may help ensure that a child has an asthma action plan in time for the school nurse to review it with the child’s teachers and bus drivers.

Moral Theories

Moral development is a complex process that is not fully understood. It involves learning what a person should and should not do, but it is more than merely the imprinting of parents’ rules and virtues or values on children. The term **moral** means “relating to right and wrong.” The terms *moral-ity*, *moral behavior*, and *moral development* need to be distinguished from each other. **Morality** refers to the requirements necessary for people to live together in society, **moral behavior** is the way an individual perceives and responds to those requirements, and **moral development** is the pattern of change in moral behavior with age. Refer to the exemplar on Morality in the module on Ethics for more information.

Kohlberg (1927–1987)

Lawrence Kohlberg’s theory specifically addresses moral development in children and adults (Kohlberg, 1981, 1984). Kohlberg was not concerned with the morality of an individual’s decision; rather, he focused on the reasons an individual makes a decision. According to Kohlberg, moral development progresses through three levels and six stages. Levels and stages are not always linked to a certain developmental stage, because some people progress to a higher level of moral development than others. It is worth noting that Kohlberg’s theory of moral development has been criticized for a number of points, including emphasis on moral reasoning rather than moral action, failing to consider the role of the family in the development of the individual, sexual bias, and cultural insensitivity (Santrock, 2015). For example, after more than 10 years of research with female subjects, Carol Gilligan (1982) reported that women often consider the dilemmas Kohlberg used in research to be irrelevant.

Gilligan (1936–)

Gilligan proposed that moral development proceeds through three levels and two transitions, with each level representing a more complex understanding of the relationship of self and others and each transition resulting in a crucial reevaluation of the conflict between selfishness and responsibility (Campbell, 2010; Murray & Zentner, 2001, p. 251).

Gilligan (1982) proposes that because women often see morality in the integrity of relationships and caring, the moral problems they encounter are different from those of men. Men tend to consider what is right to be what is just, whereas for women what is right is taking responsibility for others as a self-chosen decision (p. 140). The ethic of justice, or fairness, is based on the idea of equality: Everyone should receive the same treatment. This is the development path usually followed by men and widely accepted by moral theorists. By contrast, the ethic of care is based on the premise of nonviolence: No one should be harmed. This is the path typically followed by women but given little attention in the literature of moral theory.

Spiritual Theories

The spiritual component of growth and development refers to individuals’ understanding of their relationship with the universe and their perceptions about the direction and meaning of life. The most influential description of *spiritual development* was offered by Fowler (1981). Although Fowler used the term “faith development”, he recognized faith as a universal human phenomenon that leads individuals to need and find meaning and an understanding of themselves in relation to their world. Refer to the module on Spirituality for more information on Fowler’s description of spiritual development.

Growth and Development Through the Lifespan

Individuals constantly change and evolve throughout their lives. While some changes are subtle and highly individualized, others are apparent and represent **developmental milestones** common to all human beings at or near a specific phase of growth and development. The stages of sexual development are covered in the module on Sexuality.

Infants (Birth to 1 Year)

Immense changes occur during the child's first year of life. The child emerges totally dependent on others, his actions primarily reflexive in nature. By the end of his first year, the infant can walk and communicate. Never again in life is development so swift.

Physical Growth and Motor Development

The infant's birth weight usually doubles by about 5 months and triples by the end of the first year. Height increases by approximately 1 foot during this year. Teeth begin to erupt at about 6 months, and by the end of the first year, the infant has six to eight deciduous teeth. Physical growth is closely associated with type and quality of feeding. Likewise, culture and nutrition impact motor function. Angulo-Barroso et al. (2011) found that in cultures with diets high in iron, such as in Ghana, the infants reach motor milestones earlier than other infants of same age. On the other hand, in cultures with diets poor in iron, infants reach motor milestones (e.g., walking without assistance) at a later age.

Body organs and systems, although not fully mature at 1 year of age, function differently than they did at birth. Kidney and liver maturation helps the 1-year-old excrete drugs or other toxic substances more readily than in the first weeks of life. The changing body proportions mirror changes in developing internal organs (**Figure 25-4** >>). Maturation of the nervous system is demonstrated by increased control over body movements, enabling the infant to sit, stand, and walk. Sensory function also increases as the infant begins to discriminate visual images, sounds, and tastes (**Table 25-4** >>).

Cognitive Development

The brain continues to increase in complexity during the first year of life. Most of the growth involves maturation of cells, with only a small increase in cell number. This growth of the brain is accompanied by development of its functions, something easily understood when one compares the behavior of the newborn to that of the 1-year-old. The newborn's eyes widen in response to sound; the 1-year-old turns to the sound and recognizes its significance. The 2-month-old cries and coos; the 1-year-old says a few words and understands

many more. The 6-week-old grasps a rattle for the first time; the 1-year-old reaches for toys and begins to feed herself.

The infant's behaviors provide clues about thought processes. Piaget's work outlines the infant's actions in a set of rapidly progressing changes in the first year of life. The infant receives stimulation through sight, sound, and feeling, which the maturing brain interprets. This input from the environment interacts with internal cognitive abilities to enhance cognitive functioning.

Psychosocial Development

The infant relies on interactions with primary care providers to meet needs and then begins to establish a sense of trust in other adults and in children. As trust develops, the infant becomes comfortable in interactions with a widening array of people.

Play

The play of infants begins in a reflexive manner. When infants move extremities or grasp objects, they experience the foundations of play. They gain pleasure from the feel and sound of these activities, and gradually perform them purposefully. For example, when a parent places a rattle in the hand of a 6-week-old infant, the infant grasps it reflexively. As the hands move randomly, the rattle makes an enjoyable sound. The infant learns to move the rattle to create the sound and then finally to grasp the toy at will to play with it.

The next phase of infant play focuses on manipulative behavior. The infant examines toys closely, looking at them, touching them, and placing them in his or her mouth. The infant learns a great deal about texture, qualities of objects, and all aspects of the surroundings. At the same time, interaction with others becomes an important part of play. The social nature of play is obvious as the infant plays with other children and adults. For example, when a parent walks by, the infant laughs and waves hands and feet wildly (**Figure 25-5** >>). The infant plays primarily alone with toys (**solitary play**) but enjoys the presence of adults or other children. Physical capabilities enable the infant to move toward and reach for objects of interest.

Figure 25-4 >> Body proportions at various ages.

TABLE 25–4 Growth and Development Milestones During Infancy

Age	Physical Growth	Fine Motor Ability	Gross Motor Ability	Sensory Ability
Birth–1 month	Gains 140–200 g (5–7 oz)/week. Grows 1.5 cm (1/2 in.) in first month. Head circumference increases 1.5 cm (1/2 in.)/month.	Forms hand into a fist. Draws arms and legs to body when crying.	Inborn reflexes such as startle and rooting are predominant activity. May lift head briefly if prone. Alerts to high-pitched voices. Comforts with touch.	Prefers to look at faces and black-and-white geometric designs. Follows objects in line of vision.
2–4 months	Gains 140–200 g (5–7 oz)/week. Grows 1.5 cm (1/2 in.)/month. Head circumference increases 1.5 cm (1/2 in.)/month. Posterior fontanel closes. Eats 120 mL/kg/24 hr (2 oz/lb/24 hr).	Holds rattle when placed in hand. Looks at and plays with own fingers. Brings hands to midline.	Moro reflex fading in strength. Can turn from side to back and then return. Head lag when pulled to sitting position decreases; sits with head held in midline with some bobbing. When prone, holds head and supports weight on forearms.	Follows objects 180 degrees. Turns head to look for voices and sounds.
4–6 months	Gains 140–200 g (5–7 oz)/week. Doubles birth weight in 5–6 months. Grows 1.5 cm (1/2 in.)/month. Head circumference increases 1.5 cm (1/2 in.)/month. Teeth may begin erupting by 6 months. Eats 100 mL/kg/24 hr (1 1/2 oz/lb/24 hr).	Grasps rattles and other objects at will; drops them to pick up another offered object. Mouths objects. Holds feet and pulls to mouth. Holds bottle. Grasps with whole hand (palmar grasp). Manipulates objects.	Holds head steady when sitting. Has no head lag when pulled to sitting. Turns from abdomen to back by 4 months and then back to abdomen by 6 months. When held standing, supports much of own weight.	Examines complex visual images. Watches the course of a falling object. Responds readily to sounds.
6–8 months	Gains 85–140 g (3–5 oz)/week. Grows 1 cm (3/8 in.)/month. Growth rate slower than first 6 months.	Bangs objects held in hands. Transfers objects from one hand to the other. Pincer grasp begins at times.	Most inborn reflexes extinguished. Sits alone steadily without support by 8 months. Likes to bounce on legs when held in standing position.	Recognizes own name and responds by looking and smiling. Enjoys playing with small and complex objects.
8–10 months	Gains 85–140 g (3–5 oz)/week. Grows 1 cm (3/8 in.)/month.	Picks up small objects. Uses pincer grasp well.	Crawls or pulls whole body along floor by arms. Creeps by using hands and knees to keep trunk off floor. Pulls self to standing and sitting by 10 months. Recovers balance when sitting.	Understands words such as “no” and “cracker.” May say one word in addition to “mama” and “dada.” Recognizes sound without difficulty.
10–12 months	Gains 85–140 g (3–5 oz)/week. Grows 1 cm (3/8 in.)/month. Head circumference equals chest circumference. Triples birth weight by 1 year.	May hold crayon or pencil and make mark on paper. Places objects into containers through holes.	Stands alone. Walks holding onto furniture. Sits down from standing.	Plays peek-a-boo and patty cake.

Source: Monkey Business Images/Getty Images.

Figure 25–5 >> This 9-month-old girl demonstrates physical, cognitive, and social capabilities while playing with blocks.

Cognitive ability is reflected in manipulation of blocks to create different sounds. Social interaction enhances play. The presence of a parent or other individual increases interest in surroundings and teaches the infant different ways to play.

Toward the end of the first year, the infant’s ability to move in space enlarges the sphere of play. Once infants crawl or walk, they can get to new places, find new toys, discover forgotten objects, or seek out other people for interaction. Play is a reflection of every aspect of development, as well as a method for enhancing learning and maturation (**Table 25–5** >>>).

Personality and Temperament

Personality and temperament vary widely among infants. For example, one infant will awaken frequently in the night, while another will sleep soundly for 8–10 hours. One infant may smile and react positively to interactions, while another

TABLE 25–5 Psychosocial Development During Infancy

Age	Play and Toys	Communication
Birth–3 months	<ul style="list-style-type: none"> ■ Prefers visual stimuli of mobiles, black-and-white patterns, mirrors. ■ Responds to auditory stimuli such as music boxes, tape players, soft voices. ■ Responds to rocking and cuddling. ■ Moves legs and arms while adult sings and talks. ■ Likes varying stimuli—different rooms, sounds, visual images. 	<ul style="list-style-type: none"> ■ Coos. ■ Babbles. ■ Cries.
3–6 months	<ul style="list-style-type: none"> ■ Prefers noise-making objects that are easily grasped, like rattles. ■ Enjoys stuffed animals and soft toys with contrasting colors. 	<ul style="list-style-type: none"> ■ Vocalizes during play and with familiar people. ■ Laughs. ■ Cries less. ■ Squeals and makes pleasure sounds. ■ Babbles multisyllabically (mamamamama).
6–9 months	<ul style="list-style-type: none"> ■ Likes teething toys. ■ Increasingly desires social interaction with adults and other children. ■ Favors soft toys that can be manipulated and mouthed. 	<ul style="list-style-type: none"> ■ Increases vowel and consonant sounds. ■ Links syllables together. ■ Uses speechlike rhythm when vocalizing with others.
9–12 months	<ul style="list-style-type: none"> ■ Enjoys large blocks, toys that pop apart and go back together, nesting cups and other objects. ■ Laughs at surprise toys like a jack-in-the-box. ■ Plays interactive games like peek-a-boo. ■ Uses push-and-pull toys. 	<ul style="list-style-type: none"> ■ Understands “no” and other simple commands. ■ Says “dada” and “mama” to identify parents. ■ Learns one or two other words. ■ Receptive speech surpasses expressive speech.

withdraws around unfamiliar people and frequently frowns and cries. Such differences in responses to the environment are believed to be inborn characteristics of temperament. Infants are born with a tendency to react in certain ways to noise and to interact differently with people. They may display varying degrees of regularity in activities of eating and sleeping, and manifest a capacity for concentrating on tasks for different amounts of time. Although an infant’s temperament cannot be changed, parents can modify the environment to promote adaptation. Strategies include using only one or two consistent babysitters or caregivers, rather than engaging new or changing caregivers frequently, and feeding the infant in a quiet setting to encourage a focus on eating.

Focus on Diversity and Culture Reaching Developmental Milestones

In some cultures, children are allowed to unfold and develop naturally at their own pace. Children wean and toilet train themselves with little interference or pressure from parents. The nurse should be sensitive to the childrearing practices of the family and support them in these culturally accepted practices.

For example, the developmental milestone for sleeping through the night is typically reached at age 4 to 5 months (Andrews & Boyle, 2016). However, in many cultures, including Native American, Alaskan Natives, and First Nations tribes, infants sleep with their mothers. Infants will wake and nurse typically every 4 hours through the night. The mothers are typically not disturbed by this on-demand feeding practice, so there is less motivation for the mother to have the child sleep through the night (Andrews & Boyle, 2016). Therefore, these infants do not reach the milestone of sleeping 8 hours a night until later in their development than infants who do not sleep with their mothers.

Communication

Communication skills are evident even at a few weeks of age. Infants communicate and engage in two-way interaction; they express comfort by soft sounds, cuddling, and eye contact. The infant displays discomfort by thrashing the extremities, arching the back, and crying vigorously. From these rudimentary skills, communication ability continues to develop until the infant speaks several words at the end of the first year of life (see Table 25–5). Nonverbal methods continue to be a primary method of communication between parent and child.

Nurses assess communication to identify possible abnormalities or developmental delays. Language ability may be assessed with a specialized language screening tool. Normal infants and toddlers understand (**receptive speech**) more words than they can speak (**expressive speech**). Abnormalities may be caused by a hearing deficit, developmental delay, or lack of verbal stimulation from caregivers. Further assessment may be required to pinpoint the cause of the abnormality.

Nursing interventions focus on providing a stimulating and comforting environment and encouraging parents to speak to infants and teach words. Hospital nurses should include the infant’s known words when providing care, and provide nonverbal support by hugging and holding. Nurses planning interventions should consider the family’s cultural patterns for communications and development.

Toddlers (1 to 3 Years)

Toddlerhood is sometimes called the first adolescence. The child from 1 to 3 years of age, who months before was merely an infant, is now displaying independence and negativism. Pride in newfound accomplishments emerges during this time.

TABLE 25-6 Growth and Development Milestones During Toddlerhood

Age	Physical Growth	Fine Motor Ability	Gross Motor Ability	Sensory Ability
1–2 years	<ul style="list-style-type: none"> ■ Gains 227 g (8 oz) or more per month. ■ Grows 9–12 cm (3.5–5 in.) during this year. ■ Anterior fontanel closes. 	<ul style="list-style-type: none"> ■ By end of second year, builds a tower of four blocks. ■ Scribbles on paper. ■ Can undress self. ■ Throws a ball. 	<ul style="list-style-type: none"> ■ Runs. ■ Walks up and down stairs. ■ Likes push-and-pull toys. 	Visual acuity 20/50
2–3 years	<ul style="list-style-type: none"> ■ Gains 1.4–2.3 kg (3–5 lb)/year. ■ Grows 5–6.5 cm (2–2.5 in.)/year. 	<ul style="list-style-type: none"> ■ Draws a circle and other rudimentary forms. ■ Learns to pour. ■ Is learning to dress self. 	<ul style="list-style-type: none"> ■ Jumps. ■ Kicks ball. ■ Throws ball overhand. 	

Physical Growth and Motor Development

The rate of growth slows during the second year of life. The child requires limited food intake during this time, a change that may cause concern to the parent. The nurse reassures parents with these concerns that this is a normal occurrence in their child's development. By age 2 years, the birth weight has usually quadrupled and the child is about one half of the adult height. Body proportions begin to change, with longer legs and a smaller head in proportion to body size than during infancy. The toddler has a pot-bellied appearance and stands with feet apart to provide a wide base of support. By approximately 33 months, eruption of the 20 deciduous teeth is complete.

Gross motor activity develops rapidly (**Table 25-6** >>>) as the toddler progresses from walking to running, kicking, and riding a tricycle. As physical maturation occurs, the toddler develops the ability to control elimination patterns.

Cognitive Development

During the toddler years, the child moves from the sensorimotor to the preoperational stage of development. The early use of language awakens in the 1-year-old the ability to think about objects or people when they are absent. Object permanence is well developed.

At about 2 years of age, the increasing use of words as symbols enables the toddler to use preoperational thought. Rudimentary problem solving, creative thought, and an understanding of cause-and-effect relationships are now possible.

Psychosocial Development

The toddler is soundly rooted in a trusting relationship and feels more comfortable asserting autonomy and separating from primary care providers. It is important for toddlers to begin asserting their autonomy within the context of safe places and relationships that promote their interaction with both adults and other children.

Play

Patterns of play emerge and change between infancy and toddlerhood. The toddler's motor skills enable him to bang pegs into a pounding board with a hammer. The social nature of toddler play is also visible. Toddlers find the company of other children pleasurable, even though socially interactive play may not occur. Toddlers tend to play with similar objects side by side, occasionally trading toys and

words (**Figure 25-6** >>>). This is called **parallel play**. Playing with other children assists toddlers to develop social skills. Toddlers engage in play activities they have seen at home, such as pounding with a hammer and talking on the phone. This imitative behavior helps them to learn new actions and skills.

Physical skills are manifested in play as toddlers push and pull objects, climb in and out and up and down, run, ride a Big Wheel, turn the pages of books, and scribble with a pen. Both gross motor and fine motor abilities are enhanced during this age period.

Cognitive understanding enables the toddler to manipulate objects and learn about their qualities. Stacking blocks and placing rings on a building tower teach spatial relationships and other lessons that provide a foundation for future learning. Various kinds of play objects should be provided for the toddler to meet play needs. These play needs can easily be met whether the child is hospitalized or at home (**Table 25-7** >>>).

Personality and Temperament

The toddler retains most of the temperamental characteristics identified during infancy, but may demonstrate some changes. The normal developmental progression of toddlerhood plays a part in responses. For example, the infant who previously responded positively to stimuli, such as a new

Source: Jupiter Images/Stockbyte/Getty Images.

Figure 25-6 >>> These toddlers display typical parallel play at daycare, playing next to but not with each other.

TABLE 25–7 Psychosocial Development During Toddlerhood

Age	Play and Toys	Communication
1–3 years	<ul style="list-style-type: none"> Refines fine motor skills by use of cloth books, large pencil and paper, wooden puzzles. Facilitates imitative behavior by playing kitchen, grocery shopping, toy telephone. Learns gross motor activities by riding Big Wheel tricycle, playing with a soft ball and bat, molding water and sand, tossing ball or beanbag. Develops cognitive skills through exposure to educational television shows, music, stories, and books. 	<ul style="list-style-type: none"> Increasingly enjoys talking. Vocabulary grows exponentially, especially when spoken and read to. Needs to release stress by pounding board, frequent gross motor activities, and occasional temper tantrums. Likes contact with other children and learns interpersonal skills.

babysitter, may appear more negative in toddlerhood. The increasing independence characteristic of this age is shown by the toddler's use of the word *no*. The parent and child constantly adapt their responses to each other and learn anew how to communicate with each other.

Communication

Because the child's capacity for development of language skills is greatest during the toddler period, adults should communicate frequently with children in this age group. This communication is critical not only to the toddler's ability to communicate simple wants and needs, but also to cognitive and language development, which affects the toddler's future literacy. Toddlers also begin to learn the social interactions and nonverbal gestures that they observe.

At the beginning of toddlerhood, the child may use four to six words in addition to "mama" and "dada." Receptive speech (the ability to understand words) far outpaces expressive speech. By the end of toddlerhood, however, the 3-year-old has a vocabulary of almost 1000 words and uses short sentences. Toddler communication includes pointing, pulling an adult over to a room or object, and speaking in **expressive jargon** (using unintelligible words with normal speech intonations as if truly communicating in words). Other communication methods include crying, pounding or stamping feet, displaying a temper tantrum, or other means that illustrate dismay. These powerful communication methods can upset parents, who often need suggestions for handling them. Adults can best assist the toddler by verbalizing the feelings shown by the toddler, by saying things like "You must be very upset that you cannot have that candy. When you stop crying you can come out of your room." Verbalizing the child's feeling and then ignoring further negative behavior ensures that the parent is not unintentionally reinforcing the inappropriate behavior. While the toddler's search for autonomy and independence creates a need for such behavior, an upset toddler may respond well to holding, rocking, and stroking.

Parents and nurses can promote a toddler's communication by speaking frequently, naming objects, giving single-step directions, explaining procedures in simple terms, expressing feelings that the toddler seems to be displaying, and encouraging speech. The toddler is at an optimal age to learn two languages. For example, if the parents wish for their child to learn two languages, the toddler will benefit from a child care experience that will expose her to a second language in addition to the language her family speaks at

home. Research continues to support the finding that those children who are bilingual have cognitive advantages over monolingual children (Ramírez & Kuhl, 2015).

The nurse who understands the communication skills of toddlers is able to assess expressive and receptive language and communicate effectively, thereby promoting positive healthcare experiences for these children. Parents often need suggestions for ways to communicate with the young child.

Preschool Children (3 to 6 Years)

The preschool years are a time of new initiative and independence. Most children are in a child care center or school for part of the day, and they learn a great deal from this social contact. Language skills are well developed, and the child is able to understand and speak clearly. Endless projects characterize the world of busy preschoolers. They may work with play dough to form animals, then cut out and paste paper, then draw and color.

Physical Growth and Motor Development

Preschoolers grow slowly and steadily, with most growth taking place in long bones of the arms and legs. The short, chubby toddler gradually gives way to a slender, long-legged preschooler (**Table 25–8** >>>).

Physical skills continue to develop. The preschooler runs with ease, holds a bat, and throws balls of various types. Writing ability increases, and the preschooler enjoys drawing and learning.

The preschool period is a good time to encourage good dental habits. Children can begin to brush their own teeth with parental supervision and help in reaching all tooth surfaces. Parents should floss children's teeth, give fluoride as prescribed if the water supply is not fluoridated, and schedule the first dental visit so the child can become accustomed to the routine of periodic dental care.

Cognitive Development

The preschooler exhibits characteristics of preoperational thought. Symbols or words are used to represent objects and people, enabling the young child to think about them. This is a milestone in intellectual development; however, the preschooler still has some limitations in thought (**Table 25–9** >>>). It is important to understand the preschooler's thought processes in order to plan appropriate teaching for healthcare and development of health habits.

TABLE 25–8 Growth and Development Milestones During the Preschool Years

Physical Growth	Fine Motor Ability	Gross Motor Ability	Sensory Ability
Gains 1.5–2.5 kg (3–5 lb)/year. Grows 4–6 cm (1 1/2–2 1/2 in.)/year.	Uses scissors. Draws circle, square, cross. Draws at least a six-part person. Enjoys art projects such as pasting, stringing beads, using clay. Learns to tie shoes at end of preschool years. Buttons clothes. Brushes teeth. Eats three meals, with snacks. Uses spoon, fork, and knife.	Throws a ball overhand. Climbs well. Rides tricycle.	Visual acuity continues to improve. Can focus on and learn letters and numbers.

Psychosocial Development

The preschooler is more independent in establishing relationships with others. The child interacts closely with children and adults and is able to plan and carry out activities.

Play

Play for the preschooler takes on a new dimension as he begins to interact with others. One child cuts out colored paper while his friend glues it on paper in a design. This new type of interaction is called **associative play**.

In addition to this social dimension, other aspects of play also differ. The preschooler enjoys large motor activities such as swinging, riding a tricycle, and throwing a ball (**Figure 25–7** ). Preschoolers demonstrate increasing manual dexterity as they create more complex drawings and manipulations of blocks and modeling. Because fantasy life is so powerful at this age, the preschooler readily uses props to engage in **dramatic play** (the living out of the drama of human life).

The nurse can use playtime to assess the preschooler's developmental level, knowledge about healthcare, and

emotions related to healthcare experiences. Observations about objects chosen for play, content of dramatic play, and pictures drawn can provide important assessment data. The nurse can also use play periods to teach the child about healthcare procedures and offer an outlet for expressing emotions (**Table 25–10** ).

The use of media such as smartphones, tablets, and computers is becoming more of the preschooler's life than ever before. In a cross-sectional study of 350 children, Kabali et al. (2015) found that almost 96.6% of children ages 1–4 had used a mobile device, such as a smartphone, and that 75% had their own device. The nurse might find hospitalized children are easily soothed and distracted by portable media devices such as tablets (Radesky, Schumacher, & Zuckerman, 2015). However, the nurse should be aware that the research is very limited on what can be considered too much screen time. The American Academy of Pediatrics (AAP) recommends that parents and other caregivers discourage the use of screen time for children under 18 months unless it is for video chatting with a loved one. For older toddlers and preschoolers, the AAP recommends limiting screen time to

TABLE 25–9 Characteristics of Thought Identified by Piaget

Characteristic	Definition	Development Stage	Nursing Implications
Object permanence	Ability to understand that when something is out of sight it still exists	Sensorimotor period, especially in coordination of secondary schemes substage from 8 to 12 months	Before development of object permanence, babies will not look for toys or other objects out of sight; as the concept is developing they are concerned when a parent leaves, because they are not certain the parent will return.
Egocentrism	Ability to see things only from one's own point of view	Preoperational thought	Peers or others who have gone through an experience will not impress the preschooler; teaching should focus on what an experience will be like for the child himself.
Transductive reasoning	Connecting two events in a cause-and-effect relationship simply because they occur together in time	Preoperational thought	Ask the child what she thinks caused an occurrence; ask how the two events are connected; correct misconceptions to lessen child's guilt.
Centration	Focusing only on one particular aspect of a situation	Preoperational thought	Listen to the child's comments and deal with concerns in order to be able to present new concepts to the child.
Magical thinking	Believing that events occur because of one's thoughts or actions	Preoperational thought	Ask young children how they became ill, or what caused a parent's or sibling's illness. Correct misconceptions when the child blames self for causing problems by wishing someone ill or having bad behavior.
Conservation	Knowing that matter is not changed when its form is altered	Concrete operational thought	Before conservation of thought is reached, the child may think that gender can be changed when hair is cut, the leg under a cast is broken in separate pieces. Ask perceptions and clarify misconceptions.

Figure 25-7 » Preschoolers have well-developed large motor skills and enjoy activities such as swinging.

an hour a day and then only for educational programming or video chatting. Young children should not engage in screen time during meals and for at least an hour before bedtime (AAP, 2016).

As with television, it is crucial to ask how parents decide which technology and content is best for their children and how they monitor and set rules for use. Violence on mobile media should be avoided, and when encountered, parents and caregivers should help their children understand it. Providers can recommend age-appropriate, educational content and suggest the use of resources such as PBS Kids (www.pbskids.org), Sesame Workshop (www.sesameworkshop.org), or Common Sense Media (www.common Sense Media.org) to guide media choices. Clinicians should strongly emphasize the benefits of parents and children using

interactive media together to enhance its educational value (Radesky et al., 2015, p. 2).

Personality and Temperament

Characteristics of personality observed in infancy tend to persist over time. The preschooler may need assistance as these characteristics are expressed in the new situations of preschool or nursery school. An excessively active child, for example, will need gentle, consistent handling to adjust to the structure of a classroom. Encourage parents to visit preschool programs to choose the one that would best foster growth in their child. Some preschoolers enjoy the structured learning of a program that focuses on cognitive skills, while others are happier and more open to learning in a small group that provides much time for free play. Nurses can help parents to identify their child's personality or temperament characteristics and to find the best environment for growth.

Communication

Language skills blossom during the preschool years. The vocabulary grows to over 2000 words, and children speak in complete sentences of several words and use all parts of speech. They practice these newfound language skills by endlessly talking and asking questions.

The sophisticated speech of preschoolers mirrors the development occurring in their minds and helps them to learn about the world around them. However, this speech can be quite deceptive. Although preschoolers use many words, their grasp of meaning is usually literal and may not match that of adults. These literal interpretations have important implications for healthcare providers. For example, the preschooler who is told she will be "put to sleep" for surgery may think of a pet recently euthanized; the child who is told that a dye will be injected for a diagnostic test may think he is going to die; mention of "a little stick" in the arm can cause images of tree branches rather than of a simple immunization.

Concrete visual aids such as pictures of a child undergoing the same procedure or a book to read together enhance teaching by meeting the child's developmental needs. Handling medical equipment such as intravenous bags and stethoscopes increases interest and helps the child to focus. Teaching may have to be done in several short sessions rather than one long session.

Some general approaches include the following:

- Allow time for the child to integrate explanations.
- Verbalize frequently to the child.

TABLE 25-10 Psychosocial Development During the Preschool Years

Age	Play and Toys	Communication
3–6 years	<p>Associative play is facilitated by simple games, puzzles, nursery rhymes, songs.</p> <p>Dramatic play is fostered by dolls and doll clothes, play houses and hospitals, dress-up clothes, puppets.</p> <p>Stress is relieved by pens, paper, glue, scissors.</p> <p>Cognitive growth is fostered by educational television shows, music, stories and books.</p>	<p>Develops and uses all parts of speech, occasionally incorrectly. Communicates with a widening array of people.</p> <p>Play with other children is a favorite activity.</p> <p>Health professionals can:</p> <ul style="list-style-type: none"> ■ Verbalize and explain procedures to children. ■ Use drawings and stories to explain care. ■ Use accurate names for bodily functions. ■ Allow the child to talk, ask questions, and make choices.

- Use drawings and stories to explain care.
- Use accurate names for bodily functions.
- Allow choices.

The preschooler's social growth and increased communication skills make these years the perfect time to introduce concepts related to problem solving and conflict resolution. Puzzles and manipulative toys help foster early problem-solving skills. Children in this age group can learn to calm themselves by learning how to take deep breaths and count to 3 or 5 when they are upset. Many preschool programs employ special curricula that help teachers and parents assist children in developing essential conflict resolution skills. Using language to resolve conflict is a protective factor that decreases the likelihood of children choosing inappropriate or violent behavior to try to get what they want or bring a distressing interaction to a close.

School-Age Children (6 to 12 Years)

School-age children demonstrate common characteristics of their age group. They are in a stage of industry in which it is important to the child to perform useful work. Meaningful activities take on great importance and are usually carried out in the company of peers. A sense of achievement in these activities is important to developing self-esteem and to preventing a sense of inferiority or poor self-worth.

Physical Growth and Motor Development

School age is the last period in which girls and boys are close in size and body proportions. As the long bones continue to grow, leg length increases (see Figure 25-4). Fat gives way to muscle, and the child appears leaner. Jaw proportions change as the first deciduous tooth is lost at 6 years and permanent teeth begin to erupt. Body organs and the immune system mature, resulting in fewer illnesses among school-age children. Medications are less likely to cause serious side effects, because they can be metabolized more easily. The urinary system can adjust to changes in fluid status. Physical skills are also refined as children begin to play sports, and fine motor skills are well developed through school activities.

Although it is commonly believed that the start of adolescence (age 12 years) heralds a growth spurt, the rapid increases in size commonly occur during school age. Girls may begin a growth spurt as early as 9 or 10 years of age and boys a year or so later (**Figure 25-8** >>). Nutritional needs increase dramatically with this spurt.

The loss of the first deciduous teeth and the eruption of permanent teeth usually occur at about age 6 years, or at the beginning of the school-age period. Of the 32 permanent teeth, 22 to 26 erupt by age 12 years and the remaining molars follow during the teenage years. See the module on Health, Wellness, Illness, and Injury for a discussion of oral care for school-age children.

Cognitive Development

The child enters the stage of concrete operational thought at about age 7 years. This stage enables school-age children to consider alternative solutions and solve problems. However, school-age children continue to rely on concrete experiences and materials to form their thought content.

Source: Highwaystarz/iStock/Getty Images.

Figure 25-8 >> Because girls have a growth spurt earlier than boys, girls often are taller than boys of the same age, as shown in this group of middle schoolers in a dress rehearsal for a choral performance.

During the school-age years, the child learns the concept of conservation (that matter is not changed when its form is altered). At earlier ages, a child believes that when water is poured from a short, wide glass into a tall, thin glass, there is more water in the taller glass. The school-age child recognizes that, although it may look like the taller glass holds more water, the quantity is the same. The concept of conservation is helpful when the nurse explains medical treatments. The school-age child understands that an incision will heal, that a cast will be removed, and that an arm will look the same as before once the intravenous infusion needle is removed. The child learns to read during this period and can concentrate for longer periods.

Psychosocial Development

The school-age child has many friends and cooperatively interacts with others to accomplish tasks. The child develops a sense of accomplishment from activities and relationships.

Play

Play for the school-age child is enhanced by increasing fine and gross motor skills. By 6 years of age, children have acquired the physical ability to hold the bat properly and may occasionally hit the ball. School-age children also understand that everyone has a role—the pitcher, the catcher, the batter, the outfielders. They cooperate with one another to form a team, are eager to learn the rules of the game, and want to ensure that these rules are followed exactly (**Table 25-11** >>).

The characteristics of play exhibited by the school-age child include cooperation with others and the ability to play a part in order to contribute to a unified whole. This type of play is called **cooperative play**. The concrete nature of cognitive thought leads to a reliance on rules to provide structure and security. Children have an increasing desire to spend much of their playtime with friends, which demonstrates the social component of play. Play is an extremely important method of learning and living for the school-age child. Active physical play has decreased in recent years as

TABLE 25–11 Psychosocial Development During the School-Age Years

Age	Activities	Communication
6–12 years	<p>Gross motor development is fostered by ball sports, skating, dance lessons, water and snow skiing/boarding, biking.</p> <p>A sense of industry is fostered by playing a musical instrument, gathering collections, starting hobbies, playing board and video games.</p> <p>Cognitive growth is facilitated by reading, crafts, word puzzles, schoolwork.</p>	<p>Use of language is mature.</p> <p>Is able to converse and discuss topics for increasing lengths of time.</p> <p>Spends many hours at school and with friends in sports or other activities.</p> <p>Health professionals can:</p> <ul style="list-style-type: none"> ■ Assess child's knowledge before teaching. ■ Allow the child to select rewards following procedures. ■ Teach techniques such as counting or visualization to manage difficult situations. ■ Include both parent and child in healthcare decisions.

television viewing and playing of computer games have increased, leading to poor nutritional status and high rates of overweight among children.

When a child is hospitalized, the separation from playmates can lead to feelings of sadness and purposelessness. Normal, rewarding parts of play should be integrated into care. Friends should be encouraged to visit or call a hospitalized child. Discharge planning for the child who has had a cast or brace applied should address the activities in which the child can participate and those the child must avoid. Nurses should reinforce the importance of playing games with friends to both parents and children.

Personality and Temperament

Characteristics seen in earlier years tend to endure in the school years. The child classified as “difficult” at an earlier age may now have trouble in the classroom. Nurses may advise parents to provide a quiet setting for homework and to reward the child for concentration. For example, after completing homework, the child may be allowed to have “screen time” (play a video game, watch television, or play on the computer or tablet). Creative efforts and alternative methods of learning should be valued. Encourage parents to see their children as individuals who may not all learn in the same way. The “slow-to-warm-up” child may need encouragement to try new activities and to share experiences with others, whereas the “easy” child will readily adapt to new schools, people, and experiences.

Communication

During the school-age years, children should learn how to use language correctly, including correcting any lingering pronunciation or grammatical errors, and learning the pragmatic (social) uses of language. Vocabulary increases, and the child learns about parts of speech in school. Children also are becoming more technologically savvy with their communication. According to a 2013 study by the Pew Research Center, 78% of children 12 to 17 years of age have their own phone (Madden et al., 2013). The majority of “tweens” use their phones for texting rather than voice communications (Madden et al., 2013).

School-age children enjoy writing and, while in the hospital, can be encouraged to keep a journal of their experiences as a method of dealing with anxiety. The literal translation of words characteristic of preschoolers is uncommon among school-age children.

Some communication strategies helpful with the school-age child include:

- Provide concrete examples of pictures or materials to accompany verbal descriptions.
- Assess knowledge before planning the instruction.
- Allow child to select rewards following procedures.
- Teach techniques such as counting or visualization to manage difficult situations.
- Include child in discussions and history with parent.

Sexuality

Awareness of gender differences and sexuality becomes more pronounced during the school years. Although children become aware of sexual differences between genders during preschool years, they deal much more consciously with sexuality during the school-age years. As children mature physically, they need information about their bodily changes so that they can develop a healthy self-image and an understanding of the relationships between their bodies and sexuality. Children become interested in sexual issues and are often exposed to erroneous information on television shows, in magazines, from internet sources, or from friends and siblings. Schools and families need to use opportunities to teach school-age children factual information about sex and to foster healthy concepts of self and others. It is advisable to ask occasional questions about sexual issues to learn how much the child knows and to provide correct information when answers demonstrate confusion.

Both friends and the media are common sources of erroneous ideas. Appropriate and inappropriate touch should be discussed, with lists of trusted people who can be approached (teachers, clergy, school counselors, family members, neighbors) to discuss any episodes with which the child feels uncomfortable. Because even these trusted people can be implicated in inappropriate episodes, the nurse should encourage the child to go to more than one person, an important approach if the child is uncomfortable about a relationship with any individual.

Adolescents (12 to 18 Years)

Adolescence is a time of passage signaling the end of childhood and the beginning of adulthood. Although adolescents differ in behaviors and accomplishments, they are all in a period of identity formation. If a healthy identity and sense

of self-worth are not developed during this period, role confusion and purposeless struggling will ensue. The adolescents in the healthcare setting will represent various degrees of identity formation, and each will offer unique challenges.

Physical Growth and Motor Development

The physical changes ending in **puberty**, or sexual maturity, begin near the end of the school-age period. The prepubescent period is marked by a growth spurt at an average age of 10 years for girls and 13 years for boys, although there is considerable variation among children. The increase in height and weight is generally remarkable and is completed in 2–3 years. The growth spurt in girls is accompanied by an increase in breast size and growth of pubic hair. Menstruation occurs last and signals achievement of puberty. In boys, the growth spurt is accompanied by growth in size of the penis and testes and by growth of pubic hair. Deepening of the voice and growth of facial hair occur later, at the time of puberty. For both boys and girls, some lack of coordination is common during growth spurts.

During adolescence children grow stronger and more muscular and establish characteristic male and female patterns of fat distribution. The apocrine and eccrine glands mature, leading to increased sweating and a distinct odor to perspiration. All body organs are now fully mature, enabling the adolescent to take adult doses of medications.

The adolescent must adapt to a rapidly changing body for several years. These physical changes and hormonal variations offer challenges to identity formation. See the Focus on Integrative Health.

Cognitive Development

Adolescence marks the beginning of Piaget's last stage of cognitive development, the stage of formal operational thought. The adolescent no longer depends on concrete experiences as the basis of thought but develops the ability to reason abstractly. The adolescent can understand concepts such as justice, truth, beauty, and power. The adolescent revels in this newfound ability and spends a great deal of time thinking, reading, and talking about abstract concepts.

Focus on Integrative Health Weight Loss Supplements

Adolescents are major consumers of complementary and alternative medicine products, including dietary supplements and herbal therapies. The primary reason adolescents use herbal therapies is for weight loss. Unfortunately, many "holistic" products are unregulated and may be poisonous when not taken as directed or when taken in combination with other substances. These characteristics may escape the attention of the adolescent (Pomeranz et al., 2015). Dietary supplements, particularly those for weight loss and/or for energy, can cause cardiac symptoms, including chest pain, tachycardia, and heart palpitations (Geller et al., 2015). Adolescents are also less likely to report use of complementary medicines (National Center for Complementary and Integrative Health [NCCIH], 2016a). Therefore, the nurse should encourage both parents and adolescents to report any use of supplements, herbal remedies, or other complementary medicines.

Adolescents seek to establish their own identity and values. They may rebel against parental authority as they try out new activities and behaviors. Although this is normal for adolescents, it can create a number of difficulties at home and school as adolescents try to balance their need to express themselves against the expectations of parents, teachers, and other authority figures.

Psychosocial Development

The adolescent is mature in relationships with others. The key aspect that teens work on during relationships and activities is establishing a meaningful identity.

Activities

Activities represent a central focus for the adolescent. Maturity leads to new activities. Adolescents may drive, ride buses, or bike independently. They are less dependent on parents for transportation and spend more time with friends or doing activities. Activities include participation in sports and extracurricular school clubs, as well as "hanging out" and attending movies or concerts with friends. Activities also drive psychosocial development, as the peer group becomes the focus of activities, regardless of the teen's interests. Peers are important in establishing identity and providing meaning. Although same-sex interactions dominate, boy–girl relationships are more common than at earlier stages. Adolescents thus participate in and learn from social interactions fundamental to adult relationships. They also begin to develop abstract thought and analysis through conversations at home and at school.

Social media, texting, and other interactive technology has also become an integral part of the adolescent's social life and culture (Minges et al., 2015). Ninety-five percent of adolescents use the internet or other online media (Madden et al., 2013). Adolescents "hang out" not only in coffee shops and malls, but also in chat rooms, online games, and via group texts.

Personality and Temperament

Characteristics of temperament manifested during childhood usually remain stable in the teenage years. For instance, the adolescent who was a calm, scheduled infant and child often demonstrates initiative to regulate study times and other routines. Similarly, the adolescent who was an easily stimulated infant may now have a messy room, a harried schedule with assignments always completed late, and an interest in many activities. It is also common for an adolescent who was an easy child to become more difficult because of the psychologic changes of adolescence and the need to assert independence.

As during the child's earlier ages, the nurse's role may be to inform parents of different personality types and to help them support the teen's uniqueness while providing necessary structure and feedback. Nurses can help parents understand their teen's personality type and work with the adolescent to meet expectations of teachers and others in authority.

Communication

Adolescents understand and use all parts of speech. They commonly use colloquialisms and slang when speaking—or texting—with their peers.

The adolescent increasingly leaves the home base and establishes close ties with peers. These relationships become the basis for identity formation. A period of stress or crisis generally occurs before a strong identity can emerge. The adolescent may try out new roles by learning a new sport or other skills, experimenting with drugs or alcohol, wearing different styles of clothing, or trying other activities. It is important to provide positive role models and a variety of experiences to help the adolescent make wise choices.

The adolescent also has a need to leave the past, to be different, and to change from former patterns to establish a self-identity. Rules that are repeated constantly and dogmatically will probably be broken in the adolescent's quest for self-awareness. This poses difficulties when the adolescent has a health problem that requires ongoing care, such as diabetes or cardiac illness. Introducing the adolescent to other teens who manage the same problem appropriately usually is more successful in getting the adolescent to comply with a care plan than telling the adolescent what to do.

Teens need privacy during patient interviews or interventions. Even if a parent is present for part of a health history or examination, the adolescent should be given the opportunity to relay information to or ask questions of the healthcare provider alone. The adolescent should be given a choice of whether to have a parent present during an examination or while care is provided. Most information shared by an adolescent is confidential. Some states mandate disclosure of certain information to parents such as an adolescent's desire for an abortion. In these cases, the adolescent should be informed of what information will be disclosed to the parent.

In the hospital setting, nurses and care staff should allow adolescents the freedom of choice whenever possible, including preferences for evening or morning bathing, the type of clothes to wear while hospitalized, timing of treatments, and visitation guidelines. Use of contracts with adolescents may increase adherence with healthcare recommendations. Firmness, gentleness, choices, and respect must be balanced during care of adolescent patients.

Some specific communication strategies that help with the adolescent:

- Provide written and verbal explanations.
- Direct history and explanations to teen alone; then include parent.
- Allow for safe exploration of topics by suggesting that the teen is similar to other teens. ("Many teens with diabetes have questions about. . . . How about you?")
- Arrange meetings for discussions with other teens.

Sexuality

Sexuality is influenced by physical maturation and increased hormonal secretion, which are integral to the adolescent's development of physiologic sexual maturity. Psychosocially, this complex process involves growing interactions with members of the opposite sex, an interplay of the forces of society and family, and identity formation. The early adolescent progresses from attending dances and other social events with members of the opposite sex to the late adolescent who is mature sexually and may have regular sexual encounters.

Just as some adolescents are exploring their feelings for those of the opposite sex (heterosexual), others are finding

that their attraction lies with those of the same gender (homosexual) or may begin to identify as bisexual (attracted to both genders). Most adolescents who feel supported and safe will have a positive adolescence (Centers for Disease Control and Prevention [CDC], 2014). Unfortunately, LGBTQ (lesbian, gay, bisexual, transgender, queer/questioning) youth have a great incidence of bullying, violence, and harassment (CDC, 2014). Partially because of negative interactions with peers and society, LGBTQ youth are more likely to abuse substances or report mental health problems such as anxiety and depression, and more likely to attempt suicide than their peers (CDC, 2014). Nurses are instrumental in helping LGBTQ youths by providing information for them and their parents, integrating LGBTQ content into sexual education curricula, and providing referrals for health and social care when needed. Nurses must examine their own beliefs and communication styles to provide culturally competent care. School nurses can play a particularly positive role in the safety and security of LGBTQ youths. School nurses can provide confidential healthcare and education to the LGBTQ student, collaborate with faculty and staff at a school, and provide support, education, and resources for parents and community members (National Association of School Nurses, 2016).

Trends indicate that adolescents are not as sexually active as in the past. According to the CDC (2016a), 41% of high school students have had sexual intercourse, a decrease from 47% in 2012 (CDC, 2012). Thirty percent of high school students reported having sex in the past 3 months (CDC, 2016a). Although fewer high school students are having sex, those who are sexually active are engaged in risky behaviors. For example, 43% reported not using a condom; 14% reported not using any form of birth control (CDC, 2016a). Many school districts now provide some teaching on STIs and HIV. Health histories include questions on sexual activity, STIs, and birth control use and understanding. Most hospitals routinely perform pregnancy screening on adolescent girls before elective procedures. More and more clinics are prophylactically screening teens for STIs with simple urine tests.

Adolescents will benefit from clear information about sexuality, an opportunity to develop relationships with adolescents in various settings, an open atmosphere at home and school where problems and issues can be discussed, and previous experience in problem solving and decision making. Alternatives and support for their decisions should be available.

In addition, the nurse who encounters a sexually active teenager should remember the nurse may be the very first healthcare provider with whom the teenager discusses his sexuality. The nurse who refrains from asserting her own personal beliefs and who emphasizes open communication and active listening will strengthen the teen's confidence in the healthcare system and increase the likelihood that the teen will seek help from a healthcare professional in the future.

Adults

The transition from adolescence to adulthood is complex. Unlike when individuals were infants and children with very clear milestones, adulthood does not have such defined markers. Yet, the adult continues to pass through stages or complete tasks that encompass the individual's physical, emotional, social, spiritual, and economic self.

Multisystem Effects of Aging

Sensory

- High frequency hearing loss
- Visual changes
- Sense of taste diminishes

Endocrine

- Gradual decrease in glucose tolerance

Urinary

- Kidneys become less efficient at removing waste from blood
- ↓ bladder capacity

Musculoskeletal

- ↓ muscle mass, especially in women
- Muscle mass decreases rapidly without exercise
- Thinning of intervertebral discs results in loss of height
- ↑ risk of osteoporosis (women)

Integumentary

- ↓ turgor, moisture, and subcutaneous fat
- Hairline recedes in men
- Loss of melanin in hair shaft causes graying

Respiratory

- Arteries stiffen and blood oxygenation levels decrease
- ↓ maximum breathing capacity

Cardiovascular

- Blood vessels lose elasticity
- ↑ systolic blood pressure
- Heart muscle thickens
- ↓ pumping rate

Gastrointestinal

- Large intestine gradually loses muscle tone
- Constipation
- ↓ gastric secretions

Young Adults

Many societies, such as those in the United States, consider adulthood to start at the age of 18 years. At this age, many adolescents begin to enjoy several adult privileges, such as voting and opening a bank account. At the age of 18, individuals can seek medical care without parental consent and can make medical decisions independently. With new laws regarding medical insurance in place, many young adults stay on their parents' insurance plans. The individual is still depending on the parents' insurance but is able to make medical decisions.

Economic status is no longer a sign of adulthood. In addition to staying on their parents' insurance plans, many young adults are staying with their parents into their mid-20s or later. Many are delaying marriage and childrearing until later in adulthood. The average age for first birth is 26.3, with a growing number of women having their first child between ages 30 and 35 (National Center for Health Statistics, 2016). Prominent life changes and stressors for young adults include going to (and paying for) college, choosing and establishing a career, and finding a significant other or spouse.

In terms of physical development, most individuals are still growing. In particular, men may not reach their full height until around age 20. Studies continue to show that the human brain is not fully mature until around the age of 25 (Arain et al., 2013). In the early to mid-20s, most individuals are at their peak physical condition. Causes of mortality and morbidity are mainly attributed to unintentional injury (i.e., motor vehicle crashes) and intentional trauma (homicide and suicide) (National Center for Health Statistics, 2015).

The health assessment of the young adult should include such vital signs as blood pressure, height, and weight (**Table 25-12** >>>). Vision and hearing screenings should also be considered, particularly since many young people are of the "earbud generation." Assessment questions should address stressors, diet recall, activity level and exercise, family history,

TABLE 25-12 Physical Status and Changes in the Young Adult Years

Assessment	Status During the 20s	Status During the 30s
Skin	Smooth, even temperature	Beginning of wrinkles
Hair	Slightly oily, shiny Beginning of balding	Beginning of graying Balding
Vision	Snellen 20/20	Some loss of visual acuity and accommodation
Musculoskeletal	Strong, coordinated	Some loss of strength and muscle mass
Cardiovascular	Maximum cardiac output 60–90 beats/min Mean BP: 120/80	Slight decline in cardiac output 60–90 beats/min Mean BP: 120/80
Respiratory	Rate: 12–20 Full vital capacity	Rate: 12–20 Decline in vital capacity

smoking history, and alcohol/substance use. Additional data necessary to appropriately assess young adults include sexual history and activity, menstrual concerns and patterns, and use of birth control, including condom use. As with the adolescent patient, the nurse should be open to questions and ready to educate the patient on sexual concerns. Health screenings should include STIs.

Middle Adults

The "middle" years of adulthood are typically considered to be between the ages of 40 and 65 years. Often called the "sandwich" generation, those who are in this stage of life often find themselves taking care of both their children (and sometimes, grandchildren) and their own aging parents. This creates a new set of stressors. In some cases, the individual must also cope with divorce or loss of a significant other.

In this stage of life, the body begins to experience changes related to aging (**Table 25-13** >>>). Risk factors for heart disease, such as hypertension and elevated lipids, and related vascular problems start during this life period. Arthritis and back problems often arise during middle adulthood. Difficulty in mobility, most commonly due to spinal/back issues and arthritis, may cause disability in individuals in this age group (Courtney-Long et al., 2015).

The health assessment of the middle-aged adult should include vision and hearing screenings and vital signs, as well as height, weight, and BMI. Along with a complete physical assessment, these indicators can all be useful in

TABLE 25-13 Physical Changes in the Middle Adult Years

Assessment	Changes
Skin	<ul style="list-style-type: none"> Decreased turgor, moisture, and subcutaneous fat result in wrinkles. Fat is deposited in the abdominal and hip areas.
Hair	<ul style="list-style-type: none"> Loss of melanin in hair shaft causes graying. Hairline recedes in men.
Sensory	<ul style="list-style-type: none"> Visual acuity for near vision decreases (presbyopia) during the 40s. Auditory acuity for high-frequency sounds decreases (presbycusis); more common in men. Sense of taste diminishes.
Musculoskeletal	<ul style="list-style-type: none"> Skeletal muscle mass decreases by about age 60. Thinning of intervertebral discs results in loss of height (about 2.5 cm [1 in.]). Postmenopausal women may have loss of calcium and develop osteoporosis.
Cardiovascular	<ul style="list-style-type: none"> Blood vessels lose elasticity. Systolic blood pressure may increase.
Respiratory	<ul style="list-style-type: none"> Loss of vital capacity (about 1 L from age 20 to 60) occurs.
Gastrointestinal	<ul style="list-style-type: none"> Large intestine gradually loses muscle tone; constipation may result. Gastric secretions are decreased.
Genitourinary	<ul style="list-style-type: none"> Hormonal changes occur: menopause, women (↓ estrogen); andropause, men (↓ testosterone).
Endocrine	<ul style="list-style-type: none"> Gradual decrease in glucose tolerance occurs.

establishing a baseline against which healthcare providers can compare changes over time. Assessment questions should address exercise and activity levels, diet and food choices, family history, alcohol/substance use, smoking history, and stressors. Sexual history and activity should be addressed in all individuals in this age group, even those who are married. Other health screenings that should be discussed with the adult patient include Pap smears, mammography, colonoscopy, fasting glucose, and lipid panels.

Older Adults

The World Health Organization (WHO) (2016) recognizes older adulthood as beginning at the age of 60. In the United States, the beginning of older adulthood is generally recognized as age 65, in part because at this age Americans qualify for Medicare benefits. The experiences of older adulthood vary considerably from one individual to the next. Some may retire at or before age 65, whereas others may work for many years afterward. Some older adults continue to be “sandwiched” with much older parents and younger generations of children and grandchildren.

Older adulthood is often thought of as a stage of loss and mourning. Many older adults experience loss of friends, relatives, and spouses. Some mourn physical loss, such as mobility due to arthritis or breasts due to cancer. Yet, many older adults continue to live healthy, active, happy lives. Older adults also continue to be sexually active well into their 80s and 90s. Because of advancements in preventive medicine and healthcare, many individuals are transitioning into older adulthood with few chronic conditions. However, as the body matures, chronic conditions can be complicated by the normal stages of aging. Risk for developing cardiovascular disease, cancer, type 2 diabetes (T2D), and neurocognitive disorders such as Alzheimer disease increases. Therefore, the nurse needs to be especially concerned about screening and further progression of a chronic disease.

As with all adults, the health assessment begins with vital signs. Height and weight are especially important, as it is during this stage in life that older adults start to experience degenerative changes in the spinal column, causing shrinking. Loss of muscle mass is common. Older adults are at greater risk for sensory losses, such as hearing or vision loss. Of course, a complete physical assessment of all systems should be included in the nurse’s health assessment. Assessment questions should include exercise habits and tolerance, diet and appetite, ability to do activities of daily living, and tobacco/alcohol/substance use. According to the National Institutes of Health (n.d.), approximately 55% of older adults drink alcohol, which increases the older adult’s risk for injury. Assessments of the older adult should include safety, functional status (e.g., self-care, mobility), and mental status to establish a baseline (see the module on Cognition). Normal age-related changes of aging are outlined in **Table 25–14** >>.

Alterations to Development

Developmental disabilities are a cluster of conditions that occur as the result of impairment in motor function, speech and language development, behavioral patterns, or learning ability (CDC, 2015a). To recognize delays or deviations from normal patterns of development, the nurse must be

knowledgeable about normal developmental milestones. Although this module focuses on impairments that affect pediatric development, it is important to remember that development continues throughout the lifespan and alterations may occur at any point. Any noted alteration should be investigated further. Management of developmental delays varies and may require use of an interprofessional team, depending on the nature of the alterations and the individual’s needs. In addition, nurses assess each patient’s individual developmental level and incorporate that into the plan of care. This is especially important when considering patient teaching and planning for the patient’s care needs following discharge.

Alterations and Manifestations

Alterations in development may occur in a single area or multiple areas. Alterations may be referred to as a delay, a deficit, or a disorder. While developmental delays are primarily thought of as childhood disorders and improve or disappear with intervention and use and practice of skills, some (such as attention-deficity/hyperactivity disorder and autism spectrum disorder) will challenge the individual for the length of the lifespan. In addition, deficits in any area may occur in adulthood as the result of injury, stroke, or other trauma.

Communication

The term *communication disorder* refers to any delay or deficit in one of the following areas: speech, language, voice, or swallowing. Of these, speech and language disorders are the most prevalent (Black, Varhartian, & Hoffman, 2015). A child with a speech delay has difficulty making the sounds of language—that is, not being able to articulate specific sounds or speaking with a stutter. A child with a language delay may have difficulty accessing receptive language or may have difficulty expressing language. Language delays also encompass the acquisition of vocabulary. A child with a pragmatic language delay has difficulty using language in social contexts (American Speech-Language-Hearing Association, 2017).

Although hearing children may not necessarily benefit from learning sign language, research has shown that children with developmental delays and cognitive differences do benefit from learning sign language. Sign language has been particularly beneficial to those born with Down syndrome and autism as a nonverbal means of communication (Vandereet et al., 2011).

Motor Function

Motor delays are often more easily identified as a child fails to achieve certain milestones or experiences losses of previous gains. Motor delays may be seen in fine motor skills, gross motor skills, or both. Some 6% of children will experience developmental coordination disorder, which is usually identified when the child enters kindergarten. While some children will achieve all milestones, just at a later age, others, such as those with cerebral palsy, may never meet certain milestones (Noritz & Murphy, 2013). Tic disorders, such as Tourette syndrome, are characterized by rapid, recurrent movements or vocalizations and are considered a form of motor disorder. Tics are common in childhood but generally abate as the child matures (American Psychiatric Association [APA], 2013).

TABLE 25–14 Physical Changes in the Older Adult Years

Assessment	Changes
Skin	<ul style="list-style-type: none"> ■ Decreased turgor and sebaceous gland activity result in dry, wrinkled skin. ■ Melanocytes cluster, causing “age spots” or “liver spots.”
Hair and nails	<ul style="list-style-type: none"> ■ Scalp, axillary, and pubic hair thins; nose and ear hair thickens. Women may develop facial hair. ■ Nails grow more slowly; may become thick and brittle.
Sensory	<ul style="list-style-type: none"> ■ Visual field narrows, and depth perception is distorted. ■ Pupils are smaller, reducing night vision. ■ Lenses yellow and become opaque, resulting in distortion of green, blue, and violet tones and increased sensitivity to glare. ■ Production of tears decreases. ■ Sense of smell decreases. ■ Age-related hearing loss progresses, involving middle- and low-frequency sounds. ■ Threshold for pain and touch increases. ■ Alterations in proprioception (sense of physical position) may occur.
Musculoskeletal	<ul style="list-style-type: none"> ■ Loss of overall mass, strength, and movement of muscles occurs; tremors may occur. ■ Loss of bone structure and deterioration of cartilage in joints result in increased risk of fractures and limitation of range of motion.
Cardiovascular	<ul style="list-style-type: none"> ■ Systolic blood pressure rises. ■ Cardiac output decreases. ■ Peripheral resistance increases, and capillary walls thicken.
Respiratory	<ul style="list-style-type: none"> ■ Loss of vital capacity continues as the lungs become less elastic and more rigid. ■ Anteroposterior chest diameter increases; kyphosis occurs. ■ Although blood carbon dioxide levels remain relatively constant, blood oxygen levels decrease by 10–15%.
Gastrointestinal	<ul style="list-style-type: none"> ■ Production of saliva decreases, and declining number of taste buds reduces the number of accurate receptors for salt and sweet. ■ Gag reflex is decreased, and stomach motility and emptying are reduced. ■ Both large and small intestines undergo some atrophy, with decreased peristalsis. ■ The liver decreases in weight and storage capacity; incidence of gallstones increases; pancreatic enzymes decrease.
Genitourinary	<ul style="list-style-type: none"> ■ Kidneys lose mass, and the glomerular filtration rate is reduced (by nearly 50% from young adulthood to old age). ■ Bladder capacity decreases, and the micturition reflex is delayed. Urinary retention is more common. ■ Women may have stress incontinence; men may have an enlarged prostate gland. ■ Reproductive changes in men include decreases in sperm count and testosterone; the testes becoming smaller; and an increase in the length of time to achieve an erection. ■ Reproductive changes in women include a decrease in estrogen levels, breast tissue, and vaginal lubrication; alkalinization of vaginal secretions; and atrophy of the vagina, uterus, ovaries, and urethra.
Endocrine	<ul style="list-style-type: none"> ■ Pituitary gland loses weight and vascularity. ■ Thyroid gland becomes more fibrous, and plasma T₃ decreases. ■ Pancreas releases insulin more slowly; increased blood glucose levels are common. ■ Adrenal glands produce less cortisol.

For children having difficulty with fine motor skills, such as grasping and transferring objects, evaluation by an occupational therapist is recommended. Children who have difficulty meeting gross motor milestones will require evaluation by a physical therapist.

Cognition

A child experiencing a cognitive delay has difficulty with thinking and problem solving in relation to developmental milestones. For example, a 3-year-old who is unable to work with everyday objects (e.g., button, zipper), turn a door handle, or put together a three- or four-piece puzzle is showing evidence of not meeting developmental milestones for cognitive ability (CDC, 2016b). Preterm infants are at greater risk for cognitive delays than full-term infants (Lobo & Galloway, 2013). Cognitive delays are seen in children with a variety of disorders, including autism spectrum disorder, cerebral palsy, and Down syndrome. Children with

intellectual disability will exhibit cognitive delays as well as difficulty with adaptive functioning. Children experiencing cognitive delays benefit from evaluation by an interprofessional team that includes a child psychologist, speech-language pathologist, occupational therapist, and physical therapist, as well as a nurse and the child’s primary care provider.

Adaptive Functioning

Adaptive functioning encompasses life and social skills. Individuals who have difficulty adapting to different people and environments—at home, work, and school—face many challenges. Adaptive functioning and cognition are closely linked. For example, a small study of school-age children found that children who had difficulty controlling their inhibitions exhibited poorer adaptive functioning. Younger children in particular experienced greater teacher reports of inattention (Vuontela et al., 2013). While a number of studies

have found a correlation between executive function and adaptive behavior in children with ADHD, researchers are also finding that poor executive functioning is associated with poor adaptive behavior in children with histories of heavy prenatal alcohol exposure (Ware et al., 2012). These children also benefit from evaluation by an interprofessional team.

Etiology

Certain alterations in development have a single manifestation; however, the alteration may stem from one of many different etiologies. For example, congenital anomalies, infantile glaucoma, and retinopathy of prematurity can all lead to visual impairment in neonates. In other cases, a single defect may manifest in an array of signs and symptoms. Fragile X syndrome (FXS) is a genetic disorder in which the absence of one protein impairs brain development and may yield multiple effects, including impairments related to language, learning, and social interaction (CDC, 2016c). Other developmental disabilities come about from exposure to fetal toxins, such as alcohol. Fetal alcohol spectrum disorders (FASDs) occur when pregnant mothers consume alcohol. Those born with FASDs have a host of challenges, including intellectual and neurologic, visual and hearing, as well as behavioral and mental health (CDC, 2015b). Infectious agents, such as viruses and bacteria, can cause fetal harm. Zika, a virus transmitted by certain breeds of mosquitoes, has been linked to miscarriage, impaired growth, microcephaly, neurologic deficits, eye damage, and hearing loss (CDC, 2016d).

Other developmental disabilities include attention-deficit/hyperactivity disorder (ADHD), intellectual disability (ID), Down syndrome (or trisomy 21), muscular dystrophy (MD), and Tourette syndrome. The exemplars in this module explore three developmental impairments commonly diagnosed initially in pediatric patients—ADHD, autism spectrum disorder (ASD), and cerebral palsy (CP)—and one seen in infants and older adults—failure to thrive (FTT).

» Stay Current: For discussion of additional pediatric developmental disorders, visit the CDC's information center at <http://www.cdc.gov/ncbddd/developmentaldisabilities/index.html>.

Prevalence

Approximately 1 in 6 children in the United States is impaired by one or more developmental disabilities or by other forms of developmental delays (Boyle et al., 2011). Trends continue to show no significant change in disability rates other than in ASDs, which continue to rise (Van Naarden Braun et al., 2015). There are many different theories as to the cause of the rise in ASD diagnoses, including greater awareness of autism, better diagnostic tools, and change in the language used to poll parents (Zablotsky et al., 2015).

Other disabilities tracked by the CDC include ID, CP, vision impairment, and hearing loss. Currently, the CDC's Metropolitan Atlanta Developmental Disabilities Surveillance Program (MADDSP) is the hallmark tracking site for trends in childhood disabilities. Van Naarden Braun et al. (2015) found no significant change in the numbers of children with CP, at 3.5 per 1000 children. Approximately 13.6 per 1000 children have ID without ASD. Note that 28% of children who are identified as ID also have ASD. ASD is seen in 15.5 per 1000 children. In terms of ASD, boys are more

likely to have ASD, with approximately 1 in 40 boys compared with 1 in 182 girls (Van Naarden Braun et al., 2015).

Genetic Considerations and Nonmodifiable Risk Factors

In some cases, developmental delays are inevitable because of genetic abnormalities. Because chromosomes and genes carry messages that encode for certain characteristics, they also can carry diseases. Although some genetic mutations are incompatible with life and result in fetal death, live births can occur with others.

Chromosomal disorders may be caused by an array of factors, such as radiation exposure, parental age, exposure to infectious agents, or parental disease states; however, sometimes their causes cannot be determined. For example, there is increasing evidence linking genetics to ASD (Huquet, Ey, & Bourgeron, 2013). Some children inherit genes that lead to diseases such as cystic fibrosis; others may have a mutation that manifests in the disease. A family history of these diseases is usually present, but because genes sometimes mutate, an initial incidence of a genetic disorder may appear with no identifiable history.

Premature birth, multiple gestation, and low birth weight are also linked to an increased risk for several types of developmental disorders (CDC, 2015c). In all cases, early identification and referral to appropriate resources can help a patient to achieve the highest level of developmental functioning possible based on the abnormality.

Case Study » Part 1

Farah Mohamed, 24 years old, is a Somali refugee who immigrated to the United States at the age of 10. She is married and has a 2-year-old son, Amiir Yusef. She brings Amiir to the family practice clinic for his well-child visit. As his mother carries him from the lobby, you notice Amiir squirming the entire time. When you reach the examination room, Amiir screams in a high pitch and pulls away from his mother. During the assessment, you notice that Amiir is rocking back and forth on the floor as he sits with a toy vacuum, making R-noises. The mother remarks, "He loves vacuums. Sometimes, he screams and screams at the closet until I bring him the vacuum. I have to turn it on, and then he is happy. That toy vacuum is his favorite toy. He shows more love to the vacuum than he does to me."

When discussing Amiir's development, Ms. Mohamed tells you that he was born early, at 36 weeks, after she had been on bedrest for early cervical effacement. She shares that her pregnancy was difficult because she had hyperemesis gravidarum (intractable vomiting) through much of her pregnancy. She tells you that he was a quiet baby, and he did not like to be touched. She reports he still does not like to be held. She tells you, "I think he was angry I did not take better care of him when I was pregnant. He still is angry with me."

As your conversation and assessment progresses, you gather:

- Amiir was sitting by himself at 6 months.
- He did not crawl, but was able to pull himself up at 10 months.
- He walked independently at 13 months.
- He has difficulty holding a spoon and fork. Instead he likes to eat with his hands.
- His vocabulary is very limited.

Ms. Mohamed tells you she is worried about her son because he doesn't seem like other children. She shares, "My husband just graduated from college and is starting a new job. I am now going to

college, and so I am not home much with Amiir. He spends most of his time with my mother. She does not speak English, and she puts Amiir in front of the television so that he will learn English. Is this why he doesn't really speak? Is it because he is confused about which language he should learn?"

Clinical Reasoning Questions Level I

1. Identify two or more developmental milestones that Amiir has met and two that he has not met. At what age should he have met the milestones that he has not met?
2. Using Erikson's theory of developmental stages, what is Amiir's current developmental task? What is Ms. Mohamed's developmental task?
3. Ms. Mohamed blames Amiir's vocabulary on the fact that he is growing up in a bilingual family. Could this indeed be the cause of Amiir's limited vocabulary? Why or why not?

Clinical Reasoning Questions Level II

4. Write two nursing diagnoses for this case study that could be used in the plan of care of Amiir and/or Ms. Mohamed.
5. Ms. Mohamed blames herself for Amiir's behavior. How would the nurse respond to her comments regarding blame for her difficult pregnancy?
6. After you complete your assessment, you are concerned that Amiir may have autism. What data collected during the assessment support or refute your suspicion? What additional data should be collected?

Concepts Related to Development

As stated earlier, most people with mild alterations in development, whether they occur in childhood or as the result of injury or trauma in adulthood, will be able to overcome them with appropriate interventions. For those with more significant delays or alterations, however, the implications for health, wellness, illness, injury, and functioning in all areas of life are great. The presence of a developmental disability increases the individual's risk for injury, abuse, and exploitation and increases difficulty with self-care, activities of daily living, and responding to and participating in treatment for acute or chronic illness.

Selected concepts integral to development are presented in the Concepts Related to Development feature. They are presented in alphabetical order.

Health Promotion

Health promotion to reduce risk for developmental disabilities in children focuses on maternal well-being. Preterm birth is the number one cause of long-term neurologic disabilities in children (CDC, 2015d). Several maternal factors have been linked with early deliveries, including age, race, socioeconomic status, health status, pregnancy abnormalities, and behavioral issues (CDC, 2015d). Behavioral factors include substance use, inadequate prenatal care, and psychologic influences (CDC, 2015d). Infants who are premature have immature body systems, requiring medical support in the newborn period.

Some developmental delays can be prevented by educating the pregnant patient in the care of her baby in utero. Education regarding proper prenatal care should start with the first prenatal visit. The nurse has the opportunity to begin the educational process of lifelong health promotion by starting with prenatal education. After birth, the focus

shifts to helping parents raise a healthy child in a safe environment, giving that child the optimal ability to develop and thrive.

Prenatal Considerations

The mother's nutrition and general state of health play a part in pregnancy outcome. Even before the woman considers becoming pregnant, she should consider taking a prenatal vitamin with at least 400 mcg of folic acid for at least 1 month before conceiving to prevent such birth defects as anencephaly and spinal bifida (CDC, 2015e). The use of prenatal vitamins should continue throughout the pregnancy and postpartum stages to prevent anemia in the mother and baby, as well as other vitamin and mineral deficiencies.

Prescription medications, over-the-counter medications, and herbal supplements are not necessarily safe for the fetus. Differences in physiology related to gastric emptying, renal clearance, drug distribution, and other factors contribute to variations in pharmacokinetics during pregnancy. Drugs can cause teratogenesis (abnormal development of the fetus) or mutagenesis (permanent changes in the fetus's genetic material). Certain drugs can cause bleeding, stained teeth, impaired hearing, or other defects in the infant. In 2014, the U.S. Food and Drug Administration (FDA) published the Pregnancy and Lactation Labeling Rule, which requires that drug labels be formatted to assist healthcare providers in assessing risk versus benefit for pregnant women and nursing mothers who need to take medication (FDA, 2014).

>> Stay Current: See samples of the new drug labels at <http://www.fda.gov/Drugs/DevelopmentApprovalProcess/DevelopmentResources/Labeling/ucm093307.htm>.

Although some medications are safe during certain periods of the pregnancy, there is the potential for those same medications to be dangerous in other stages, depending on fetal development and approaching delivery. For example, ibuprofen, a nonsteroidal anti-inflammatory drug, has been found in a few studies to interfere with conception and cause miscarriages. In the later portion of the first trimester and second semester, there are no reported problems. However, after 30 weeks of pregnancy, the mother is advised not to take ibuprofen because of its potential to decrease of amniotic fluid and potential heart defects in the fetus (Organization of Teratology Information Specialists, 2014). To help healthcare providers and pharmacists provide evidence-based information regarding safe medication use by pregnant women and breastfeeding mothers, the CDC has paired with the Organization of Teratology Information Specialists (OTIS) to create a clearinghouse for information at www.mohtertobaby.org

Some maternal illnesses are harmful to the developing fetus. Cytomegalovirus (CMV) infection is quite common in adults, children, and newborn babies. The CDC (2016d) estimates that 1 in 150 babies are born each year with this virus. Although many babies are infected via their mothers, few will have lasting effects. However, those who are infected, and affected, may be born with microcephaly, hearing loss, vision loss, intellectual disabilities, and major organ issues (CDC, 2016e). A fetus can also acquire chronic infections, such as AIDS and HIV infection or hepatitis B, from the mother.

Concepts Related to Development

CONCEPT	RELATIONSHIP TO DEVELOPMENT	NURSING IMPLICATIONS
Assessment	Language, motor, cognitive, and adaptive functioning delays or deficits can make assessment a challenge.	<ul style="list-style-type: none"> Adapt the assessment to the individual's developmental level. Include family and caregivers in the assessment as appropriate, but take care to promote autonomy on the part of the patient.
Family	Moderate to severe alterations in development may disrupt family processes as family members struggle to integrate the individual who is delayed or disabled into family activities and communication patterns. Families also must integrate therapies and interventions into their daily schedules.	<ul style="list-style-type: none"> Assess family functioning. Assess family supports. Provide referrals to area resources as needed.
Health, Wellness, Illness, and Injury	<p>Individuals with developmental deficits or disorders benefit from appropriate nutrition, rest, and physical exercise. By reducing risk factors related to these areas, patients will be more likely to achieve better outcomes and integrate more successfully at home, work, and school.</p> <p>Illness can interfere with normal developmental processes. For example, toddlers who previously were toileting independently may regress during periods of hospitalization. In older adults, hospitalization can cause cognitive disturbances and impair functioning in other areas.</p>	<ul style="list-style-type: none"> Assess sleep and rest patterns. Assess meal patterns and dietary intake. Assess level, amount, and type of exercise. Encourage patients and families to participate in healthy behaviors related to sleep hygiene, eating habits, and exercise. Provide referrals as needed for evaluation or support in these areas. Assess functioning before hospitalization to establish baseline. Communicate developmental level to providers who will be working with the patient. Plan interventions and communications according to developmental level. Assess for regression or deterioration at regular intervals. Provide interventions necessary to promote return to functioning.
Safety	Deficits or delays may increase an individual's risk for injury or illness. For example, an individual with cognitive and adaptive functioning deficits may not recognize illness or injury requiring attention from a healthcare provider. Similarly, an individual with cognitive or adaptive functioning deficits may have difficulty following a treatment regimen without adequate supervision.	<ul style="list-style-type: none"> Assess personal, home, and environmental safety factors. Link patients and families with resources that can promote skills that increase safety. Simplify treatment instructions and regimen whenever possible.
Stress and Coping	Developmental delays or deficits can cause distress to the individual, caregivers/family, and those with whom the individual interacts at school and work.	<ul style="list-style-type: none"> Assess individual and family coping mechanisms. Provide developmentally appropriate suggestions for improving coping skills.
Trauma	Individuals with developmental delays and disabilities are at increased risk for abuse from family members and strangers and at increased risk for sexual exploitation. Families and providers can be reluctant to discuss personal safety with these patients, putting them at even greater risk.	<ul style="list-style-type: none"> Assess patient and family understanding of the risks for abuse. Provide patient and family education related to risks and personal safety practices.

Chronic maternal distress, anxiety, and/or depression can affect the fetus. A study by Bolten et al. (2011) showed that excess stress hormones such as cortisol pass through the placenta and can result in lower birth weight and size. Subsequent studies continue to show that maternal stress can

affect the fetus and later child development. Maternal stress has even been linked to increased likelihood of childhood obesity (Liu et al., 2016).

The best outcomes for infants occur when mothers eat well; exercise regularly; seek early prenatal care; refrain from use of

drugs, alcohol, tobacco, and excessive caffeine; and follow general principles of good health and infection prevention.

Environmental Factors

Adequate nutrition is an essential component of growth and development. For example, poorly nourished children are more likely to get infections than are well-nourished children. Infection, then, can cause further malnutrition as the individual may not want to eat or, because of such compensatory reactions such as diarrhea, may not be able to absorb nutrition. In addition, poorly nourished children may not attain their full height potential. Inadequate nutrition during pregnancy and the first few years of life may also impact brain development. See the module on Nutrition for more information.

Other environmental factors that can influence growth and development are the living conditions of the child (e.g., homelessness), socioeconomic status (e.g., poverty versus financial stability), climate, and community (e.g., providing developmental support versus exposing the child to hazards). Illness or injury can affect growth and development. Being hospitalized is stressful for a child and can affect the child's coping mechanisms. Prolonged or chronic illness may affect normal developmental processes, including psychosocial development. See the exemplar on Environmental Quality in the module on Advocacy for more information.

Screenings

Well-child visits are perhaps the most effective initial method of screening for developmental disorders. Through regularly assessing the child at set intervals, the healthcare provider is able to identify the child's degree of achievement of milestones related to growth and development. Developmental assessments are performed in the clinical setting, as well as in home, school, and community settings. In 2008, the National Early Childhood Technical Assistance Center (NECTAC) compiled a review of screening instruments that emphasized social and emotional development for young children ages birth through 5. The NECTAC listed 23 different instruments that may be selected and used by professionals, and another 15 instruments appropriate for use by caregivers or family members (Ringwalt, 2008). The Children's Health Fund of New York identified 50 different screening instruments for use with children ages birth to 72 months (Grant, Gracy, & Brito, 2010). Two of the more commonly used screening tools are the Ages and Stages Questionnaire (ASQ) and the Battelle Developmental Inventory Screening Test (BDIST). The ASQ is appropriate for children birth to 6 months and relies on the parent's report of the child's communication and motor skills, social skills, and problem solving ability. The BDIST is appropriate for children 12 to 60 months old and uses both parent report and direct observation of the child to assess skills in a variety of areas. Screening instruments used to screen for ASD and ADHD are outlined in those exemplars.

>> Stay Current: For more information on specific developmental screenings, visit the CDC's child development and screening information center at <http://www.cdc.gov/ncbddd/childdevelopment/freematerials.html>.

Anticipatory Guidance

Anticipatory guidance related to developmental and age-related risks for injury is discussed in the module on Safety.

Nursing Assessment

In nursing, developmental theories can be useful in guiding assessment, explaining behavior, and providing a direction for nursing interventions. An understanding of a child's intellectual ability helps a nurse to anticipate and explain certain reactions, responses, and needs. Nurses can then encourage patient behavior that is appropriate for that particular developmental stage.

In adult care, knowledge about the physical, cognitive, and psychologic aspects of the aging process is a fundamental aspect of administering sensitive nursing care. For example, nurses can use their familiarity with the theories of development to help patients understand and anticipate the psychosocial changes that take place after retirement or the physical limitations that come with aging.

Assessment of those with developmental differences requires that the nurse have not only a firm foundation in developmental theories and concepts, but also an understanding of the impact of those differences. For example, many cognitive tests require the individual to read or respond to pictures, actions that may not be possible for an individual with limited vision.

Pain is a subjective experience that is perceived differently across the lifespan. Healthcare providers often do not take into account Piaget's stages of cognitive development; yet, by doing so, the nurse can have a better understanding of the patient's perspective of pain and treat accordingly (Brain, 2000). For example, toddlers and young children in the preoperative phase are not able to connect illness with pain, and therefore will blame others for their pain. For example, a toddler will associate postoperative pain with the nurse who provides treatments.

Older adults see pain as a natural progression of aging. There is the misconception held by both patients and providers that pain is a normal of function of aging (Thielke, Sale, & Reid, 2012). Many elderly patients tend to downplay the extent of their pain for a variety of reasons, which leads to undertreatment of pain (Sale, Gignac, & Hawker, 2006). The nurse should be aware that when assessing for pain, the older adult might not rate his or her pain realistically.

Children with developmental delays or sensory deficits, such as those seen in ASD, often do not sense pain as others do. One child may giggle or laugh with shots, saying they "tickle," whereas another child will not tolerate the feel of mittens on the hands. Even though these children may not perceive pain as others might, they do experience pain. Unfortunately, many children with developmental delays and sensory deficits are not able to communicate their discomforts (Czarnecki et al., 2015). Allowing parents and caregivers to have an active role in pain management, such as in the case of surgery, is crucial in providing relief to these children, especially those who are nonverbal (Czarnecki et al., 2015).

Observation and Patient/Family Interview

Parents and caregivers of children are reliable resources of information about their child's behaviors and milestones (CDC, 2016b). The assessment should be conducted in a well-lit, quiet room with space for the family, patient, and nurse. Small spaces may make it difficult to observe the pediatric patient at play; dim rooms may make it difficult for the older patient to see.

The nurse should plan for plenty of time for the interview and should not rush the observation/interview process.

During the assessment interview, the nurse can observe the child for certain behaviors and physical traits. For example, the nurse would observe if an infant at the 6-month well-baby check can hold her head upright. With toddlers and older children, the nurse can provide age-appropriate toys, puzzles, and crayons, pencils, and paper. The nurse can observe for eye contact, overall appearance, interaction with family members and the nurse, and other visuals, such as body language, that can help the nurse gather the data to make an appropriate nursing plan.

The nursing interview is family-centered, culturally competent, and specific to the patient's age and developmental stage. Use open-ended questions and allow plenty of time for the patient and family members to answer questions and interject.

As necessary, provide an interpreter for patients whose primary language is not that of the nurse interviewer. Be aware of any cultural considerations during the interview and/or observation. In some cultures, the patient does not answer direct questions; rather, a spokesperson answers for the patient. In other cultures, the parents might find it disrespectful for the child to play while the nurse is doing the interview. The nurse can explain the importance of watching the child for certain developmental behaviors.

As with any nursing assessment, the interview should include complete health history. Interviews involving pediatric patients typically also include prenatal and birth history, including any complications. Biographical data and health history, including immunizations, current medications, and family history, should be included in this assessment, as well as a review of systems. See the module on Assessment for more information.

Nurses use information about developmental milestones to assess children, to identify those with delays, and to plan interventions that will foster development. Potential risks—such as prematurity, international adoption, and presence of health problems—necessitate a more frequent and in-depth assessment of observed milestones. Nurses compare the expected findings with assessment results, make referrals for further evaluation when appropriate, and use the results to plan nursing interventions.

Cultural Considerations

Culture influences development in numerous ways, including through traditional practices and genetic variations among some ethnic groups. The traditional customs of the many cultural groups represented in North America influence the development of children in these groups. Nutritional practices of various ethnic groups may influence the rate of growth for infants. In addition, development may be influenced by childrearing practices. In some cultures and families, children are carried next to the parent or caregiver rather than carried in a car seat or pushed in a stroller. It is important for nurses to take cultural practices into account when performing developmental screening; some tests may not be culturally sensitive and can inaccurately label a child as delayed when the pattern of development is simply different in the group, perhaps because of the family's childrearing practices. In other situations, the delay of a milestone might not be recognized because of culture. For

instance, a study showed that delays in ASD diagnosis in African American children were due to cultural practices and interpretations of behaviors (Burkett et al., 2015).

All cultural groups have rules regarding patterns of social interaction. Schedules of language acquisition are determined by the number of languages spoken and the amount of speech in the home. The particular social roles men and women assume in the culture affect school activities and ultimately career choices. Attitudes toward touching and other methods of encouraging developmental skills vary among cultures. Genetic traits common in certain ethnic or cultural groups may predispose children to being at the upper or lower ranges of growth and may influence other physical characteristics.

Physical Examination

The physical examination includes a review of systems as well as height, weight, and for children older than 2 years of age, a body mass index (BMI) assessment. In young children especially, any physical distress or change in weight/BMI or motor function may be an early indicator of nutritional or developmental issues. The feature on Development Assessment lists broad categories of areas to assess for individuals at various ages.

Diagnostic Tests

Laboratory diagnostic tests generally are not used to determine developmental status. Medical evaluations typically rule out organic reasons for developmental delays, such as lead poisoning, but from there, most developmental delays are diagnosed through other means. Observational tools, questionnaires, and screening tests are some of the tools that are most helpful in determining developmental status.

Case Study » Part 2

After you complete your assessment of Amiir Yusef, you share your findings with the nurse practitioner. The nurse practitioner also is concerned after her assessment. As you did, she found that Amiir would not make eye contact, showed affection toward an inanimate object, had limited vocabulary, skipped a milestone (crawling), and seems to not like tactile stimuli. She arranges for Amiir to have comprehensive testing by a child neuropsychologist.

As you are reviewing the discharge instructions with Ms. Mohamed, she begins to cry. She tells you, "I don't understand what this means. I have heard of this autism, but what is it? Is this from his vaccinations? I have heard in my community that I should not do vaccinations. What have I done? It is Allah's will."

Clinical Reasoning Questions Level I

1. Ms. Mohamed is visibly upset by the potential diagnosis of her son having autism. Reflect on therapeutic communication techniques to use when talking with Ms. Mohamed. What would you tell her to reassure her?
2. Ms. Mohamed, who is Muslim, made the comment, "It is Allah's will." What does that mean in terms of Ms. Mohamed's spiritual self?

Clinical Reasoning Questions Level II

3. *Refer to the exemplar on Autism.* How would you explain the definition of autism to Ms. Mohamed?
4. What are the causes of autism? How would you respond to Ms. Mohamed's question regarding vaccinations causing autism?
5. Ms. Mohamed requests information regarding diagnostic testing for autism. What information would you give Ms. Mohamed regarding how autism is diagnosed?

Independent Interventions

Often, patients with impaired development will demonstrate alterations in more than one area of function. For that reason, the treatment approach is varied.

As with all patient care, safety is the highest priority. All children with impaired mobility are at an exceptionally high risk for injury. For ambulatory children, the nurse should ensure that the child is assisted with activities as needed and that properly fitted orthotic devices are being effectively used. In addition, range-of-motion (ROM) exercises should be implemented in order to promote flexibility and reduce contracture formation. Families and caregivers should be instructed about injury prevention within the home, including keeping walkways free from loose rugs, electrical cords, or any other obstacles.

Patients affected by developmental impairment, as well as their caregivers and family members, face challenges that extend into the physical and psychosocial realm. For those individuals who require lifelong treatment of a severe condition, financial stress is a serious concern. The nurse caring for these individuals and their families should offer to facilitate connections with support groups and community resources, including agencies that offer assistance through financial aid or services.

As mentioned before, teaching patient safety will be based on the individual's needs, family situation, and home environment. General needs include the following:

- **Health needs:** Provide demonstrations of interventions to be done at home (e.g., trach care or tube feedings) and ask for return demonstrations.
- **Physical environment:** Provide safety instructions about smoke detectors, use of strobe lights as signals for the hearing impaired, and other safety devices. Provide patient and family education related to potential hazards in the home.
- **Communication needs:** Develop a safety plan for emergencies that the parent and/or the patient and/or family can communicate and practice often with the patient. If the patient is nonverbal, collaborate with the family to create a visual or symbol safety plan for the patient.
 - Instruct the family to contact the local emergency dispatch and have the house “flagged” that a patient with communication and/or other special needs lives at that number. Those with limited communication or cognitive delays can be taught to call 911 and know that help will arrive.

- Watch the patient demonstrate how to call 911. If possible, have the patient demonstrate how to call other important numbers.
- **Cognitive needs:** Encourage parents to let their child explore and experience his or her surroundings. Humans on all cognitive levels experience and learn via sensory input. Consult with school providers and other health-care team members to find adaptive equipment that the child can use to participate in different activities safely.

Collaborative Therapies

Collaborative interventions for individuals with developmental delays and disabilities are highly individualized and yet are partially determined by the services available in the community. For individuals of all ages, the goal is to help the patient achieve the greatest level of independence in the least restrictive environment possible.

Early Intervention Services

In the United States, growth and development surveillance begins at birth. Nurses and other providers conduct routine and specific assessments following labor and delivery, prior to discharge, and in the neonatal intensive care unit. Early intervention services may begin that soon for children who are identified with a growth or development issue in the hospital. Early intervention services are designed to enhance both the health and development of infants and young children with or at risk for disabilities.

Developmental screenings continue at well-child visits and follow the recommendations of the AAP (2006). For children whose screenings suggest the need for further evaluation, the family is usually referred to the agency that oversees early intervention services in their community. Funding for early childhood intervention services is usually a combination of federal and state sources and is authorized under Part C of the Individuals with Disabilities in Education Act. Early intervention agencies employ nurses, pediatricians, child psychologists or other mental health professionals, speech-language pathologists (SLPs), occupational therapists (OTs), physical therapists (PTs), and other professionals as necessary to diagnose and meet the needs of children in their communities. Early childhood intervention agencies serve children ages 0 to 3. Together with the parent, the interprofessional team will develop an **individualized family service plan** (IFSP) that identifies the child and family's strengths and weaknesses and designs activities and goals to help the child meet developmental milestones. The family is included to ensure that parents receive appropriate education and to help them learn how to support their child's development.

Nurses working in early childhood intervention may assist with both physical and health screenings and assessments. In addition, they may provide direct follow-up services for children who are medically fragile or have a medical need with or without a co-occurring developmental issue. For example, a nurse from the local health department or the early childhood intervention agency may assist a child in daycare with parenteral feedings or administer growth hormone shots to a child who has been found to have a deficiency in growth hormone.

Early identification of children in need of these services is critical to ensure the best possible outcomes. In a systematic review of studies of occupational therapy services provided to young children, the reviewers noted that low-birth-weight infants who received early intervention services at home from birth to age 1 and then for an additional 2 years at child care centers had significantly higher cognitive function at age 3 (Frolek, Clark, & Schlaback, 2013). The reviewers also noted the importance of establishing partnerships between interprofessional early intervention team members and parents.

School-based Interventions

Once a child turns 3, responsibility for oversight of developmental delay interventions passes to the child's public school system. Public schools employ early childhood specialists, SLPs, OTs, PTs, and child mental health professionals to assist in diagnosis and planning for children with special needs. Children with special health needs may benefit from a 504 plan that the interprofessional team and parent develop. These plans may include accommodations (such as sitting at the front of the class) or ensure the provision of health-related interventions. For children who need educational support to address their developmental needs, the parent and the interprofessional team will develop an **individualized education plan** (IEP). As with early intervention services, most funding for IEP services is made possible by a combination of federal funding through the Individuals with Disabilities Act and state funds.

Illness, Injury, and Trauma

At any stage of life, the onset of acute or chronic illness, injury, or trauma can impair development or function. For all patients, nurses working in acute and long-term/rehabilitation settings conduct functional assessments and work to ensure that patients do not regress or lose ability to function. Adults who have lost or impaired functioning of a limb or body part require evaluation by an OT and/or PT. Adults who have lost any speech, language, or communication function due to stroke, injury, or other trauma should be evaluated by an SLP.

Lifespan Considerations

As stated earlier, many developmental delays may be overcome with timely and appropriate interventions. Some children, however, face long-term challenges and even disability. Individuals with developmental disability face greater risks for abuse and neglect, inappropriate treatment, and placement in more restrictive environments. At all ages and stages, the nurse acts as an advocate for the patient, seeking solutions that will help the patient live the fullest, best life in the least restrictive environment possible.

Adolescents and Younger Adults

The transition from childhood to adolescence and early adulthood is a challenging time for the individual and a stressful one for parents and family members. Just like their peers, teens with developmental differences typically seek greater independence from their parents, and parents and their growing children experience new stressors as the child matures toward adulthood (Rehm et al., 2012). Gaining

independence is key for both parents and children alike. Some children with developmental impairments may have difficulty attaining independence and need greater support or encouragement than others.

Children “age out” of the system at 18 or on graduation from high school, and many of the supports once available to adolescents and their parents are no longer available. Challenges associated with this stage of development include transitioning to work or, for some, college; augmenting strained financial resources; and navigating disability program requirements and restrictions. Children with significant cognitive and/or adaptive impairments may leave home later in life; some may never leave home and will always require some level of supervision. Aging parents worry about how to plan for their adult child’s safety after their deaths (Barron et al., 2016).

Risks for abuse and exploitation continue as the adolescent and young adult begins to take public transportation, go to work, or engage in new situations such as moving into a group home or various levels of assisted living situations. These housing alternatives can provide helpful, safe environments where adults with disabilities can thrive and gain independence.

Nurses working with adolescents and young adults with disabilities can provide support and encouragement to these patients and their families. Specific interventions may include assessing and providing information regarding personal and environmental safety; referring patients and families to peer support and vocational education programs; establishing case management services; and encouraging parents and families to make legal and financial arrangements for the patient (Rehm et al., 2012).

Pregnant Women

Evidence related to women with intellectual and developmental disabilities (IDD) during pregnancy appears to be limited. A study that compared the deliveries of 340 women with IDD and the general population found that pregnant women with IDD were more likely to be delivered by cesarean section and experience longer hospital stays. They experienced greater rates of adverse outcomes, and their babies were more likely to be low birth weight and premature (Parish et al., 2015). Specifically, mothers with FASD had higher mortality rate than non-FASD mothers (Li et al., 2011). Another study found that pregnant women with intellectual or developmental disability experienced greater social and health disparities during pregnancy (Brown et al., 2016). Despite the limited evidence, implications for nursing are clear: pregnant women with intellectual or developmental disability require careful interprofessional care during and following pregnancy. Nurses caring for these women must familiarize themselves with area resources in order to provide timely and helpful referrals.

Older Adults

One quarter of older adults with developmental disabilities live independently or with a spouse, with the majority living with a family member of some kind (Factor, Heller, & Janecki, 2012). Preexisting disability in the older adult increases the individual’s risk for early symptom onset of chronic illness, inappropriate treatment, and placement in a

more restrictive environment (Bishop & Lucchino, n.d.; Factor et al., 2012). For older adults with intellectual or developmental disabilities who present with symptoms of an emerging neurocognitive disorder, medical rule-outs are necessary to determine whether the adverse effects of a medication or environmental changes may be causing the alterations in cognition. Communication deficits can result in challenging behaviors in the older adult with a developmental disability. This, combined with the increased cost for care and often fragmented resources, creates an increased risk for patient frustration and caregiver burnout (Bishop & Lucchino, n.d.). Older adults with developmental disabilities also experience long wait lists for services (Factor et al., 2012). Nurses working with this population serve as advocates to help these patients navigate the services in their communities; assess patients’ physical and mental health as well as adaptive and social functioning; and assess both patient and family needs.

Case Study » Part 3

Ms. Mohamed returns to the clinic for a follow-up appointment with her mother, Fartuun Eyl, and husband, Yuusef Yusef. Amiir has been diagnosed with autism by a pediatric neuropsychologist. During your initial interview, Mr. Yusef shares he does not trust the diagnosis of the neuropsychologist. He tells you, “This doctor, he did not know my son. How can he tell if my son has autism? I do not believe him.”

While Mr. Yusef is talking to you, his wife starts to cry. Amiir’s grandmother starts speaking in Somali, and the family has a discussion in their primary language. During this time, Amiir is sitting on the ground, hugging his toy vacuum. The volume of the family discussing becomes louder. Amiir starts to scream in a high pitch. The family stops talking, and Ms. Mohamed attempts to comfort Amiir, but he pulls away. Mr. Yusef apologizes, telling you, “This is very hard for my wife and me. We love our son very much. We want only the best for him.”

After meeting with the nurse practitioner regarding the results of the testing, the family meets with you for further education. Both Mr. Yusef and Ms. Mohamed express concern for Amiir’s future. They tell you that in Somalia, children do not have autism, so the concept of autism is very new for them. The grandmother, who does not speak English, also asks questions through the daughter who interprets for her. The family is referred to a specialty center for different therapies.

Clinical Reasoning Questions Level I

1. Refer to the exemplar on Autism and other resources. Explain why Amiir began to scream when the family’s discussion became louder. How can the family avoid such events in the future?
2. The family makes the statement that autism does not exist in Somalia. How does the nurse explain this discrepancy?
3. What resources are available in your own community to support children age 2 through 5 who are determined to be on the autism spectrum? Which of these might be appropriate for or helpful to Amiir and his family? Why?

Clinical Reasoning Questions Level II

4. Refer to the module on Grief and Loss. Is there a possibility that Amiir’s caregivers are grieving his diagnosis? Why or why not? If the family is grieving, using a theory of grieving, categorize the family in a stage or phase of grieving. How can the nurse help the family cope with this diagnosis?
5. You notice that Ms. Mohamed and Mr. Yusef are translating for Ms. Eyl. She appears to have many questions. How should you respond to Ms. Eyl’s language barrier?

REVIEW The Concept of Development

RELATE Link the Concepts

Linking the concept of development with the concept of infection:

1. Explain the impact of infection on prenatal development.
2. When caring for pregnant patients, how might the nurse promote infection prevention for both mother and fetus?

Linking the concept of development with the concept of family:

3. Explain the interrelationship between an individual's successful achievement of developmental milestones and the developmental health of the individual's family unit.
4. Describe specific aspects of family function that may be impacted when one family member is diagnosed with a developmental disorder.

Linking the concept of development with the concept of ethics:

5. You are caring for an 8-month-old infant who appears to be undernourished. Along the infant's arms and back, you note what appear to be bruises. The child's mother reports that she recently lost her job and can barely afford to pay her rent or other bills. As a nurse, what is the primary issue and what actions are required of you?
6. Identify potential ethical concerns that may arise as a result of using prenatal testing (e.g., amniocentesis and chorionic villus sampling) to diagnose developmental disorders in utero.

REFLECT Apply Your Knowledge

Abby is a 15-year-old girl who has recently graduated into the local high school. She has a diagnosis of Down syndrome and is considered moderate-to-high functioning. The school nurse is attending the girl's IEP meeting with the rest of the school team. When the mother of the girl is asked how about the transition from the small middle school to the larger high school, the mother relates, "I am worried about Abby. She has become so involved in so many things. She talks about new friends and wants to go to so many activities. She even has started dating! This boy has asked Abby to go to Homecoming, but I am nervous! Should I let her go?"

1. Why is the school nurse part of an IEP team?
2. How should the school nurse answer the mother's question?
3. What role can the school nurse have in Abby's development and safety? What education can the school nurse provide the mother? Provide Abby?

Exemplar 25.A Attention-Deficit/Hyperactivity Disorder

Exemplar Learning Outcomes

25.A Analyze ADHD as it relates to development.

- Describe the pathophysiology of ADHD.
- Describe the etiology of ADHD.
- Compare the risk factors and prevention of ADHD.
- Identify the clinical manifestations of ADHD.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with ADHD.

- Differentiate care of patients with ADHD across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with ADHD.

Exemplar Key Terms

Attention-deficit disorder (ADD), 1818

Attention-deficit/hyperactivity disorder (ADHD), 1817

Overview

At one time, **attention-deficit/hyperactivity disorder (ADHD)** was considered a childhood condition, outgrown in adolescence and of little consequence for adults. Research indicates, however, that the disorder persists into adulthood in 30 to 70% of individuals. Classic characteristics exhibited by an individual with ADHD include difficulty completing tasks that require focused concentration, as well as hyperactivity, hyperkinesia (excessive movement), and impulsivity (APA, 2015; Roman-Urrestarazu et al., 2016). Hyperactivity and impulsivity may improve as the child nears adulthood, with inattentiveness appearing as the most persistent characteristic.

Studies have shown that while some adolescents may no longer meet diagnostic criteria or exhibit only mild symptoms, MRI scans continue to show brain abnormalities and deficits in memory function (Roman-Urrestarazu et al., 2016).

ADHD is often a missed diagnosis in the adolescent and adult. The adolescent's diagnosis is often complicated by other co-occurring behaviors and mental health diagnoses during this developmental stage (Children and Adults with Attention-Deficit/Hyperactivity Disorder [CHADD], 2016a). The adolescent may have difficulty due to the increasing cognitive demands of school and socialization. As a result, what is seen by parents, educators, and other

adults as “just being a teen” or as defiant behavior might actually be ADHD. Among adults, ADHD is a known risk factor for antisocial behavior, substance abuse, involvement in serious accidents, academic underachievement, and low occupational success. In adults, inattention is more persistent than hyperactivity or impulsivity.

Roughly one third of adults with ADHD are not diagnosed until after 18 years of age. Approximately 41% of adults with ADHD go on to have a child with the disorder, suggesting a genetic component to the disease (American Academy of Child and Adolescent Psychiatry, 2016). Adult women in particular are misdiagnosed (CHADD, 2016b). Statistically, ADHD is equal between the genders and behaviors are very similar (Cortese et al., 2016), yet, females tend not to be diagnosed as readily as males throughout the lifespan. There are several rationales for this, especially the lack of hyperactivity exhibited in girls. Instead, many girls display inattentiveness and/or depression and stress (Rizzo, 2016; CHADD, 2016b).

The term **attention-deficit disorder (ADD)** is sometimes used to describe individuals who experience the inattentiveness and difficulty concentrating related to ADHD, but who are without the associated hyperactivity that accompanies ADHD. However, in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5), the American Psychiatric Association officially recognizes only ADHD, the manifestations of which are described using specifiers (APA, 2013).

Pathophysiology and Etiology

Pathophysiology

The pathophysiology of ADHD is unclear, but some brain characteristics provide clues. Some children may have a deficit in the catecholamines dopamine and norepinephrine, which lowers the threshold for stimulus input. The disorder is marked by a delay in brain maturation in the areas of self-regulation. Increased input from stimuli and decreased self-regulation cause the hallmark inability to inhibit stimuli and motor activity. Some children exhibit additional problems such as aggressive behaviors, learning disabilities, and motor disorders.

Etiology

Although a variety of physical and neurologic disorders are associated with ADHD, children with identifiable causes represent a small proportion of this population. ADHD may result from several different mechanisms involving interaction of genetic, biological, and environmental risk factors. Examples of known associations include exposure to high levels of lead in childhood and prenatal exposure to alcohol or tobacco smoke. Studies have shown a strong association with preterm birth and that poor fetal growth is a contributing factor (Sucksdorff et al., 2015). Other prenatal factors associated with a higher incidence of ADHD include preterm labor, impaired placental functioning, and impaired oxygenation. Seizures and serious head injury are other potential associations.

Risk Factors

Genetic factors are implicated in the development of ADHD. Although ADHD occurs more commonly within families (25% have a first-degree relative with the disorder), a single

gene has not been located and a specific mechanism of genetic transmission is not known. It is believed that a genetic predisposition interacts with the child’s environment, so that both factors contribute to the appearance of the condition. Family stress, poverty, and poor nutrition may be contributing factors in some cases.

Prevention

At this time, there is no known way to prevent the development of ADHD. Women should avoid smoking, drugs, and alcohol during pregnancy to help prevent behaviors that are similar to ADHD. Likewise, women should seek prenatal care to avoid preterm birth and monitor for low fetal growth. According to Sucksdorff et al. (2015), the risk for ADHD increased for each gestational week the infant is preterm.

Clinical Manifestations

Children with ADHD have problems related to decreased attention span, impulsiveness, and/or increased motor activity (**Figure 25–9** »). Symptoms can range from mild to severe. The child has difficulty completing tasks, fidgets constantly, is frequently loud, and interrupts others. Sleep disturbances are common. Because of these behaviors, the child often has difficulty developing and maintaining social relationships and may be shunned or teased by other children. Furthermore, the child with ADHD is subjected to bullying not only in school, but also within the family by parents and siblings (Peasgood et al., 2016). Overall, those

Source: George Dodson/Pearson Education, Inc.

Figure 25–9 » This child with ADHD was challenged by a visit to a healthcare facility for dental care. He found it difficult to remain in the chair for the examination, and once it was over, he rapidly ran from one piece of equipment to another in the facility. He asked what things were for but did not wait for answers. His engaging personality emerged as he posed briefly for a picture. Such behaviors can be exhausting for parents to manage and may create safety hazards in the healthcare setting.

Clinical Manifestations and Therapies

ADHD

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
ADHD may have a genetic basis; however, there is no clearly established cause for this disorder.	<ul style="list-style-type: none"> Symptoms of ADHD fall into three groups: <ul style="list-style-type: none"> Hyperactivity Impulsive behavior Lack of attention 	<ul style="list-style-type: none"> Make environmental modifications. Reduce environmental stimuli. Encourage planned seating in classrooms, group settings. Promote consistent limit setting. Behavioral therapy: <ul style="list-style-type: none"> Reward appropriate behavior. Apply timely, appropriate consequences for inappropriate behavior. Teach strategies to improve focus, coping. Medications: See Medications feature.

with ADHD report lower happiness and quality of life (Peasgood et al., 2016).

Typically, girls with ADHD show less aggression and impulsiveness than boys, but far more anxiety, mood swings, social withdrawal, rejection, and cognitive and language problems. Girls tend to be older at the time of diagnosis.

Collaboration

The successful diagnosis and treatment of the child or adult with ADHD requires a collaborative effort that may involve any combination of the following: parents, nurses, and physicians; teachers, school nurses, and school psychologists or other mental health specialists; and speech and language therapists.

Diagnostic Tests

Diagnosis begins with a careful history of the child, including family history, birth history, growth and developmental milestones, behaviors such as sleep and eating patterns, progression and patterns in school, social and environmental conditions, and reports from parents and teachers. A physical examination should be performed to rule out neurologic diseases and other health problems. The mental health specialist then tests the child and administers questionnaires to the parent and teacher. It is important to identify other conditions that may mimic ADHD or exist in conjunction with the disorders. These conditions may include depression, anxiety, learning disorder, conduct disorder, oppositional defiant disorder, or sleep disturbances (CHADD, 2016a).

Specific diagnostic criteria must be applied to all children with the potential diagnosis of ADHD (**Box 25-2**). Behaviors at home and school or at daycare must be evaluated because abnormal patterns in two settings are needed for diagnosis. A variety of tests are available for the trained professional to use in establishing the diagnosis (**Table 25-15**).

Based on the findings, desired outcomes are established for the child's performance and management of the disorder. Treatment is established to meet the desired behavioral

outcomes and includes a combination of approaches, such as environmental changes, behavior therapy, and pharmacotherapy. Pharmacotherapy is by far the most common approach across the lifespan with more than 70% of patients

Box 25-2

ADHD: A Closer Look

ADHD is marked by a persistent pattern of a cluster of symptoms that occur in multiple areas (e.g., home and school) of daily life and that fall within three categories: hyperactivity, impulsive behavior, and inattention. Symptoms must occur over a period of 6 months or more for a diagnosis of ADHD to be considered (APA, 2013; Mayo Clinic, 2017; National Institute of Mental Health [NIMH], 2016a).

Hyperactivity: Excessive movement characterizes the hyperactivity seen in ADHD. Examples include fidgeting, restlessness (especially in adolescents and adults), running or climbing at inappropriate times, inability to engage quietly in activities, and wearing others out with activity.

Impulsive behaviors: Examples of impulsive behaviors include interrupting others, intruding on others (e.g., taking another's toy), and having difficulty waiting turns. Impulsive talking or blurting out may also be observed. Impulsivity also may be characterized by poor decision making without regard to consequences.

Inattention: Inattention in the case of the individual with ADHD is not merely a lack of attention or a tendency to be easily distracted, although those certainly occur. The individual with ADHD may:

- Be unable to pay close attention; make careless mistakes
- Have difficulty focusing on those speaking to him or on activities
- Fail to follow directions or finish tasks
- Be disorganized
- Be reluctant to participate in activities that require effort
- Lose things or forget tasks

being prescribed a stimulant (Oehrlein et al., 2016). Treatment is expected to be long term.

Children are usually brought for evaluation when behaviors escalate to the point of interfering with the daily functioning of teachers or parents. When children have learning disabilities or anxiety disorders, the problem is commonly misdiagnosed as ADHD without further evaluation of the child's symptoms. ADHD can be diagnosed by a mental health professional or a medical provider. Careful management of ADHD in childhood may lead to better social functioning later in life, as well as better relationships with family and peers.

Pharmacologic Therapy

Children with moderate to severe ADHD are treated with pharmacotherapy (see the Medications feature). Stimulants are primarily prescribed; however, there are three nonstimulant medications approved by the FDA (2016) for children: Strattera (atomoxetine), Intuniv (guanfacine), and Kapvay (clonidine). Paradoxically, in patients with ADHD, psychostimulants help improve focus and attention, as opposed to yielding increased hyperactivity. Usually, a favorable response (a decrease in impulsive behaviors and an increase in the ability to sit still and attend to an activity for at least 15 minutes) is seen in the first 10 days of treatment and frequently with the first few doses. All psychostimulants are Schedule II drugs, which means that a monthly prescription must be obtained from a healthcare practitioner. Side effects include headaches, insomnia, tachycardia, and anorexia. A child's growth pattern should be carefully monitored while taking these medications. A "drug holiday," during which the child does not take the medication during weekends or over school breaks, can be considered and discussed with the prescribing provider.

SAFETY ALERT Many medications used to treat ADHD are central nervous system (CNS) stimulants. As such, they have a potential for abuse, especially among teens and young adults who take them as an appetite suppressant or in order to stay awake. In the adult population, the nurse should be aware of the increased risk of potentially fatal cardiovascular effects of stimulant medication (FDA, 2011).

Nonpharmacologic Therapy

Although medications are an important part of the treatment plan for the patient with ADHD, nonpharmacologic

therapies are also integral components of care. Environmental modification and behavioral therapy can greatly improve outcomes for patients with ADHD and enhance their daily quality of life.

Environmental Modification

Children with ADHD often benefit from environmental changes. Decreasing stimulation by turning off the television, keeping the environment quiet, and maintaining an orderly and clutter-free desk or study area may help the child to stay focused on the task at hand. Another relatively simple change is appropriate classroom placement, preferably in a small class with a teacher who can provide close supervision and a structured daily routine. Consistent limits and expectations should be set for the child. Routines and signaled transitions help the child to feel organized. Children living in chaotic homes and communities may function better if the environment can be simplified. When aggressive behaviors occur, therapeutic approaches such as play and group therapy may be useful.

Behavioral Therapy

Behavioral therapy involves rewarding the child for desired behaviors and applying consequences for undesirable behaviors. Children may be rewarded by praise or earn points toward a movie or another desired outing for staying seated during meals or quietly listening in a classroom. Cues are established so that a child can subtly be reminded when impulsive or hyperactive behaviors are escalating. Behavioral therapy is most effective when all adults who are in close contact with the child, such as parents and teachers, are involved in and supportive of the program.

In a hallmark study conducted by NIMH, behavioral therapy in combination with medication has shown to be the best practice for treatment of ADHD (Molina et al., 2009). The AAP (2011) recommends that toddlers and small children should first be treated with behavioral therapy and later treated with medications if symptoms continue to be troublesome.

Complementary Health Approaches

According to the NCCIH (2016b), there is no scientific evidence supporting the use of complementary health approaches in the treatment of ADHD. Several areas of complementary medicine have been studied, including diet

Medications

ADHD

CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION	NURSING CONSIDERATIONS
CNS Stimulants Drug examples: Amphetamine-dextroamphetamine (Adderall) Dexmethylphenidate (Focalin) Methylphenidate (Ritalin, Concerta) Dextroamphetamine (Dexedrine) Lisdexamfetamine (Vyvanse) Methamphetamine (Desoxyn)	The mechanisms of action for stimulants in the treatment of ADHD is poorly understood. It is thought to block the reuptake of dopamine and norepinephrine. May also be used for: Narcolepsy	<ul style="list-style-type: none"> Teach patients and parents about side effects such as headaches, insomnia, and anorexia. Monitor patient's growth while on this medication. Ask about a "drug holiday" on weekends and school breaks. <i>Potential for abuse:</i> Some children will sell the drug at school.
Nonstimulants Drug examples: Atomoxetine (Strattera) Clonidine (Kapvay) Guanfacine (Intuniv)	The mechanism of action of nonstimulants in the treatment of ADHD is poorly understood. Atomoxetine is a selective norepinephrine reuptake inhibitor. Both clonidine and guanfacine are antihypertensives that are also used for ADHD. They are best used conjunctively with a stimulant.	<ul style="list-style-type: none"> Has less abuse potential since nonstimulant. Teach parents to be alert for serious side effects, including psychosis and suicidal tendencies, particularly with atomoxetine. Monitor hepatic function while on atomoxetine. Monitor blood pressure while on clonidine or guanfacine. Use with caution in patients with heart disease.
Psychostimulant Skin Patch Drug example: Methylphenidate (Daytrana)	The mechanism of action for stimulants in the treatment of ADHD is poorly understood. It is thought to block the reuptake of dopamine and norepinephrine.	<ul style="list-style-type: none"> Teach patients to alternate patch placement between left and right hips. Watch for skin irritations. Has been known to cause permanent leukoderma in some children. Teach patient to remove patch after 9 hours. Same side effect profile as oral medications.

Source: Data from Adams, M. P., Holland, L. N., & Urban, C. (2017). *Pharmacology for nurses: A pathophysiologic approach* (5th ed.). Hoboken, NJ: Pearson Education.

regimens, diet supplements, and neurofeedback (NCCIH, 2016b). Most of the popular supplements and special diets (such as the Feingold diet) have been disproved to alleviate the symptoms of ADHD.

Although it does not help reduce hyperactivity and other symptoms of ADHD, melatonin might help some patients who have difficulty with sleep. Mind/body therapies, such as yoga and massage likewise do not help with symptoms, but may help with sleep.

Lifespan Considerations

As stated in the Overview, although ADHD was once thought of as a childhood disorder, it is now being diagnosed in younger children and in adults. ADHD manifests in different ways across the lifespan. Nurses should be alert for the following signs of ADHD in patients of all ages.

ADHD in Toddlers and Preschoolers

Diagnosing ADHD in toddlers is difficult. Many of the normal behaviors of toddlers and preschoolers are similar to those seen in ADHD, such as trouble concentrating or

taking turns. However, children as young as 3 years of age can be diagnosed with ADHD (NIMH, 2016a). Young children with ADHD tend to be more disruptive than those without. Some children are so disruptive they are expelled from preschool. Often, those children with ADHD tend to get special education placement. Young children with ADHD tend to have more injuries and take greater risks than their peers.

ADHD in School-Age Children and Adolescents

ADHD is typically diagnosed once the child reaches school age and the hyperactivity and impulsivity prevalent with this disorder manifest in the classroom setting. Children with ADHD often have academic difficulties regardless of their cognitive abilities. Creating peer relationships is an important part of development, but because of the behaviors of ADHD, children sometimes struggle with making and maintaining friends. Children with ADHD also are more prone to accidents and injuries due to risk-taking behaviors and lack of forethought.

As a child with ADHD progresses into adolescence, there is less hyperactivity but fidgeting and restless are still present. Impulsive behaviors and inattentiveness persist at this age and can continue into adulthood. Many of the behaviors of ADHD in adolescence could be considered antisocial, which in turn makes it difficult for the teen with ADHD to make and keep friends. School typically continues to be a challenge because of inability to focus and stay organized.

ADHD in Adults

The diagnosis of ADHD in the adult is often followed with a sense of relief. As children, these adults often exhibited mild symptoms, and therefore were not diagnosed. As they moved into adulthood, they continued to struggle with personal and social relationships, workplace responsibilities, and time management. Both young and older adults with ADHD exhibit antisocial behavior, have difficulties maintaining jobs, and participate in risky behaviors. The risky behaviors in particular are a concern for the nurse. Chemical dependency, assault, and trauma are commonly seen in adults with ADHD, particularly those who have gone undiagnosed and untreated. Compared to women without ADHD, adult women with ADHD are three times as likely to experience generalized anxiety, sexual abuse, suicidal thoughts, and chronic pain (Fuller-Thomson, Lewis, & Agbeyaka, 2016). Women with ADHD are twice as likely as their healthy counterparts to experience chemical dependency, poverty, and depression (Fuller-Thomson et al., 2016).

NURSING PROCESS

Especially when caring for pediatric patients, parents and caregivers are integral to each phase of the nursing process. In particular, because collection of assessment data depends largely on patient interviews, the nurse should establish effective communication patterns with the parents and caregivers.

Assessment

The nurse often encounters the family who is concerned about the child's behavior before a diagnosis has been made. Assessment of a patient with ADHD can sometimes be difficult, as ADHD is a complex neurodevelopmental disorder that is not always obvious. Moreover, the time a nurse spends with a patient is usually short, and the diagnosis of ADHD typically requires many interactions.

- **Observation and patient interview.** Because ADHD has two major presentations, inattentive or hyperactive/impulsive, the nurse should look for signs of either of these behaviors. Watch to see if the patient appears to be listening and/or paying attention to the nurse during discussions. Observe for sign of hyperactivity, such as fidgeting and inability to sit in one place. Listen for rapid, excessive speech patterns.

Ask about family and birth history and have parents describe their child's behaviors. In the adult, the significant other or friends would be a good resource for behavior assessment. As appropriate, perform developmental screenings and look specifically for attention span and physical activity. Refer the family to their pediatric healthcare home for further assessment, then to a mental healthcare specialist

who is experienced in diagnosing ADHD. Adults can be diagnosed by either a mental health provider or a primary care provider, preferably someone with whom the patient has a long-term relationship.

The nurse may encounter the child with ADHD in the hospital when parents bring the child for treatment of an injury (e.g., fracture) or another problem. Explore in detail the parents' report of the child's attention span. Usually within a few minutes in an unstructured setting or waiting area, the child with ADHD becomes restless and searches for distraction. Gather information about the child's activity level and impulsiveness. Find out how the family manages at home and what treatments are being applied. For the hospitalized adult, data collection and assessment for ADHD are more complicated. Like the pediatric patient, the adult patient may become inattentive or restless and fidgety. Assess patient self-care and history of injuries consistent with ADHD behaviors.

- **Physical examination.** The physical exam of the patient with ADHD across the lifespan will not show any physical abnormalities unless the patient is being seen for injuries related to hyperactive and impulsive behaviors.

Diagnosis

Examples of nursing diagnoses that may be appropriate for both with a patient of any age who has ADHD include the following:

- *Injury, Risk for*
- *Imbalanced Nutrition: Less Than Body Requirements, Risk for*
- *Verbal Communication, Impaired*
- *Social Interaction, Impaired*
- *Self-Esteem, Chronic Low*
- *Caregiver Role Strain, Risk for.*

(NANDA-I © 2014)

Focus on Diversity and Culture

Differences in Ethnicity and ADHD Diagnosis

Past research into trends of ADHD and ethnicity and race had shown a greater percentage of White boys in middle to upper social economic classes being diagnosed with ADHD. However, current research indicates children of color of all socioeconomic status are underdiagnosed (Gómez-Benito et al., 2015; Siegel et al., 2016). Although the literature is inconclusive in regard to ethnic/racial trends of ADHD, it appears that ADHD is present in all ethnic and racial groups. Culture might play a significant factor in underdiagnosis. For example, in some cultures, energetic behaviors and fidgeting are not viewed as undesirable in children. As a result, parents might not seek out a diagnosis. Parenting style, which is influenced by culture, may also play a part in differential diagnosis. Practitioners of one culture might not appreciate the behaviors of a child of another culture. Other factors involved in diagnostic disparities may include financial means, lack of access to specialty providers, mistrust of providers from the dominant culture, and stigma.

Planning

Planning for the patient with ADHD may include the following goals:

- The pediatric patient will have a plan to facilitate learning and support appropriate behaviors at home and at school.
- The adult patient will have a plan in place to meet workplace expectations and responsibilities.
- The patient will remain safe from self-harm and/or physical injury.
- The patient will adhere to the treatment regimen.
- The patient and the patient's family will understand appropriate resources available in the community.

Implementation

Children with ADHD present a number of challenges to their parents and teachers. The nurse may need to provide patient teaching to both parents and teachers regarding medications and their side effects, the importance of decreasing stimuli and minimizing distractions, and the need for consistency and patience with behavior management plans. Some trial and error may be necessary before the child's treatment team (including parents and teachers) finds the combination of therapies that is most effective for the child.

Implementation of the nursing plan with the adult patient is even more of a challenge because much of the responsibility of follow-through is the patient's. Treatment adherence will be a high priority. The adult patient may not have the support system a child has and may benefit from case management to assist with medication adherence, support systems, and community resources.

Administer Pharmacologic Treatments

Stimulant and nonstimulant medications increase the patient's attention span and decrease distractibility. Interventions related to pharmacologic treatment include the following:

- Teach patient and parents or family members to be alert for the common side effects of these medications, including anorexia, insomnia, and tachycardia.
- Administer medication early in the day to help alleviate insomnia. Anorexia can be managed by giving medication at mealtimes.
- Perform careful periodic monitoring of weight, height, and blood pressure.
- Instruct families about the abuse potential of stimulant drugs; these drugs should be locked up and administered only as directed.

Minimize Environmental Distractions

Patients with ADHD benefit from fewer environmental distractions. For children:

- Keep potentially harmful equipment out of reach.
- Limit and monitor "screen" time.
- Provide a quiet, clutter-free area for study time.
- Use shades to darken the room during naps or at bedtime and minimize noise.

Source: MIXA next/Getty Images.

Figure 25-10 >> Managing the environment to provide quiet places with minimal distractions is often necessary for the child with ADHD. This boy reads and does homework in a room with no pictures, no music, and only his homework on his desk. He also is assisted by structure, such as a scheduled time for homework, with short breaks to walk around every 10 to 15 minutes.

- Teach parents to minimize distractions at home during periods when the child needs to concentrate (e.g., when doing schoolwork) (**Figure 25-10** >>).
- When the child is hospitalized, minimizing environmental distractions may mean placement in a room with only one other child.

Adults may benefit from similar environmental modifications, including maintaining a quiet, clutter-free area for work and limiting screen time, especially when completing tasks and for an hour or more before bedtime.

Implement Behavioral Management Plans

Behavior modification programs can help reduce specific impulsive behaviors. An example is setting up a reward program for the child who has taken medication as ordered or completed a homework assignment. Depending on the child's age, the rewards may be daily as well as weekly or monthly. For example, one completed homework assignment might be rewarded with 30 minutes of basketball or a bike ride, and assignments completed for a week might be rewarded with participation in an activity of the child's choice on the weekend.

Provide Emotional Support

Family support is essential. Educate family members and patients about the importance of appropriate expectations and consequences of behaviors. Teach skills such as making lists of tasks to accomplish; following routines for eating, sleeping, recreation, and, for children, schoolwork; and minimizing stimuli in the environment when completing work.

When the child is hospitalized for another condition, the time may provide a brief respite from constant care by the parent. The activity, impulsivity, and general high energy of children with ADHD can fatigue parents. When

the child is hospitalized, parents may want to spend a few hours each day at home or at a nearby residence for families. Ask them how they manage at home and offer ideas for respite care.

Patients who are diagnosed with ADHD as adults often need emotional support. While some are relieved to understand the cause of some of the hardships in their lives, others are dismayed by the diagnosis. Refer adult patients to mental health counselors as appropriate. Evidence-based practice has shown that cognitive-behavioral therapy combined with medications provides the best outcomes for adults with ADHD (Cherkasova et al., 2016).

Promote Self-Esteem

Patients with ADHD are easily frustrated, in part by their own behaviors and in part by the reactions of others. This frustration easily leads to loss of self-esteem. Nurses help patients with ADHD understand the disorder at a developmentally appropriate level, and also facilitate a trusting relationship with healthcare providers. Patients of all ages with ADHD who build healthy relationships with healthcare providers are more likely to seek help. Interventions to promote self-esteem may include:

- Emphasize the positive aspects of behavior and treat instances of negative behavior as learning opportunities.

- Encourage skills at which the patient excels and consider the use of support groups in school or in the community.
- Offer praise for successfully following tasks or meeting goals. For example, praise the adult patient whose spouse reports improved communication with children and other family members or the hospitalized child who helps carry toys around to other children.

Educate Families

Although families of all patients benefit from education about ADHD, parents of affected children need particular support to understand the diagnosis and to learn how to manage the child. Explain what the diagnosis is and what is known about attention-deficit disorders. Provide written materials, internet sites, and an opportunity to ask questions.

Emphasize the importance of a stable environment at home as well as at school. At home, the child may have difficulty staying on task. Parents need to consider the child's age and developmental appropriateness of tasks, give clear and simple instructions, and provide frequent reminders to ensure completion. Routines in the evening can promote good sleep patterns.

The nurse can serve as a liaison to teachers and school personnel or as the case manager for the child. See the Patient Teaching box for suggestions on how parents and teachers

Patient Teaching

Optimizing the Educational Experience for the Child with ADHD

Schools are now changing their perspective on children with ADHD. Prior to the DSM-5, ADHD was seen as a disruptive behavior disorder that highly impacted the school setting. Now that ADHD is seen as a neurodevelopmental disorder, schools are approaching the behaviors of ADHD students differently. The key to supporting the child with ADHD in school is a strong parent-teacher relationship. Parents can work with teachers to provide a school environment that fosters attention and learning. Some ideas that may be helpful include the following:

- Have the child sit near the front of the class, preferably away from doors or windows.
- Plan a reminder (for the child) that is apparent to the teacher and student but not to other children when the child needs to concentrate on attention. This might be an object placed on the student's desk or a light hand placed on the shoulder or arm.
- Go over assignments and tests with the child in person to explain areas that are understood and those that need attention. Give instructions verbally and in written form and repeat them more than once.
- Provide opportunities to take notes and make lists of assignments and mark off when accomplished. Have a planned

time to go through the child's backpack daily to find notices and to ensure that homework is completed and in a uniform location.

- Use computers, note-taking partners, or recording devices for making lists and taking notes.
- If the child has well-developed fine or gross motor skills, integrate motor movement into learning situations whenever possible. Allow the child to run occasional errands to provide additional opportunities for movement.
- Provide quiet places with minimal distraction for examinations. Offer additional time.
- Allow time for organizing clothing, desk, and other areas.
- Find the child's areas of excellence and allow for performance in these ways. Some children are talented in dance, others in art or extemporaneous speech.
- Never call the child names, make fun of behavior or performance, or call the child "hyperactive" in front of other children, teachers, or parents.
- Incorporate social and behavioral skills into the child's learning plan.

Sources: Based on Call-Schmidt, T., & Maharaj, G. (2004). Using nonpharmacological treatments in conjunction with stimulant medications for children with ADHD. *Journal of Pediatric Health Care*, 18, 255–259; National Alliance on Mental Illness (NAMI). (n.d.). ADHD and school: *Helping your child succeed in the classroom*. Retrieved from <http://www.nami.org/Template.cfm?Section=ADHD&Template=/ContentManagement/ContentDisplay.cfm&ContentID=106379>; Toplek, M. (2015). ADHD: Making a difference for children and youth in the schools. *Perspectives on Language and Literacy*, 41(1), 7–8.

can work together to optimize the child's educational experience. An IEP may be needed, with clear expected outcomes stated for the child's behaviors. IEPs or periods of instruction free from the distractions of the entire class may enable the child to improve school performance. Parents may have difficulty understanding the need for these approaches because the child often tests at above-average intelligence.

As the child grows older, provide explanations about the disorder and information about techniques that will assist in dealing with problems. Emphasize the importance of doing homework or other tasks requiring concentration in a quiet environment without background noise from a television or radio. Encourage children with ADHD to keep assignment notebooks and use checklists to help them accomplish specific tasks.

Evaluation

Expected outcomes of nursing care for the child with ADHD include the following:

- The parents and child demonstrate understanding of the disorder.

- The family accurately and safely manages medication administration.
- The child maintains a weight that is within normal limits.
- The child demonstrates an increase in attentiveness and a decrease in hyperactivity, impulsivity, and sleep disturbance.
- The child displays formation of a positive self-image.
- The child manifests formation of healthy social interactions with peers and family.
- The child achieves educational performance to maximum potential.

Expected outcomes for an adult with ADHD are very similar to that of a child and may also include:

- The patient remains safe and free from self-harm.
- The patient adheres to the treatment regimen.
- The patient verbalizes responsibilities are being met, such as employment.

Nursing Care Plan

A Patient with ADHD

Melanie Taylor, age 8, visits her pediatrician's office for a routine checkup. Her mother, Mrs. Taylor, reports that Melanie is not doing well in school and that she is a difficult child to raise. Upon further questioning, Mrs. Taylor reports that her daughter is forgetful, has trouble focusing, and often does not respond to her name being called. She has to repeatedly ask her to perform her

chores, get ready for bed, or do her homework. Melanie does not sleep well at night, and most nights she crawls into her parents' bed. One night Mrs. Taylor awoke to find Melanie watching TV at 2 a.m. in the family room. Melanie's teacher has suggested she be evaluated for possible ADHD.

ASSESSMENT	DIAGNOSES	PLANNING
<p>The nurse interviews Melanie, who says she doesn't like school because "it's too hard" and the teacher "always tells me to sit still."</p> <p>Upon reviewing Melanie's medical history, the nurse finds the patient's growth and development have been normal to date. Mrs. Taylor's pregnancy and delivery were unremarkable.</p> <p>The physical examination is normal, although the nurse notes that Melanie often requires repetition of instructions such as "Touch your finger to your nose" before she complies. Both Melanie and her mother appear tired and yawn several times during the nurse's time with them.</p> <p>The provider speaks with Melanie and Mrs. Taylor, suggesting that the signs and symptoms are highly suspicious of ADHD, and provides a referral for the family to meet with a psychologist specializing in the care of patients with this disorder.</p> <p>The nurse provides Ms. Taylor with a Conners' Parent Rating Scale to complete and gives her a copy of the Teacher Rating Scale to give to Melanie's teacher for completion before seeing the counselor, who will evaluate the results.</p>	<ul style="list-style-type: none"> ■ <i>Self-Esteem, Situational Low, Risk for</i> ■ <i>Sleep Pattern, Disturbed</i> ■ <i>Caregiver Role Strain, Risk for</i> ■ <i>Fatigue</i> <p>(NANDA-I © 2014)</p>	<ul style="list-style-type: none"> ■ The patient (Melanie) will sleep through the night, remaining in her own bed. ■ The patient will participate in a therapeutic regimen as recommended by the physician/healthcare provider. ■ The patient's parents and teachers will participate in the therapeutic regimen. ■ The patient will increase her ability to remain on task by 5-minute intervals over a period of 6–8 weeks, until she can remain on task for a minimum of 20 minutes at a time. ■ The patient will keep track of her belongings. ■ The patient will respond when spoken to the first time.

(continued on next page)

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Explain diagnosis in terms Melanie can understand, and help Melanie understand that she is not “abnormal” but “unique” in how her brain works.
- Help Mrs. Taylor set rules related to sleep that will promote Melanie’s sleep hygiene.
- Assist patient to understand how her potential diagnosis of ADHD impacts her thinking as well as how treatment can help her perform better in school.
- Determine if Melanie or Mrs. Taylor have questions related to ADHD.
- Suggest strategies for helping Melanie improve her concentration and memory.
- Teach positive behavioral skills through role play, role modeling, and discussion.
- Convey confidence in patient’s and mother’s ability to handle situation.
- Encourage increased responsibility for self, as appropriate.
- Encourage Melanie to accept new challenges.
- Monitor Melanie’s statements of self-worth and frequency of self-negating verbalizations.

EVALUATION

Mrs. Taylor and Melanie return at the end of 3 months. Mrs. Taylor reports that Melanie is doing better at paying attention both at home and at school, and that she is able to maintain attention for 20 minutes “most of the time.” Both of them are sleeping better. Melanie is

able to answer the nurse’s questions readily and describes things that she does to keep track of her belongings and try to stay on task. Melanie voices pride in her improvement at school.

CRITICAL THINKING

1. Mrs. Taylor asks the nurse, privately out of range of Melanie’s hearing, if the diagnosis resulted from something she did as a parent or while pregnant. How would you respond?
2. Melanie tells the nurse, “I’m so stupid compared to the other kids in my class. I guess ADHD means I’m brain damaged.” How would you respond?
3. Is it possible to adequately treat ADHD without the use of medications? Explain your answer.

REVIEW Attention-Deficit/Hyperactivity Disorder

RELATE Link the Concepts and Exemplars

Linking the exemplar of attention-deficit/hyperactivity disorder with the concept of family:

1. How can the nurse support the family of a child with ADHD?
2. What if the family is a single parent? A grandparent?

Linking the exemplar of attention-deficit/hyperactivity disorder with the concept of safety:

3. What interventions are important for the nurse to initiate to maintain the safety of a patient with ADHD?
4. When caring for an adolescent with ADHD, how would you teach automobile safety?

REFLECT Apply Your Knowledge

Jason is an active, healthy 11-year-old boy. He is currently in fifth grade at the public elementary school near his home. He lives with his mother Evelyn and his 14-year-old sister Jenna. He has not had much contact with his father. Jason’s home life has been somewhat stressful

the past year or so because of ongoing fights between his mother and oldest sister Jessica; the conflict resulted in Jessica moving out of the house. Jason gets along well with his mother, but he has typical sibling conflicts with Jenna.

Jason has had problems in school for the past 3 years. Teachers report that he has difficulty staying on task and won’t follow directions. Although he made some progress last year with his fourth-grade teacher, his grades have been consistently poor. His mother tries to help him with homework after school or in the evening; these sessions frequently turn into battlegrounds. It takes Jason hours to complete fairly simple assignments, resulting in a great deal of frustration for both Jason and his mother. The fact that he frequently comes home from school with headaches further aggravates the situation.

In addition to problems with academics, Jason has problems with social interactions. His teachers find him to be disruptive in the classroom. During the past year, he has often been sent to the principal’s office for misbehaving. He has few friends and is a frequent target of teasing at school. Most of his time at home is spent playing video and computer games and watching TV.

1. What are the priorities of nursing care for Jason?
2. What outcomes would be appropriate for this patient?
3. What independent nursing interventions would you initiate for this patient?

Exemplar 25.B

Autism Spectrum Disorder

Exemplar Learning Outcomes

25.B Analyze ASD as it relates to development.

- Describe the pathophysiology of ASD.
- Describe the etiology of ASD.
- Compare the risk factors and prevention of ASD.
- Identify the clinical manifestations of ASD.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with ASD.

Overview

The patient with **autism spectrum disorder (ASD)** characteristically demonstrates impaired communication and social interaction patterns, and the presence of repetitive, restrictive, and stereotyped behaviors. Manifestations of ASD range across a spectrum from mild to severe. Children and adults with ASD often experience impairments of language, cognition, and social skills that make them seem different from others. The prevalence of ASD is approximately 1 in 68 individuals in the United States. It is far more common in males (1 in 42) than females (1 in 189) (CDC, 2016f). A number of other conditions have a high co-occurrence with autism, including intellectual differences, mood or other mental health disorders, seizures, immune dysfunctions, and gastrointestinal issues (Autism Speaks, 2016). Managing ASD can be harrowing for both patients and family members. Nurses play an essential role in providing essential information and emotional support related to managing the diagnosis and promoting health and wellness for both the patient with autism and family members and caregivers.

» **Stay Current:** Keep abreast of statistics, research, and treatment at www.autismspeaks.org.

Pathophysiology and Etiology

Pathophysiology

The pathophysiology of autism is not well understood. What is known is that those with autism have defects in the genes and gene expression in the areas of cell-cycle expression. The construction of the brain is atypical in comparison to those without autism. MRIs and other imaging has shown there are abnormalities of neurons of the cerebral cortex. The frontal and temporal lobes are particularly susceptible to these abnormal neuron patches. The frontal lobe is responsible for social behaviors, motor function, problem solving, and other higher functions. The temporal lobe is responsible for language and sensory input. These neuron irregularities are thought to be responsible for the dysfunction and behaviors associated with autism. These abnormalities are created during fetal development. Because the infant brain continues to develop, with early intervention, the brain can develop neuron networking around the defective neuron

- Differentiate care of patients with ASD across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with ASD.

 Stereotypy, 1828

abnormalities and/or use pathways from nearby areas of the brain (Stoner et al., 2014).

Etiology

Although the etiology of ASD remains unknown, it is believed to be associated with a complex interplay between genetic, epigenetic, immunologic, and environmental factors. More than 800 ASD predisposition genes have been identified, and many of these implicate functional pathways related to synaptic organization and activity; chromatin remodeling; and Wnt signaling during development (Krumm et al., 2014; Yin & Schaaf, 2016).

Risk Factors

Without a specific etiology, determining risk for autism is difficult. However, research continues to point toward genetics and the influence of agents on genes. Children with genetic abnormalities such as tuberous sclerosis, fragile X syndrome, Down syndrome, congenital rubella syndrome, and neurofibromatosis have an increased occurrence of autism. Children who have family members with autism are more likely to be autistic. Boys have a higher rate of ASD than girls. Likewise, teratogens, such as valproic acid and thalidomide, have been linked to autism (CDC, 2016f).

Advanced maternal age has been associated with autism, but research is now finding that the ages of the both parents plays a factor. An extensive, global study found that mothers of age greater than 40 years and fathers of age greater than 50 years were more likely to have children with autism than those of other ages. Maternal age also played a factor in those children who were born to mothers younger than 20 years. The study also found that if there is a great age disparity between parents (greater than 10 years), there was a higher incidence of autism (Sandin et al., 2015).

Prevention

As with the prevention of any developmental condition, excellent prenatal care is essential to helping prevent autism. Prior to pregnancy, the woman should take folic acid and strive to be in good health. If the mother is on medication, including antiepileptics, she should discuss the benefits and risks of her medication and pregnancy. The woman should also discuss genetic counseling with her provider if there are family members with autism.

It is important to emphasize that multiple studies have found no link between immunizations and autism (Mayo Clinic, 2014; Stefano, Price, & Weintraub, 2013). Therefore, pregnant women should be vaccinated to prevent infection, a known cause of birth defects. During pregnancy, the mother should avoid alcohol, tobacco, infection, toxic substances, and other known causes of birth defects. While these measures might not necessarily prevent autism, they will help improve the chances of a healthy baby being born.

Clinical Manifestations

The essential features of autism typically become apparent by the time a child is 3 years of age. The core characteristics of autism are:

- Social deficits
- Language impairment
- Repetitive behaviors.

Social interactions are always complex and involve perceptions of the other individual as well as social behaviors. The patient with ASD does not learn the common characteristics of these social interchanges. As a result, the patient may be unable to converse normally, may fail to initiate conversations, and/or may fail to understand or observe nonverbal behavior.

Children with ASD manifest disturbances in the rate or sequence of development, with onset of abnormal functioning in at least one of the following areas prior to age 3: social interaction, language used in social interactions, and imaginative play.

In addition to difficulty relating to others or responding to social and emotional cues, **stereotypy**, or rigid and obsessive behavior, may be observed. Characteristically, these repetitive behaviors in affected children include head banging, twirling in circles, biting themselves, and flapping their hands or arms. The child's behavior may be self-stimulating or self-destructive. Responses to sensory stimuli are frequently abnormal and include an extreme aversion to touch, loud noises, and bright lights (**Figure 25–11** »). Emotional lability (rapid, significant mood changes) is common.

Source: Maria Dubova/iStock/Getty Images.

Figure 25–11 » This child with autism chooses to wear headphones whenever he leaves the house because loud noises hurt his ears and frighten him. The headphones give him a sense of security, making it easier for him to go out and interact with others.

Communication difficulties or delays in speech and language are common and are often the first symptoms that lead to diagnosis. Absence of babbling and other communication by 1 year of age, absence of two-word phrases by 2 years, and deterioration of previous language skills are characteristic of autism. Language acquisition, including verbal and nonverbal communication patterns, such as eye contact, will vary based on the severity of the disorder. Some children and adults with ASD can participate fully in conversations, but may show characteristic behaviors such as marked lack of eye contact and lack of emotional reciprocity. They may or may not understand humor and other subtleties of language.

For children with ASD, speech patterns are likely to show certain abnormalities, such as the following:

- Using *you* in place of *I*
- Engaging in **echolalia** (a compulsive parroting of a word or phrase just spoken by another)
- Repeating questions rather than answering them
- Being fascinated with rhythmic, repetitive songs and verses.

Behaviors of children with ASDs show several differences from typically developing children's behaviors. Children with ASD may have a great difficulty dealing with new situations and typically show agitation and withdrawal when routines are changed. Children with ASD do not commonly explore objects, but have stereotyped behaviors. They may line up objects, play with the same objects over and over, and have certain rituals that must be performed. They often become upset if these normal routines are disrupted. Rituals may involve eating only certain types or colors of foods or eating in specific patterns.

Patients with ASD may manifest disturbances in the rate or sequence of development. Pediatric patients may be cognitively impaired, but they can demonstrate a wide range of intellectual ability and functioning. Cognitive impairment may be manifested early in life by slow developmental progression, particularly in social skills. Some children with ASD are of at least average intelligence, and some are highly gifted. Some children with ASD are impaired in particular areas of development, while others are above normal.

Most children with autism do not present with physical signs. Unfortunately, this can create problems for the higher functioning child, who might be perceived as "odd" or socially aloof. These individuals are often bullied and ostracized as a result. A minority of those with autism have macrocephaly, or brain overgrowth. Approximately 9.1% of individuals with autism will have a larger than normal head circumference. An analysis of several studies found the lower the level of functioning, the greater the likelihood the autistic individual had macrocephaly (Sacco, Gabriele, & Persico, 2015).

The clinical manifestations and therapies for ASD are outlined in the following feature.

Collaboration

A number of agencies and resources are available to support the child with ASD. Many communities have an inter-professional committee or team that meets regularly to

Clinical Manifestations and Therapies

Autism Spectrum Disorder

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Level I	<ul style="list-style-type: none"> Difficulty initiating social interactions Difficulty maintaining social interactions Inflexible behaviors affect functioning at home and/or school Problems with organization 	<ul style="list-style-type: none"> Visual cues and reminders Speech/language therapy Occupational therapy (gross and fine motor skills, ADLs) Behavioral therapy (e.g., applied behavior analysis [ABA]) or reinforcements
Level II	<ul style="list-style-type: none"> Significant deficits in communication skills in all areas Reduced or unusual responses to social overtures from others Unable to initiate social interaction Difficulty coping with transitions or change Repetitive behaviors appear obvious to others and interfere with functioning in multiple situations Difficulty switching activities 	<ul style="list-style-type: none"> Visual cues and reminders Sign language Speech/language therapy Occupational therapy (gross and fine motor skills; ADLs) Behavioral therapy (ABA) or reinforcements
Level III	<ul style="list-style-type: none"> Severe communication deficits Minimal response to social overtures Inflexible or restricted behaviors that severely impact functioning Marked distress on switching activities 	<ul style="list-style-type: none"> Visual cues and reminders Sign language Speech/language therapy Occupational therapy (gross and fine motor skills, ADLs) Behavioral therapy (ABA) or reinforcements

review services available in their area for children with special needs, including ASD. By law, public schools are charged with the responsibility of facilitating and providing services for children with ASD and other disabilities. For preschool-age children, services may be provided directly by the school system or in collaboration with a preschool developmental day center. Some private schools do accept and provide accommodations for children with autism, and some private schools are created exclusively for students with learning challenges. However, private schools are not required by law to provide accommodations for children with disabilities. Nurses frequently serve on interprofessional teams to ensure that medical and mental health needs of children with ASD are included in supportive plans. Team members may include parents, nurses, physicians, teachers, mental health professionals, occupational therapists, and physical therapists.

The overall prognosis for children with ASD to become functioning members of society is guarded. The extent to which adequate adjustment is achieved varies greatly. Successful adjustment is more likely for children with higher IQs, adequate speech, and access to specialized programs.

Diagnostic Tests

There is no laboratory test or imaging that can diagnose autism. Diagnosis is based on the presence of specific criteria, as described in the DSM-5. An early childhood intervention specialist, who may be a pediatrician or other licensed healthcare provider, may conduct an initial screening as well

as testing to rule out a medical cause of the child's behavior. Tests may include neuroimaging (CT scan or MRI), lead screening, DNA analysis, and electroencephalography.

Pharmacologic Therapy

It is important for the nurse to teach families and patients that there is no pill or medication that will “cure” autism. The FDA (2015) warns consumers of false advertising and cures for autism, including chelation therapy and mineral solutions. These “treatments” have been known to cause adverse effects, including nausea, vomiting, and electrolyte imbalances. One example is the Miracle Mineral Solution, which when mixed according to the directions, creates bleach that is then ingested by the unsuspecting consumer (FDA, 2015).

For some patients, medications are used to manage behaviors and associated symptoms. Medications used in the care of patients with ASD may include stimulants, selective serotonin reuptake inhibitors (SSRIs), and mood stabilizers. For example, fluoxetine, an SSRI, has been shown to help with repetitive behaviors; while risperidone, a second-generation antipsychotic, is used for ASD irritability (LeClerc & Easley, 2015).

SAFETY ALERT Children with autism might not respond to medications as other children do. Some negative behaviors might increase with medications. Other medications may cause severe depression and suicidal thoughts. Children with autism should be monitored closely when starting new medications.

Focus on Diversity and Culture

Disparities in Early Diagnosis

Current data show that in the United States, ASD is most common in non-Hispanic White children, followed by African American, Asian/Pacific Islander, Hispanic, and Native Indian/Native Alaskan (Christensen et al., 2016). However, autism may be more prevalent than is suspected in communities of color but underreported because of educational and cultural barriers. For example, Latina mothers are less likely to report their children not reaching milestones when seeking medical care for their children, making early detection of ASD or other developmental disorders difficult (Ratto, Reznick, & Turner-Brown, 2015). Diagnosis of children of color usually occurs at some point during the school-age years. As a consequence of the delayed diagnosis, these children tend to have more severe ASD. Several factors may be in play as to why parents of children with ASD do not seek diagnosis and treatment. Those factors include language barriers, lack of education regarding milestones and child behavior, social stigma of having a child with a disability, and challenges with healthcare, insurance, and/or financial resources (Christensen et al., 2016). As a result, more communities are creating centers focused on education, resources, and support for families of color with children with autism (Hewitt et al., 2013). Healthcare providers also play a part in late diagnosis of ASD in children of color. Again, language barriers play a key part. In addition, lack of cultural understanding on behalf of the provider may create a barrier and cause late diagnosis or misdiagnosis. Providers who educate themselves on cultural norms and barriers to care are more likely to be more effective in noting signs of autism. Screenings done with tools written in the language of the patient are less likely to lose meaning in translation. Educational material regarding developmental milestones and autism awareness at clinics and other community places should be printed in several languages. If possible, educational videos or multimedia education should also be available patients with low reading proficiency.

Nonpharmacologic Therapy

The infant brain is still developing and creating pathways and neurons. Research has shown a strong link between brain development and autism. As a result, early intervention to help facilitate healthy brain development is likely to decrease the severity of symptoms and behaviors in the young child with ASD. In addition, those children who receive intense therapies in early childhood have better long-term outcomes and maintain higher functionality (Estes et al., 2015).

Children are taught how to focus and apply learning. Treatment focuses on behavior management to reward appropriate behaviors, foster positive or adaptive coping skills, and facilitate effective communication. The goals of treatment are to reduce rigidity or stereotypy (repetitive, obsessive, machinelike movements) and other maladaptive behaviors.

Applied behavior analysis (ABA) is a commonly used treatment approach for autism. Based on the principles of B. F. Skinner's model that behaviors are reinforced with either positive or negative consequences, children with autism are taught behaviors with positive reinforcement or rewards. For example, a toddler who does not make eye contact may be taught to do so by being rewarded with a

piece of cereal, or a 5-year-old might get a sticker on his shirt every time he completes a sentence.

ABA is very structured, intense, and lengthy, typically 6 to 8 hours a day for a minimum of 25 hours a week with a certified therapist. Parents are the continuation of the therapy when the therapist is not in the home. There are several types of ABA therapy, including Discrete Trial Training (DTT), Early Intensive Behavioral Intervention (EIBI), Pivotal Response Training (PRT), and Verbal Behavior Intervention (VBI) (CDC, 2015d).

Complementary Health Approaches

When faced with the diagnosis of autism in a child, many parents seek different therapies and treatments. It is estimated that approximately 30% of children with ASD have been treated with complementary and alternative therapies (Perrin et al., 2012), despite the fact that research continues to show that most complementary and alternative therapies are not effective in the treatment of autism (Brondino et al., 2015; CDC, 2015d; NCCIH, 2016c).

A popular option with parents of children with ASD is implementation of a gluten-free, casein-free (GFCF) diet. This has gained sufficient popularity that there are entire websites and programs devoted to this diet. Essentially, the GFCF diet eliminates the proteins gluten and casein from the patient's diet. Parents have reported improvement in behaviors in some children who follow this diet, and case studies have been documented (Elder et al., 2015). However, evidence to support this diet is lacking (Elder et al., 2015; CDC, 2015d). Nurses working with patients considering the GFCF diet should encourage them to consult with a nutritionist or registered dietitian who can help them make sure that they plan GFCF meals that will meet their child's nutritional needs.

Nurses can help parents evaluate studies on complementary care and encourage parents to initiate only one treatment at a time; the effectiveness of any one treatment cannot be measured properly if it is initiated in conjunction with other therapies. At each healthcare interaction, the nurse working with a patient with ASD should ask about therapies being used and discuss safeguards to avoid any undesired side effects.

Lifespan Considerations

Childhood ASD persists into adulthood. Children who receive timely intervention and whose parents and treatment teams collaborate to find the best treatment for them as individuals have the greatest chance of becoming successfully functioning adults. Even high-functioning adults with ASD continue to struggle with communication skills, especially understanding nonverbal communication and socialization. Adults with ASD are most successful when they seek employment opportunities and activities that play to their strengths.

Many communities provide job training and supervised work programs for adults with ASD. Many adults with less severe ASD are active community members, becoming fully employed and living independently. Others need more support and may choose to continue to live with their parents or to reside in a group living environment that provides additional support. A number of government programs exist to assist these individuals with financial support. Information on these programs is available from the Social Security Administration

as well as local state and country social services. In addition, such nonprofit organizations as Easter Seals and Goodwill offer employment opportunities and resources. Finally, several internet resources, such as AutismSpeaks.org, are available for adults with autism to navigate different systems.

Few clinics exist that specifically treat adults with ASD, making it challenging for these adults to get the best level of care. Many adults with ASD who cannot function independently or whose families can no longer provide care for them end up being financially subsidized by the state. With the steady rise in the number of children diagnosed with this disorder comes a resulting increase in the number of adults with the disorder. The financial impact on state governments is significant and is likely to increase steadily for many years. This is all the more reason why children with ASD need to be identified early, so that they may have access to treatments and therapies that give them the best chance to become fully functioning adults.

As the person with autism matures, the likelihood of developing a mental health condition, such as anxiety or depression, also increases. The person with autism may not recognize the signs of mental illness; likewise, practitioners might not recognize signs of mental illness in the adult autistic patient (Moss et al., 2015). In turn, the individual with ASD may show decrease of functioning that is not related to autism, but rather, to undiagnosed mental illness. This adds to the burden of care.

Autism is a lifelong condition, but the greater concentration of research, resources, funding, and support is focused on children and young adults. Research on adults with ASD remains lacking, especially for the geriatric population. Diagnosis in the elderly population is rarely done. However, studies are showing that undiagnosed ASD may be hampering the quality of life in the elderly. Geurts, Stek, and Comijs (2016) found that in older adults, approximately 31% of patients with depression also show signs of autism. This study also concluded that like their younger counterparts, older adults with autism often develop mental illness.

NURSING PROCESS

Throughout application of the nursing process, the patient's parents or caregivers will be integral team members. Because much of the assessment data are collected by way of interview, the nurse should prioritize the establishment of effective, open communication patterns with the patient's primary caregivers and family members.

Assessment

The nurse may encounter the child with ASD when parents seek care for a suspected hearing impairment, speech difficulty, or developmental delay. Early and frequent developmental screening of all children can help in referral for thorough assessment and identification of cases.

- **Observation and patient/family interview.** Parents may report abnormal interaction such as lack of eye contact, disinterest in cuddling, minimal facial responsiveness, and failure to talk. Be alert to observations by the parents that the baby or young child does not look at them or provide other developmental or behavioral cues. Initial assessment focuses on language development, response

to others, and hearing acuity. Become familiar with the following “red flags” of the American Academy of Neurology and Child Neurology Society that require immediate evaluation (Pickles et al., 2009):

- No babbling or communication gestures by 12 months
- No single word by 16 months
- No spontaneous two words by 24 months
- Loss of language or social skills previously achieved.

Note both maternal and parental ages of the child at birth. Consider genetic history of autism or like behaviors in the patient's families. Ask about birth history, including possible neonatal exposure to medications such as antiepileptics, as well as exposure to toxins or alcohol. Carefully evaluate the child for history of developmental milestones and refer for abnormalities. Perform developmental screening that considers several areas of development, including motor activity, social skills, and language, or refer the family to a professional or community resource that provides such screenings. Recall that the child may have normal performance in one area such as motor skills, but delayed development in another area such as language skills. Likewise, language may be normal for age, but social interactions delayed. Include questions about adaptive skills such as toilet training and feeding patterns. Inquire about school performance, because some areas may be normal while others are delayed. Observe the child in play situations and evaluate the use of creative and exploratory play versus more repetitive patterns.

When a child with a diagnosis of ASD is hospitalized for a concurrent problem, obtain a history from the parents regarding the child's routines, rituals, and likes and dislikes, as well as ways to promote interaction and cooperation. Children with ASD may carry a special toy or object that they play with during times of stress. Ask parents about these objects and their use. Ask about the child's behaviors and observe them on admission. Obtain a history of acute and chronic illnesses and injuries. Ask about eating patterns and food restrictions. Inquire about complementary health approaches in a nonjudgmental and supportive manner.

For the adult patient with ASD, the nurse should remember that behaviors of other mental health conditions are similar and possibly overlap autism behaviors. These conditions include schizophrenia, ADHD, and obsessive-compulsive disorder (OCD) (NIMH, 2016b). Similar behaviors regarding ability to socialize, eye contact, sensory disorders, and repetitive behaviors will be present in the adult with ASD. Most adults who are diagnosed later in life will be considered higher functioning and very well may have careers and families. Many adults initiate the diagnosis with their provider. Some express relief after their diagnosis, as their behaviors have a etiology. Yet others may express sadness because there is no “cure” for ASD.

Just as with the evaluation of a child who potentially has autism, the nurse will question the adult patient regarding family history, neonatal exposures, birth history, and developmental history. Family members and others close to the patient are helpful in filling in any gaps the patient is unable to answer.

- **Physical examination.** The physical exam for autism often will reveal no abnormalities because of the neurodevelopmental nature of this disorder. However, the nurse may face challenges in the physical assessment because of behavioral issues. Nurses will have to adapt the physical exam according to the patient's temperament, cognitive level, sensory perceptions, and developmental stage.

Patients with ASD who have sensory deficits or behaviors often do not like being touched. The patient might complain that a light touch hurts, yet giggle with immunizations. If asked to change into a gown, the patient may not like the material of the gown against the skin, becoming irritable or focused on the gown rather than the exam.

The patient may not sit still for the exam. The patient might also display flapping, rocking, or head-banging as a way to self-soothe during the exam. If the patient becomes irritable, the patient might have what is perceived as a temper tantrum, otherwise known as an "autistic meltdown" in some circles. The nurse will have to ensure the patient's safety during this time.

Many individuals with ASD do not like quick transitions. Just as with neurotypical children, the nurse should tell the patient before doing a certain assessment. For example, before assessing a patient's eyes with a penlight, the nurse should tell the patient first before shining a bright beam.

If the patient is nonverbal, the nurse should not assume the patient does not understand language. The nurse should continue to talk and explain things during the assessment. The nurse should also consider alternative communication tools in order to ask the patient questions. Some patients use such means as pictures, sign language, and technology (e.g., smartphone apps that convert pictures into spoken words) to communicate.

Encourage the patient or parents to bring something that brings comfort, such as a blanket or favorite object. Perform the exam in small, short steps, and consider giving the patient a reward, with each step (as typically done in ABA treatments). The nurse should never restrain a patient, particularly an older child or adult, to complete an exam. Examination of the adult patient will be very similar, but is likely to be less challenging than examining a child. However, many adults with ASD do have sensory perception issues, and others have difficulty with communication. The communication challenges may be more along the lines of the social awkwardness of the exam. The patient might pull away from certain aspects of the physical exam. The nurse should advise the patient of each step of the exam, paying careful attention to transitions and actions.

Diagnosis

Nursing diagnoses must be tailored to fit the individual needs of the patient. Nursing diagnoses that may be appropriate for inclusion in the plan of care for the patient as well as the family include:

- *Injury, Risk for*
- *Development, Delayed*
- *Knowledge Deficit*
- *Verbal Communication, Impaired*

- *Social Interaction, Impaired*
- *Caregiver Role Strain*
- *Family Coping, Compromised.*

(NANDA-I © 2014)

Planning

Nursing care of children with ASD focuses on preventing injury, stabilizing environmental stimuli, providing supportive care, enhancing communication, giving the parents anticipatory guidance, and providing emotional support. Appropriate outcomes for a child with ASD may include the following:

- The child will remain free of injury.
- The child will acquire communication strategies that enable communication with others.
- The child will be able to perform self-care to maximum potential.
- The child will demonstrate consistent developmental progress.
- The child will participate in small group activities with family members or peers.
- The child's symptoms will be managed successfully.

Nursing care of adults with a new diagnosis of ASD focuses on education and coping. Care of the adult with a current diagnosis of ASD focuses on assessing and promoting social interactions, continued education regarding diagnosis, and establishing and maintaining individual functions. Planning may include the following goals:

- The patient will remain free from injury.
- The patient will verbalize understanding of diagnosis.
- The patient will demonstrate positive coping skills.
- The patient will participate in social activities with peers, coworkers, and family members.
- The patient will maintain independence to the full potential of the individual.

Implementation

Working with patients with ASD and their families requires patience, sensitivity, and understanding. Working with families, particularly with children and their parents, requires the nurse to remember that there is more than one patient involved in the treatment plan. While some parents may be aggressive about seeking information and resources, others may be too overwhelmed and exhausted from caring for their child to do this. For these parents, the nurse may be the most important, most accessible, and most caring resource available to them. Nurses must take the time to provide patient teaching and support and affirm parents' efforts to help their children.

Adults with ASD will want to have structure and a predictable course of action. Adults with ASD often are very punctual and time-conscious. Nurses should be aware that any delay in treatments may cause anxiety in the ASD adult. For example, if the nurse makes an appointment with the patient for 9:30 a.m., the nurse should strive to be on time. There is the possibility that some patients will become anxious at 9:32 a.m. Nurses will need to provide education for

the adult patient, as well as any family members involved. Emotional support may be in order, particularly for the adult patient who will not benefit from ABA and other early interventions. Support services and groups also are not readily available for the adult patient. However, there are internet support groups through such websites as Autism Speaks and the National Autism Network. Case management services may help the adult with ASD navigate through the healthcare system.

Prevent Injury

Monitor children with ASD at all times, including bath time and bedtime. Close supervision ensures that the child does not obtain any harmful objects or engage in dangerous behaviors. For the child who engages in head banging or other harmful behaviors, bicycle helmets and hand mitts can be the least restrictive method for providing safety. They enable the child to participate in activities and engage in a social environment to the degree possible.

Provide Anticipatory Guidance

Many children with ASD will require lifelong supervision and support, especially if the disorder is accompanied by intellectual disability. Some children may grow up to lead independent lives, although they will have social limitations with impaired interpersonal relationships. Encourage parents to promote the child's development through behavior modification and specialized educational programs. The overall goal is to provide the child with the guidance, education, and support necessary for optimal functioning.

Address Environmental Issues

Patients with ASD interpret and respond to the environment differently than other individuals. Sounds that are not distressing to the average individual may be interpreted as loud, frightening, and overwhelming. They may respond to different sounds or environments by withdrawing, crying, or using ritualistic behaviors such as arm-flapping, which may or may not be self-injurious.

The patient needs to be oriented to new settings such as a hospital room and should be encouraged to bring familiar items from home. To avoid distressing the patient, minimize relocation of objects within the environment.

Provide Supportive Care

Developing a trusting relationship with the patient who has ASD is often difficult. Adjust communication techniques and teach to the patient's developmental level. Ask about the patient's usual home routines and maintain these routines as much as possible when the patient is out of the home.

Because self-care abilities are often limited, the child or adult with ASD may need assistance to meet basic needs. When possible, schedule daily care and routine procedures at consistent times to maintain predictability. Identify rituals for naptime and bedtime and maintain them to promote rest and sleep. Integrate patterns that facilitate intake of nutritious foods at mealtimes.

For children, school programs and IEPs can help the child learn self-care skills. Parents are integral parts of the treatment team when the child's learning goals are established in early intervention or school programs. If the child is

hospitalized, encourage parents to remain with the child and to participate in daily care planning.

All patients with ASD need emotional support. Children who are developing successfully may face new challenges with the onset of the emotional and hormonal changes of adolescence. As social circles develop in middle and high school, the adolescent with autism may become more painfully aware of being different from her peers. The nurse may see this when a parent brings in a child after a scuffle at school or for help with increasing self-destructive behaviors as the child struggles to deal with the many changes inherent in adolescence. The nurse can provide crucial information about the physical changes adolescents experience and help the parent modify the plan of care to include opportunities for building new skills the child needs to navigate this difficult time.

Enhance Communication

Because patients with autism have impaired communication skills, nursing care focuses on using and improving communication with the patient. When speaking, use short, direct sentences (Maher, 2012). If the patient responds well to visual cues, then pictures, computers, and other visual aids may form an important part of interaction. Some patients with limited verbal skills are able to learn and communicate through sign language, pictures, talking boxes, and smartphone apps.

Children with ASD benefit greatly from speech and language therapy. Encourage parents of these children to maintain close contact with speech therapists. Use of consistent communication techniques at home and at school provides further stability for the child and increases opportunities for successful communication.

Facilitate Community-based Care

Families need a great deal of support to cope with the challenges of caring for the child for adult family member with ASD. Many communities offer training programs for parents, in addition to support groups. Help parents identify resources for child care, such as special toddler programs and preschools. Provide resources for case management, respite care, and governmental services, including Social Security benefits to help with the added cost of ASD treatments.

Nurses working in these community training programs and support services can offer a variety of education for parents to cope with the stresses of having a child with ASD. Nurses can provide classes in stress-reduction techniques, stress management, self-care, and mind-body therapies.

The patient may need specialized transportation services or other social supports. The school-age child will need an IEP. The parent or primary caregiver often has difficulty obtaining respite care and may need assistance to find suitable resources. Siblings of children with autism may need help explaining the disorder to their friends or teachers. The nurse can be instrumental in assisting these siblings in understanding and explaining autism. Family support programs are available in some states to provide assistance to parents.

Local support groups for parents of autistic children are available in most areas. Families can also be referred local chapters of national autism programs. There are support groups for teens and adults with ASD as well. Many connect via social media networks and internet resources.

Social media is becoming a more popular way for those with ASD to socialize and plan get-togethers. While the research is in its early stages, those with ASD tend to be technologically savvy and use social media to find friends, which might be difficult in other social settings. Mazurek (2013) conducted a study to examine the use of social media networks by adults with ASD. Nearly 80% of those in the study used these networks to make social connections. Some of these connections led to face-to-face friendships. Social media may help the patient with ASD move past initial socialization awkwardness and help promote lasting friendships.

>> Stay Current: Patients of all ages with ASD and their families can find lots of support online and in their communities. Autism Speaks, <https://www.autismspeaks.org>; Autism Society of America, <http://www.autism-society.org>; and the National Autism Network, <http://nationalautismnetwork.com/index.html> are websites that are current on best practices for autism in several areas, including research, education, therapies, and other things related to autism.

Evaluation

At each healthcare interaction, the nurse discusses the child's progress with the parents, including any injuries that have occurred since the previous visit and the steps being taken to prevent recurrence. The nurse asks parents what type of

environments the child is in during the day, paying particular attention to the frequency of transitions and changes in caregivers. For example, a child with ASD who attends school or an early intervention program at a preschool will do well having the same caregiver drop off the child in the morning and pick up the child at the end of the school day.

For children who are enrolled in early intervention programs or who have IEPs at school, the nurse should participate as part of the treatment team when possible. If this is not possible, the nurse should ask the parent how the child's treatment is progressing and continue to encourage open communication between the parents and the treatment team. For children who are taking medication to treat a comorbid disorder such as depression or ADHD, the nurse should, with parent permission, provide the necessary information to the treatment team so that the team is aware of potential side effects.

For adult patients with ASD, the nurse should inquire about coping strategies, workplace relationships, family relationships, anxieties, and social connections. Nurses may also ask about the usefulness of resources and support services. If the adult is taking medications, the nurse can evaluate for the desired effects and side effects of the medication.

REVIEW Autism Spectrum Disorder

RELATE Link the Concepts and Exemplars

Linking the exemplar of autism spectrum disorder with the concept of family:

1. How can the nurse support the family of a child with ASD?
2. How might other children in the family be impacted by a sibling with ASD?

Linking the exemplar of autism spectrum disorder with the concept of safety:

3. What interventions are important for the nurse to initiate to maintain the safety of a patient with autism?
4. What would be important at school?

REFLECT Apply Your Knowledge

Chad, age 4, was recently diagnosed with autism spectrum disorder. Chad's mother keeps ruminating about her pregnancy, wondering what she did that "caused" Chad's illness. Chad recently became angry and reacted by banging his head against the wall. His parents told the nurse they do not believe that the doctor made the right diagnosis.

1. Based on the case study, what are the priorities of nursing care for Chad?
2. Based on the statement made by Chad's parents, what are his parents experiencing?
3. How might the nurse locate resources to help Chad's parents learn more about having a child with autism? What resources might the nurse find?

25.C Analyze CP as it relates to development.

- Describe the pathophysiology of CP.
- Describe the etiology of CP.
- Compare the risk factors and prevention of CP.
- Identify the clinical manifestations of CP.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with CP.

- Differentiate care of patients with CP across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with CP.

Exemplar Key Term

Cerebral palsy (CP), 1835

Overview

Cerebral palsy (CP) is a group of chronic conditions affecting body movement, coordination, and posture that results from a nonprogressive abnormality of the immature brain. CP often is the result of some type of insult to the developing brain of the fetus, neonate, or infant that occurs in the later stages of pregnancy, during birth, or within the first 2 years after birth. The impact of the disease can range from mild to profound mobility issues (**Figure 25–12** >>). CP may or may not include intellectual disability.

Cerebral palsy occurs in an estimated 1 per 323 births (Christensen et al., 2016). Four types of motor dysfunction are seen with CP—spastic, dyskinetic, ataxic, and mixed—and are related to the location of brain insult. Spastic CP, the most common type, affects approximately 80% of those diagnosed with CP (CDC, 2016g).

Pathophysiology and Etiology

Pathophysiology

Cerebral palsy involves abnormal development or damage to the immature brain that affects motor function and muscles (CDC, 2015e). There are two main categories: congenital and acquired. Congenital CP occurs during fetal development, birth, and the neonatal period. Acquired CP happens after the first 28 days of life. The specific insult leading to CP may not be identifiable if it occurs during the prenatal period. After

delivery, the cause of the damage (for example, encephalitis) is more likely to be identified. CP may result in decrease in muscle tone, muscle stretch reflexes, postural reactions, and primitive reflexes; it may also result in seizures, mental retardation, and/or hearing problems. The outcome depends on the area of the brain affected, the severity of the event, the duration of the insult, and the child's age at the time of the event.

Pathogenesis of CP is multifactorial and depends on the cause of the insult to the brain. Brain damage associated with cerebral palsy occurs in the motor areas of the brain, impairing the body's ability to control movement and adjust posture appropriately. CP is neither contagious nor inherited, and it is not progressive. It cannot be cured, but the associated symptoms can be managed.

CP often is identified when children fail to meet expected developmental milestones and diagnostic testing is ordered to pinpoint the reason for the delay. Symptoms and manifestations vary from person to person depending on the exact neurologic impact of the event.

Etiology

Approximately 85–90% of children with CP are diagnosed with congenital CP (CDC, 2015e). At one time, hypoxia was considered the primary culprit for congenital CP; however, research now indicates that it is only responsible for a small number of cases. Instead, pathogens, toxins, trauma, and genetic mutations that affect the development of the brain are now suspected causes of CP.

The pathology of the brain injury depends on the etiology. For instance, pathogens that directly attack the brain—such as *Streptococcus pneumoniae* (pneumococcus), which is responsible for the majority of meningitis in infants—cause cellular damage through the consumption of the brain's tissue and production of the by-product lactic acid. Trauma stretches and shears neural pathways and brain tissue. Neurotoxins, such as bilirubin, accumulate in the bloodstream and eventually injure the nerve cells in the brain.

The role of DNA in the development of CP is coming to greater light with the advancement of genetics. Genetic mutations have been found in individuals with CP in recent studies. In addition, males, who are considered vulnerable to genetic mutations because of the XY chromosome configuration, are more likely to have CP than females (MacLennan, Thompson, & Gecz, 2015).

Risk Factors

Risk factors for cerebral palsy include events and exposures that may cause damage to the developing brain. Risk factors do not necessarily mean, however, that the infant has or will develop cerebral palsy. For instance, children conceived via assisted reproductive technology (ART) have a greater incidence of cerebral palsy; however, many conceived via ART do not develop CP.

Risk factors associated with congenital CP occurring in utero include infections such as pelvic inflammatory disease (PID), rubella, chickenpox, CMV, and bacterial infections. Fevers in the mother prior to birth also may contribute to the development of CP. Cytokines, which are produced with fevers and certain infections, are thought to cause damage to neurons in the developing fetus's brain (CDC, 2015e). Blood type incompatibility between the fetus and mother may

A

Figure 25–12 >> Individuals with CP can have mild to profound mobility issues and may be able to walk unaided, need an assistive device **A**, or use a wheelchair **B**.

cause CP. If the mother is exposed to toxins, such as mercury, there is a greater chance of CP. Likewise, if the mother has such conditions as seizures, thyroid disease, or proteinuria, there is a slightly greater chance of CP (National Institute of Neurological Disorders and Stroke [NINDS], 2016).

Birth and the health of the neonate are significant factors that contribute to the risk of developing CP. Risk factors associated with delivery include breech delivery, tight and nuchal cords, shoulder dystocia, uterine rupture, placenta previa, and fetal stress and hypoxia (CDC, 2015e; NINDS, 2016; MacLennan et al., 2015).

Approximately 35% of CP cases occur in individuals with a history of preterm birth. Studies have found the earlier in gestational age the infant is born, the greater the likelihood the infant will have CP (MacLennan et al., 2015). Multiple fetuses are also at risk, partially due to the greater chance of preterm birth. Low birth weight, also associated with preterm birth and/or multiples, is also considered a risk factor. Neonates delivered with low Apgar scores have a greater risk of CP as well.

During the neonatal period, infants who have severe jaundice are at risk for developing CP due to hyperbilirubinemia. As mentioned previously, bilirubin is considered a neurotoxin and can damage the fragile neonatal brain on the cellular level. Because the neonatal immune system is immature, the infant is particularly susceptible to meningitis and encephalitis, two conditions also associated with CP.

Brain trauma is also a risk factor for CP. Neonates may experience trauma during birth from precipitous delivery, prolonged delivery, and other causes. After delivery, infants may experience trauma from shaken baby syndrome, being dropped, or improper placement in a car seat, as well as other means. The damage from these traumas puts the infant at risk for CP.

Prevention

The greatest risk for CP is preterm labor. Nurses should educate mothers-to-be on the prevention of preterm labor, including encouraging good prenatal care and visits with a provider. Nurses should also educate the pregnant patient on the signs and symptoms of preterm labor. Mothers with multiples in particular should have a close relationship with their providers to monitor the pregnancy. If the mother is placed on bedrest, the nurse should encourage the mother to comply with treatment in order to deliver a healthy baby.

Because maternal infection is associated with the development of CP, infection prevention, including maintaining good hand hygiene, is a primary goal. Keeping current with vaccinations is also a means by which a pregnant patient can reduce the risk for having a baby born with CP. After birth, parents should avoid exposure of their infant to the potential of infection, including using good hand hygiene when caring for the infant. Vaccinations are essential in preventing certain infections that may cause CP, including the *Haemophilus influenza* vaccination that helps prevent the most common form of bacterial meningitis.

Injury prevention, including properly securing infants during motor vehicle travel and taking measures to prevent falls, serves to protect the child from brain trauma. Nurses should also educate parents on stress reduction and prevention of shaken baby syndrome.

» **Stay Current:** Shaken baby syndrome, also referred to as abusive head trauma or shaken infant syndrome, occurs when a parent or caregiver severely shakes a baby out of frustration. For more information, go to the National Center on Shaken Baby Syndrome, www.dontshake.org.

Clinical Manifestations

Cerebral palsy is characterized by abnormal muscle tone and lack of coordination, with spasticity found in the majority of cases. Children have a variety of symptoms depending on their age. See **Table 25–16** » for symptoms by type of central nervous system injury. Symptoms vary depending on the area of the brain involved and the degree of insult.

Children with CP usually are delayed in meeting developmental milestones. For example, at 6 months of age, they may have persistent back arching, show little spontaneous movement, and be unable to sit up. They frequently have other problems, including visual defects such as strabismus (abnormal alignment of the eyes or “crossed eyes”), nystagmus (involuntary rapid eye movement), or refractory errors; hearing loss; language delay; speech impediment; or seizures. Feeding may be difficult because of oral motor involvement. Intellectual impairment is seen in 30–50% of persons with CP. Intellectual challenges are more commonly seen in those with spastic quadriplegia; those with CP and a seizure disorder are most likely to have an intellectual disability.

Collaboration

Care of the patient with CP requires an interprofessional team of nurses, physical therapists, occupational therapists, physicians, speech therapists, dietitians, and social workers or case managers. Cerebral palsy is a lifelong condition that requires special consideration, particularly in the growing child who quickly outgrows assistive devices and must meet changing developmental needs.

TABLE 25–16 Clinical Characteristics of Cerebral Palsy

Clinical Characteristics	Definitions
Hypotonia	Floppiness, increased range of motion of joints, diminished reflex response
Hypertonia, rigidity, spasticity	Tense, tight muscles Uncoordinated, awkward, stiff movements; scissoring or crossing of the legs; exaggerated reflex reactions
Athetosis	Constant involuntary writhing motions that are more severe distally
Ataxia	Poor muscle control during voluntary movement, poor balance
Hemiplegia	Involvement of one side of the body, with the upper extremities being more dysfunctional than the lower extremities
Diplegia	Involvement of all extremities, but the lower extremities are more affected than the upper, usually spastic
Quadriplegia	Involvement of all extremities with the arms in flexion and legs in extension

Clinical Manifestations and Therapies

Cerebral Palsy

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Spastic	<ul style="list-style-type: none"> Persistent hypertonia, rigidity 	<ul style="list-style-type: none"> Physical therapy Muscle relaxants Braces, splints, and orthotics
<i>Cerebral cortex or pyramidal tract injury</i>	<ul style="list-style-type: none"> Exaggerated deep tendon reflexes 	<ul style="list-style-type: none"> In addition to therapies used for spastic CP, surgery may be required to loosen contractures or to repair curvature of the spine.
<i>Most common form of CP, comprising 80% of cases (CDC, 2015e)</i>	<ul style="list-style-type: none"> Persistent primitive reflexes Leads to contractures and abnormal curvature of the spine 	
Dyskinetic	<ul style="list-style-type: none"> Impairment of voluntary muscle control accompanied by appearance of involuntary movements (e.g., tics, chorea) 	
<i>Extrapyramidal, basal ganglia injury</i>	<ul style="list-style-type: none"> Bizarre twisting movements Tremors, difficulty with fine and purposeful motor movements Exaggerated posturing Rigid muscle tone when awake and normal or decreased muscle tone when asleep Inconsistent muscle tone that may change hour to hour or day to day 	
<i>Ataxic cerebellar (extrapyramidal) injury</i>	<ul style="list-style-type: none"> Abnormalities of voluntary movement involving balance and position of the trunk and limbs Difficulty controlling hand and arm movements when reaching Increased or decreased muscle tone Hypotonia in infancy Muscle instability and wide-based, unsteady gait 	<ul style="list-style-type: none"> Canes, crutches, walkers, and other orthotics may be needed to promote mobility.
Mixed injuries to multiple areas	<ul style="list-style-type: none"> No dominant motor pattern Unique compensatory movements and posture to maintain control over specific neuromotor deficits Combination of characteristics from other types 	

» **Stay Current:** For more information on CP, visit the National Institutes of Health at www.nlm.nih.gov/medlineplus/cerebralpalsy.html.

Diagnostic Tests

Diagnosis is usually based on clinical findings. CP is difficult to diagnose in the early months of life, because it must be distinguished from other neurologic conditions and signs and may be subtle. Cerebral palsy is usually suspected between age 18 months to 2 years, and later confirmed around the age of 5 years (McIntyre, 2015; NINDS, 2016). However, earlier diagnosis is recommended, particularly in those children with high risk factors.

Suspicious findings include an infant who is small for his age or has a history of prematurity; low birth weight; low Apgar score (0–3 at 5 minutes); or the occurrence of an inflammatory, traumatic, or anoxic event (Ahlin et al., 2013). However, the majority of children who develop CP have

normal Apgar scores at birth. Ultrasonography can be used to detect fetal and neonatal abnormalities of the brain, such as intraventricular hemorrhage. Neuromotor tests are used to evaluate the presence of normal movement patterns and absence of primitive reflexes and abnormal tone. Once CP is suspected, CT scans, MRI, and positron emission tomography may be performed.

Surgery

Surgical interventions may be required to improve function by balancing muscle power and stabilizing uncontrollable joints. The Achilles tendon may be lengthened to increase range of motion in the ankle, which allows the heel to touch the floor and thus improves ambulation. The hamstrings may be released to correct knee flexion contractures. Other procedures may be performed to improve hip adduction or correct the foot's natural position.

Selective dorsal rhizotomy (SDR) is a surgical procedure that disconnects afferent nerves in order to reduce spasticity. This is most commonly done in the spastic diplegia subtype of CP. Although this surgery helps reduce spastic muscles and has been shown to increase functionality, it can have troubling after-effects, including muscle weakness (Josenby et al., 2015).

Pharmacologic Therapy

Medications are given to control seizures, to control spasms (skeletal muscle relaxants, baclofen, and benzodiazepines), and to minimize gastrointestinal side effects (cimetidine or ranitidine). Baclofen is administered by intrathecal pump to decrease muscle tone and vasospasms when oral administration is ineffective or causes side effects (NINDS, 2016).

Botulinum toxin (BT-A) injections have been used in to decrease spasticity and are considered standard practice. BT-A helps relax the contracted muscle. Used in conjunction with a stretching program, those who undergo this treatment report good results. Several studies have also shown the effectiveness of this therapy, including the benefits of multiple injections (NINDS, 2016; Kahraman et al., 2016).

Nonpharmacologic Therapy

Clinical therapy focuses on helping the child develop to a maximum level of independence. Early intervention services are key and may include a combination of physical, occupational, and speech therapy, as well as special education to improve motor function and ability. Braces and splints, serial casting, and positioning devices (prone wedges, standers, and side-liers) are used to promote range of motion, skeletal alignment, stability, and control of involuntary movements. They are also used to prevent contractures. Physical therapy and occupational therapy promote optimal independent functioning. Interventions vary depending on the child's needs.

Lifespan Considerations

Many children with CP grow up to be independent, functioning adults with careers, families, and social support systems (**Figure 25-13** ►). Having CP does take a toll on the adult's body. Many adults with CP have chronic pain due to the contractions of the muscles, arthritis due to the wear and tear on the joints, and persistent fatigue due to the extended energy needed to work against the contracted muscles.

Because CP puts the body in a continual stress state, many adults experience premature aging. The majority of those with CP will have signs of premature aging, including atherosclerosis, osteoarthritis, and hypertension, by their early 40s (NINDS, 2016). As individuals with CP age, they are more prone to both urinary and bowel incontinence, which can hamper their quality of life. With all these factors affecting the patient with CP, depression is not uncommon. Comorbidities such as seizures and respiratory disorders often shorten the life of the person with CP.

Source: Huntstock/Getty Images.

Figure 25-13 ► This man with CP uses a wheelchair and works on his laptop using his foot.

NURSING PROCESS

Nursing care focuses on early intervention, prevention of complications, and support of children and families to help them cope with the diagnosis of CP.

Assessment

Be alert for children whose histories indicate an increased risk for CP. It is not uncommon for children who are delayed in meeting developmental milestones or have neuromuscular abnormalities at 1 year of age to show gradual improvement in function. Studies have shown that assessment of general movements has a high predictive validity of CP among infants less than a year old (McIntyre, 2015).

Assess all children at each healthcare visit for developmental delays. Note any orthopedic, visual, auditory, or intellectual deficits. Assess for newborn reflexes, which may persist beyond the normal age in a child with CP. Identify infants who appear to have abnormal muscle tone or abnormal posture (child has an arched back, child becomes stiff when moving against gravity, child's neck or extremities have increased or decreased resistance to passive movement). A child with asymmetric or abnormal crawling using two or three extremities indicates a motor problem. Hand dominance before the preschool years is another sign of a motor problem. Record dietary intake as well as height and weight percentiles for children suspected to have or to be diagnosed with the condition.

Evaluate all infants who show symptoms of developmental delays, feeding difficulties caused by poor sucking, or abnormalities of muscle tone. Two simple screening assessments are helpful:

- Place a clean diaper on the 6- to 12-month-old infant's face. The infant without special needs will use two hands to remove it, but the infant with CP will use one hand or will not remove the cloth at all.

- Turn the infant's head to one side. A persistent asymmetric tonic neck reflex (beyond 6 months of age) indicates a pathologic condition. Suspect CP in any infant who has persistent primitive reflexes.

Diagnosis

Nursing diagnoses appropriate for inclusion in the care of the child with CP vary depending on the type of CP, the particular child's symptoms and age, and the family situation. Examples of nursing diagnoses relevant to caring for the patient with CP may include the following:

- *Injury, Risk for*
- *Mobility, Impaired*
- *Constipation, Risk for*
- *Tissue Integrity, Impaired*
- *Verbal Communication, Impaired*
- *Pain, Chronic*
- *Development, Delayed*
- *Caregiver Role Strain.*

(NANDA-I © 2014)

Planning

Because the condition can range from mild to severe and may involve numerous manifestations, care planning must be highly individualized on the basis of the specific needs of each individual. It may include the following goals:

- The patient will remain free from injury.
- The patient will demonstrate appropriate growth and development.
- The patient will maintain an appropriate diet to meet nutritional needs.
- The patient and family will monitor bony prominences to avoid altered skin integrity.

Implementation

Interventions need to be adapted to the particular child and family. Nursing care focuses on providing adequate nutrition, maintaining skin integrity, promoting physical mobility, promoting safety, promoting growth and development, teaching parents how to care for the child, and providing emotional support.

Prevent Injury

Patients with CP have varying degrees of mobility. The nurse should ensure that the patient receives the degree of assistance required for safe ambulation and that orthotic and assistive devices are properly used. Maintaining a safe environment includes eliminating all potential obstacles from walkways and providing adequate lighting. Assess caregivers and family members for awareness of safety precautions and provide teaching as needed.

Safety belts should be used for children in strollers and wheelchairs. An adaptive car safety seat may be needed to transport the child safely. A child with chronic seizures should wear a helmet to protect against further injury.

Promote Community-based Services

Children with CP need continuous support in the community. A case manager, such as the parent or a nurse, is often needed to coordinate care. Parents may need financial assistance to provide for the child's needs and to obtain appliances such as braces, wheelchairs, or adaptive utensils. As they grow, children need new adaptive devices, ongoing developmental assessment and care planning, and sometimes surgery. Although the brain lesion does not change, it manifests differently as the child grows. For example, once the child begins to walk, the extensor tone may cause tightening of the Achilles cord. Braces may decrease deformities, but surgery may be needed eventually. The nurse or healthcare provider is often the one to make referrals to early intervention programs to assist parents in meeting their child's needs. In addition, the nurse makes referrals, as appropriate, to support groups and organizations such as the United Cerebral Palsy Association and Shriners Hospitals.

An individualized transition plan developed during adolescence assists the family and adolescent with CP to develop plans for adult living. Vocational training options can be explored. The young adult (18–21 years) may be able to move into a group home or live independently if desired.

Provide Adequate Nutrition

Children with CP require high-calorie diets or supplements to the diet because of energy expenditure needed for movement and muscle contraction. Problems with swallowing, sucking, chewing, and movements in the mouth/jaw also cause nutritional challenges. Give the child soft foods in small amounts. Utensils with large, padded handles may be easier for the child to use. Oral hygiene can sometimes be an issue. Dental caries and gum disease are common in patients with CP because of difficulties with oral hygiene. This can also add to nutritional deficits if pain occurs with eating.

Maintain Skin Integrity

Take special care to protect the bony prominences from skin breakdown. Monitor the skin under splints and braces for redness. If the skin is red, the braces or splints should be removed and not replaced until the redness is gone.

Proper body alignment should be maintained at all times. Support the child with pillows, towels, and bolsters whether the child is in bed or in a chair. Support the head and body of a floppy infant. A child with spasticity may have scissored, extended legs, and a child with athetoid movements may be difficult to carry and transport.

Promote Physical Mobility

Range-of-motion exercises are essential to maintain joint flexibility and to prevent contractures. Consult with the child's physical therapist and help with recommended exercises. Teach parents to position the child to foster flexion rather than extension so that the child can more easily interact with the environment (for example, by bringing objects closer to the face). Consider the use of therapeutic massage and ROM exercise to help strengthen muscles and promote flexibility. A study showed that children who received scheduled therapeutic massage and ROM exercises had less

spasticity, stronger muscle strength, greater ROM, and higher function of ADLs (Yu et al., 2016).

As the child grows, adaptive and assistive technology may be needed to promote mobility and communication. Assistive technology is any item, equipment, or product customized for use to promote the functional capabilities and independence of an individual with disabilities. Examples include computers, adaptive utensils, and customized wheelchairs. Refer parents to the appropriate resources for help obtaining adaptive devices. Encourage parents to bring in the child's adaptive appliances (braces, positioning devices) for use during hospitalization.

Promote Growth and Development

Remember that many children with CP have physical disabilities but not necessarily intellectual disabilities. Use terminology appropriate for the child's developmental level. Help the child develop a positive self-image to ensure emotional health and social growth. Adaptive devices may be available to help the child with CP to communicate more independently. Children with a hearing impairment may need a referral to learn American Sign Language or other communication methods. Provide audio and visual activities for the child who is quadriplegic.

Provide Parent Education

Teach parents about the disorder and arrange sessions to teach them about all of the child's special needs. Teach

administration, desired effects, and side effects of medications prescribed for seizures. Make sure parents are aware of the need for dental care for children, especially those taking anticonvulsants and other medications that can impact oral health.

Parents also may need suggestions for amending parenting strategies to promote the child's autonomy and abilities.

Provide Emotional Support

Parents require emotional support to help them cope with the diagnosis. Listen to the parents' concerns and encourage them to express their feelings and ask questions. Explain what they can expect from future treatment. Refer parents to individual and family counseling if appropriate. Work with other healthcare professionals to help families adjust to this chronic disease.

Evaluation

Patients are evaluated based on their ability to meet goals identified in the plan of care, which may include the following:

- Patient's growth is appropriate for age.
- Patient meets developmental milestones appropriate for age.
- Patient's nutritional status is adequate for age and energy needs.

Nursing Care Plan

A Patient with Cerebral Palsy

Justine McBride is a 2-year-old girl. Her mother was 41 when she delivered Justine, and Justine's father was 45. Justine is the seventh

child in the family. Her mother works as a chemist in a local laboratory, and her father is an accountant for a large firm.

ASSESSMENT

Justine's mother became concerned that Justine was not walking when she turned 14 months old; all of her other children were walking by 12 months of age. Diagnostic tests were performed, and Justine was diagnosed with spastic CP.

Examination of Justine demonstrates scissoring of the legs when prone, stiff movements of arms and legs, hyperreflexia, and muscular rigidity.

DIAGNOSES

- *Mobility: Physical, Impaired* related to decreased muscle strength and control
- *Imbalanced Nutrition: Less Than Body Requirements* related to difficulty in chewing and swallowing and high metabolic needs
- *Health Management, Family, Ineffective*, related to excessive demands made on family with child's complex care needs

(NANDA-I © 2014)

PLANNING

Goals for Justine's care include the following:

- Justine will reach maximum physical mobility and all developmental milestones.
- Justine will receive adequate visual sensory/perceptual input to maximize developmental outcome.
- Justine will exhibit normal growth patterns for height, weight, and other physical parameters.
- Justine's family will successfully support all of its members.
- Justine will participate in activities to maximize development.

IMPLEMENTATION

Recreation Therapy: *Purposeful use of recreation to promote relaxation and enhancement of social skills.*

- Refer the family to an early intervention program. Encourage contact with other children through play groups or early intervention programs.
- Investigate recreational programs for children with disabilities and share information with the parents.

Family Mobilization: *Utilization of family strengths to influence Justine's health in a positive direction.*

- Allow chances for parents to verbalize the impact of CP on the family. Refer them to other parents and support groups.
- Explore community services for rehabilitation, respite care, child care, and other needs and refer family as appropriate.

Nursing Care Plan *(continued)*

- During home and office visits, review Justine's achievements and praise the family for care provided.
- Teach the family skills needed to manage Justine's care (e.g., medication administration, muscle stretching, physical rehabilitation, seizure management).
- Teach case management techniques.
- Assess needs of siblings; involve them in Justine's care as appropriate. Review with parents the needs of all children in the family.

Nutrition Management: *Assistance with or provision of a balanced dietary intake of foods and fluids.*

- Monitor height and weight and plot on a growth grid. Perform hydration status assessment.
- Teach the family techniques to promote caloric and nutrient intake.
- Position Justine upright for feedings.
- Place foods far back in the mouth to overcome tongue thrust.
- Use soft and blended foods.
- Allow extra time for chewing and swallowing.

- Obtain adaptive handles for utensils and encourage self-feeding skills.
- Apply manual jaw control technique if it helps the child to control jaw movement.
- Perform frequent respiratory assessment. Teach the family to avoid aspiration pneumonia.

Exercise Therapy, Joint Mobility: *Use of active and passive body movement to maintain or restore joint flexibility.*

- Perform development assessment and record age of achievement of milestones (e.g., reaching for objects, sitting).
- Plan activities to use gross and fine motor skills (e.g., holding a crayon or eating utensils, reaching for toys and rolling over).
- Allow time for the child to complete activities.
- Perform range-of-motion exercises every 4 hours for the child who is unable to move body parts. Position the child to promote tendon stretching (e.g., foot plantar flexion instead of dorsiflexion, legs extended instead of flexed at knees and hips).
- Arrange for and encourage parents to keep appointments with physical or rehabilitation therapist and other members of the collaborative team.

EVALUATION

The patient's progress in meeting the goals of care is based on the following expected outcomes:

- Justine reaches maximum physical mobility and all developmental milestones.
- Justine shows normal growth patterns for height, weight, and other physical parameters.

- Justine demonstrates appropriate growth and developmental progress. The family successfully supports all of its members.
- Justine engages in activities to maximize development.

CRITICAL THINKING

1. What support groups or professional organizations exist in your area that could help Justine's family cope with this diagnosis?
2. Why is involvement of the older siblings important?
3. How would you assess Justine's cognitive ability? Is cognition always impacted by CP?

REVIEW Cerebral Palsy

REVIEW Link the Concepts and Exemplars

Linking the exemplar of cerebral palsy with the concept of comfort:

1. How might you help to promote comfort in a child with CP who is required to wear braces and orthotics to bed at night?
2. If spasticity of muscles causes pain, what nonpharmacologic strategies might you recommend?

Linking the exemplar of cerebral palsy with the concept of cognition:

3. While caring for a child diagnosed with CP who also has mild cognitive impairment, how would you help the child become increasingly autonomous in performing range-of-motion exercises?
4. How might you encourage this child's parents to promote autonomy?

REFLECT Apply Your Knowledge

Frangelica Gonzalez, 12 years old, was born with CP. She began working with physical therapists when she was less than 1 year old and has worn braces on her legs and used crutches to allow her greater mobility for as long as she can remember. Her mother and father have always told her she can overcome any challenge and do anything other children do if she tries hard enough. As a result of her parent's encouragement and support, Frangelica is a member of the school swim team, plays jazz piano, and has a large circle of friends. She has a younger brother who is 9 years old, an older brother who is 15 years old, and an identical twin sister who is healthy and does not have CP.

Lately her parents have noticed that Frangelica is moody, often seeming depressed, and her twin sister told their mother that Frangelica is “tired of being different.” Frangelica has been waking in the morning offering various physical complaints as reasons why she can’t go to school that day, ranging from a stomachache to a sore foot.

1. Why might Frangelica suddenly be feeling different and trying to find reasons not to go to school?

2. What strategies might you recommend to Frangelica’s parents to help her cope with the developmental changes she is experiencing?

3. What strategies might you recommend to Frangelica to explore and cope with her feelings?

Exemplar 25.D Failure to Thrive

Exemplar Learning Outcomes

25.D Analyze failure to thrive as it relates to development.

- Describe the pathophysiology of failure to thrive.
- Describe the etiology of failure to thrive.
- Compare the risk factors and prevention of failure to thrive.
- Identify the clinical manifestations of failure to thrive.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with failure to thrive.

Overview

Failure to thrive (FTT) most commonly describes a syndrome in which an infant falls below the 5th percentile for weight and height on a standard growth chart or is falling in percentiles on a growth chart. The most common cause is malnutrition. Accurate statistics are not available because infants and children with FTT are typically undocumented (Sirotnak & Chiesa, 2016). This is because the majority of the parents of children with FTT do not or cannot seek proper and regular medical care. However, poverty rates are sometimes used, as many who live in poverty are food insecure.

Geriatric failure to thrive (GFTT) is a condition in which older patients experience a multidimensional decline in physical functioning that is characterized by weight loss of more than 5% of baseline body weight, decreased appetite, undernutrition and dehydration, depression, and cognitive and immune impairment. Similar to pediatric failure to thrive, GFTT can lead to death if left untreated.

Pathophysiology and Etiology

Pathophysiology

FTT and GFTT may stem from inadequate caloric intake, inadequate caloric absorption, or excessive caloric expenditure. In all cases, undernutrition results. Biological and psychosocial factors may also influence the development of FTT and GFTT.

GTT pathophysiology can be influenced by chronic diseases, including cancer, inflammatory diseases, chronic lung diseases, chronic renal insufficiency, and others. Medications, such as anticholinergic drugs, beta blockers, and SSRIs, can cause anorexia in the elderly patient.

Etiology

The cause of FTT can be organic, as in congenital AIDS, inborn errors of metabolism, neurologic disease, cleft palate,

■ Differentiate care of patients with failure to thrive across the lifespan.

■ Apply the nursing process in providing culturally competent care to an individual with failure to thrive.

Exemplar Key Terms

Failure to thrive (FTT), 1842

Geriatric failure to thrive (GFTT), 1842

and esophageal reflux. However, most cases of FTT are non-organic in origin. FTT resulting from nonorganic causes is called *feeding disorder of infancy or early childhood*.

Changes in body composition, imbalance between energy intake and demand, homeostatic dysregulation, and neurologic and psychologic changes are typical of GFTT. As the body ages, weight typically increases until late middle age and declines between ages 65 and 70. With this decline, lean body mass is lost. Fat mass, however, increases. The loss of lean body mass causes a decrease in the resting metabolic rate; in turn, older adults expend most of their energy performing activities of daily living (ADLs).

Certain age-related changes impact food intake and digestion. These include decreased sense of taste, decreased secretion of digestive enzymes, and decreased salivation. GI motility slows with aging, which also decreases metabolism. Dentition is also affected by aging, with older people at risk for losing teeth, having gum disease, and/or other painful mouth conditions. These changes make eating more difficult and less enjoyable; they also change older patients’ sense of being full during meals. Ultimately, this leads older adults to consume fewer calories, which means they have less energy for performing ADLs.

At the same time that metabolic rate and energy consumption are changing, decreased efficiency of body systems makes it increasingly difficult for the body to maintain homeostasis. To compensate for these changes, homeostatic mechanisms require extra energy; this energy is not necessarily available in light of dietary changes. Neurologic and psychologic changes further compound these problems. Although many older adults experience good physical and cognitive health, some experience motor and cognitive decline, making it difficult to purchase food and prepare meals, and sometimes making it difficult to remember meal-times and whether or not they’ve eaten.

Chronic diseases can also impact the older person's ability to maintain weight and nutritional status. Diabetes can cause malabsorption and end-organ damage. Parkinson disease can cause dysphagia and tremors that make it difficult to get food into the mouth. There are several other chronic diseases that can affect the body's ability to get and maintain nutrition.

Anorexia of aging, which can lead to GFTT, is a decrease in appetite and consequential decrease of nutrition intake (Landi et al., 2016). Vitamin and nutrient deficiencies are also common and decrease older patients' ability to recover from injury, illness, and infection. This impaired immunity makes older patients more susceptible to both chronic and acute illnesses; illness, in turn, makes patients more susceptible to GFTT.

Risk Factors

Infants who are deprived of mothering, especially those 3 to 15 months of age, will not learn to form significant relationships or to trust others. Touch, cuddling, and visual and auditory stimulation are all critical for the infant. Through these mechanisms, the baby comes to know self and the environment. Infants who fail to establish a loving, responsive relationship with a caregiver often fail to develop normally.

Infants and children whose parents or caregivers experience depression, substance abuse, mental retardation, or psychosis, or who have a history of abuse, are at risk for FTT. Their parents may be socially and emotionally isolated or may lack knowledge of infant nutritional and nurturing needs. A multifactorial and reciprocal interaction pattern may exist whereby the parent does not offer enough food or is not responsive to the infant's hunger cues and, as a result, the infant is irritable, not soothed, and does not give clear cues about hunger.

Children living in poverty are also at risk for FTT. When food is scarce, there is greater potential for undernutrition.

Risk factors for the older adult developing GFTT involve those conditions that lead to undernutrition. The presence of multiple chronic diseases, including diabetes, renal failure, cardiovascular disease, and neurologic disorders, increases risk for GFTT. There is a greater chance of anorexia that leads to malnutrition if the elderly patient is on more than four medications.

Sensory perception deficits can also lead to anorexia. Delirium can also cause the older adult not to have adequate nutrition. The geriatric patient who substitutes nutrition with alcohol or neglects to eat because of substance abuse is at risk for GFTT.

Mental health disorders put the older adult at risk for developing GFTT. Depression in particular is associated with GFTT. Residents in nursing homes, particularly veterans, show a greater risk of GFTT than those who live in the community (Ali, 2015).

Like children in poverty, adults who live in poor conditions and are food insecure are more likely to develop GFTT. Social isolation, widowhood, and abandonment by family/friends are also considered risk factors.

Prevention

Research suggests that educating caregivers regarding an infant's dietary and nutritional needs may help guard against development of FTT in children. Nurses can provide

resources for family with food insecurity, including referrals to local food pantries, school meals, and state and federal food assistance. Likewise, home nursing visits have been shown to significantly impact caregivers' delivery of adequate nutrition to children within the home (Cole & Lanham, 2011). Parents should be encouraged to be part of the plan, rather than feeling ashamed, in order to have a successful outcome.

Prevention of GFTT is complicated. The nurse can review the patient's medications, being observant of those medications responsible for decreased appetite. Patients can be taught to eat high-calorie, nutritionally dense foods. Other nutritional strategies can also be discussed with the patient, including eating frequent, small meals.

Nurses can refer patients to social support groups to help decrease isolation. Various charity organizations can be used to help the senior have meals delivered to the home. Case management should be considered for those individuals with several chronic diseases, as well as for those in need of financial and/or transportation assistance to buy food.

Clinical Manifestations

The characteristics of FTT are persistent failure to eat adequately with no weight gain or with weight loss in a child under 6 years of age. While FTT may be caused by a physical disorder, in 80% of cases, no definitive underlying physical disorder is identified (Cole & Lanham, 2011). Infants with feeding disorders refuse food, may have erratic sleep patterns, are irritable and difficult to soothe, fall well under expected growth patterns, and are often developmentally delayed (**Figure 25-14** ▶).

Infants with inorganic FTT show delayed development without any physical cause. They are often malnourished and fail to gain weight and grow normally. Behavior may be apathetic and withdrawn, and the child may demonstrate poor eye contact and lack anticipated stranger danger.

Figure 25-14 ▶ Infants with failure to thrive may not look severely malnourished, but they fall well below the expected weight and height norms for their age and population. This infant, who appears to be about 4 months old, is actually 8 months old. He has been hospitalized for examination of his failure to thrive and treatment of an eating disorder.

Patients with GFTT typically present with unintended weight loss, lack of appetite and energy, and diminished physical activity and strength. Muscle tone is poor; limbs are cachectic, though fat deposits appear around the midsection. Skin is dry and scaly, and wounds heal slowly and poorly. Hair is thin and nails are weak, discolored, and misshapen. Patients may complain of bone or joint pain, and edema may be present. Blood tests reveal anemia, low serum albumin and prealbumin levels, and low serum cholesterol levels.

GFTT patients are sometimes described as being “wasted” or “frail.” Wasting refers to gradual physical deterioration accompanied by a loss of strength and appetite. Frailty refers to cumulative physiologic decline that manifests itself in a wasted appearance, impaired physical abilities, decreased resistance to stressors, and diminished cognitive function. Resistance to stressors and cognitive functioning are important to consider when diagnosing GFTT because active older patients may consume fewer calories than required and experience weight loss, but be resilient to stress and have high cognitive functioning (White et al., 2012). In other words, weight loss alone is not indicative of GFTT.

Collaboration

A thorough history and physical examination are needed to rule out any chronic physical illness. The infant or child may be hospitalized so that healthcare providers can establish a routine for feeding and sleeping. The goals of treatment are to provide adequate caloric and nutritional intake, promote normal growth and development, and assist parents in developing feeding routines and responding to the infant’s cues of physical and psychological hunger.

» **Stay Current:** For a description of a collaborative healthcare team addressing FTT, visit the website of the Kennedy Krieger Institute’s Feeding Disorder Clinic at www.kennedykrieger.org/patient-care/patient-care-programs/outpatient-programs/feeding-disorders-clinic.

Diagnostic Tests

Diagnosis of FTT occurs primarily through assessment. In addition to clinical assessment, nutritional assessments are useful when evaluating patients for GFTT. Twenty-four hour recall is commonly used, though 7-day food diaries and food frequency questionnaires tend to be more accurate. The Malnutrition Universal Screening Tool (MUST), Mini Assessment (MNA), and Malnutrition Risk Scale (SCALES) may also be appropriate for identifying patients who are undernourished or at risk of being undernourished.

Body mass index (BMI) should be assessed; it is important, however, to recognize the limitations of BMI in older patients. Changes in height, posture, and muscle tone impact BMI’s overall accuracy as a health measure. Tricipital skinfold measurement, mid-upper arm circumference, and biometric impedance analysis are other useful anthropometric assessments of lean mass and fat mass.

Psychosocial assessment is an important part of any GFTT assessment, especially if patients have risk factors for depression such as the loss of a spouse or a change in living arrangements. The Geriatric Depression Scale (GDS) is frequently used for such assessments; this online tool has both a short (15 question) and long (30 question)

version. The Cornell Scale for Depression in Dementia may also be useful and is appropriate for patients with or without dementia.

» **Stay Current:** See the Geriatric Depression Scale at <http://www.medscape.com/viewarticle/447735>.

Diagnostic laboratory tests also are appropriate when assessing for GFTT. Serum proteins—including albumin, transferrin, retinol-binding proteins, and thyroxine-binding prealbumin—are typically assessed. Decreases in any of these proteins can be indicative of GFTT. These values should be considered cautiously, however, because they also serve as markers for other problems commonly associated with aging, such as inflammation and infection. Serum cholesterol and vitamin levels are also assessed.

Surgery

Surgical management of the patient with FTT will vary based on the physiologic impairment. For example, possible surgical interventions may include cleft palate repair or alleviation of a bowel obstruction.

In some cases, medical conditions contributing to GFTT, such as esophageal strictures and bowel obstructions, may require surgical treatment. The type and appropriateness of such surgical interventions depend on the specific condition.

Pharmacologic Therapy

No medications are indicated for primary treatment of FTT. Rather, the approach to treatment includes identifying the cause, resolving any barriers to obtaining and absorbing adequate caloric intake, and providing nutritional supplementation to treat deficiencies.

Pharmacologic therapies for the treatment of GFTT typically involve vitamin regimens. Vitamins D, B₁₂, and folate are commonly prescribed supplements for GFTT patients. Vitamin D and folate deficiencies typically stem from altered dietary intake; B₁₂ deficiencies, on the other hand, are most commonly caused by disease states.

In addition, if a GFTT patient is diagnosed with depression, pharmacologic therapy is likely to include tricyclic antidepressants, SSRIs, serotonin-norepinephrine reuptake inhibitors, or other second-generation antidepressants. In general, SSRIs are preferred because they have fewer adverse side effects in older patients. No matter the type of antidepressant prescribed, patients should be closely monitored for drug interactions (Wilson, Shannon & Shields, 2016).

Nonpharmacologic Therapy

Developmentally appropriate education for caregivers regarding nutrition and home care visits is believed to reduce the incidence of FTT among children. For patients who choose to breastfeed, the nurse should assess the patient’s knowledge and efficacy and provide or facilitate the provision of additional teaching as needed.

Nonpharmacologic therapies tend to focus on improving oral intake of foods and fluids. Therapies may include providing smaller, more manageable portions to decrease patient anxiety about wasted food. Portions may be fortified with additional vitamins and nutrients, and they may be softer in texture for patients with dentition problems. Snacks

should be offered, and patients should be allowed choice in menu selection whenever possible. Patients with alterations in mobility or illness should receive nursing assistance at mealtime.

For critically ill patients with GFTT, oral liquid, energy-dense, and high-quality protein supplements may be appropriate. For severely undernourished patients or those who cannot take food orally, enteral feeding is appropriate.

If underlying medical conditions contribute to GFTT, those must be treated with GFTT in mind. For example, restrictive therapeutic diets may cause weight loss; when GFTT is involved, the impacts of less restrictive diets on the two conditions should be assessed (Phillips, 2012).

NURSING PROCESS

Nursing care of the child with FTT is directed toward improving the child's nutritional intake with the end result of increasing the growth and health of the child. This may be accomplished through parent teaching; observation of child-parent interactions, especially during feeding times; and careful recording of height and weight on growth charts.

Nursing care of the older adult with GFTT involves both the acute care of the GFTT and the chronic care of any underlying disease processes. Assisting the patient to meet nutritional needs is a priority. This may include helping the patient make food choices that are nutritionally dense and easy to eat. Referral to a dietitian or nutritionist may be necessary. The nurse may also engage in therapeutic communication for the older adult who might be depressed, socially isolated, or coping with loss.

Assessment

Assessment of the child is essential for establishing the best intervention plan. Take accurate measurement of weight, height, BMI, and percentiles each time a child interacts with a healthcare provider to develop an important record of growth patterns over time. See the Focus on Diversity and Culture feature for more information on measuring growth. This helps to identify the child with an eating disorder. The child's activity level, developmental milestones, and interaction patterns also provide important information. When feeding the child, observe how the child indicates hunger or satiety, the ability of the child to be soothed, and general interaction patterns such as eye contact, touch, and cuddliness.

Ask parents about stressors in their lives that may prevent or interfere with appropriate interaction with the child. Questions about the pregnancy and delivery can elicit information about early disturbances in the child-parent relationship. Ask whether there are other children in the family and whether they have experienced feeding problems. It is important for the nurse to observe the child's and parents' behaviors when the parents feed the child; cues given by each individual and interactional modes such as rocking, singing, talking, and body postures are important.

For older adults, assess patients' opportunity for socializing during meals; intake tends to improve when others are present. In the home environment, assess the food preparation area to ensure that patients are physically capable of using necessary appliances and navigating the space. The

dining area should also be examined and any unneeded medical equipment removed. If patients in the home environment cannot prepare meals on their own, social services (e.g., "meals on wheels") should be considered (Phillips, 2012).

Diagnosis

Nursing diagnoses pertinent for the young child with FTT may include the following:

- *Imbalanced Nutrition: Less Than Body Requirements*
- *Development, Delayed*
- *Parenting, Risk for Impaired.*

Nursing diagnoses for the older adult with GFTT may include:

- *Fatigue.*
- *Imbalanced Nutrition: Less Than Body Requirements*
- *Self-Care Deficit.*

(NANDA-I © 2014)

Planning

The goals of nursing care for the child with FTT may include the following:

- Child will attain adequate growth and normal development.
- The parent-child relationship will improve.
- Parental understanding of the child's nutritional requirements will improve.
- Complications associated with poor nutrition will be prevented.

Goals for nursing care of older adults with GFTT may include:

- Patient will list five items that are nutritionally dense and include these items in a meal plan.
- Patient will have adequate mental health support and services.
- Patient will have stable sources of nutritious food and supplements as recommended by the healthcare provider.

Implementation

Nursing care centers on performing a thorough history and physical assessment, observing parent-child interactions during feeding times, and providing necessary teaching to enable parents to respond appropriately to their child's needs. Accurate weights, nutritional assessments, and developmental evaluation should be done to see if the child begins to grow more normally. Additional diagnostic tests may be given to rule out organic causes of the poor growth.

Once a diagnosis of nonorganic FTT is confirmed, parents become involved in feeding the child. Observations of feeding and continued careful physical assessments are needed. Teach parents to record carefully the child's intake at each meal or feeding. Teach parents how to understand and respond to the child's cues of hunger and satiety. Teach them to hold, rock, and touch the infant during feeding and to establish eye contact with infants and older children.

Upon discharge, refer parents to an early childhood intervention agency that can continue monitoring the home situation. Agency staff can observe feeding during a home visit and evaluate stresses and behavior patterns among family members. Frequent measurement of growth and development must be ensured so that the child is adequately nourished. Parents may need referral to community resources to help them manage stressful situations and to enhance their parenting skills.

For the older adult patient with GFTT, nursing care centers on weight gain and nutritional improvement. This will require the nurse to monitor input and output, paying mind to caloric intake and nutritional choices. Nurses should encourage nutritionally dense snacks and short, frequent meals. Addressing the underlying causes of the GFTT is also as important. For example, if the patient is prescribed several medications, the nurse can collaborate with a pharmacist and provider to evaluate the medication for anorexic side effects and consider alternatives. The nurse should consider case management for the patient. In nursing homes and transitional care units, the nurse should encourage the

resident to participate in social activities, including eating with other residents.

Evaluation

The child's outcomes are largely evaluated based on the following:

- Growth and development of the child improve.
- The parent-child relationship improves.
- The parent voices a specific action plan to improve and maintain appropriate growth of child.
- The child experiences no long-term complications as a result of FTT.

Outcomes for older adults with GFTT may include:

- The patient achieves improved nutritional status.
- The patient has food security.
- The patient uses social support systems as necessary to promote health and functioning.

REVIEW Failure to Thrive

RELATE Link the Concepts and Exemplars

Linking the exemplar of failure to thrive with the concept of acid-base balance:

1. How might excessive protein metabolism as the result of inadequate sources of energy supply from dietary intake impact the patient's acid-base balance?
2. How might altered glucose metabolism as a result of inadequate caloric intake impact the patient's acid-base balance?

Linking the exemplar of failure to thrive with the concept of elimination:

3. How might inadequate caloric and nutrient intake impact elimination?
4. If caloric and nutrient intake is increased suddenly, how might the patient's elimination habits be impacted?

REFLECT Apply Your Knowledge

Hilary is born 8 weeks prematurely at 32 weeks' gestation to a single adolescent mother. Hilary remains in the neonatal intensive care unit for 10 weeks until she is stable enough to be discharged. Her mother tries to visit at least once a week and is sometimes able to visit more often depending on whether someone can give her a ride to and from the hospital.

Hilary returns in 6 weeks following discharge and is found to have gained only 2 oz, increasing her weight from 2.32 kg (5 lb 2 oz) to 2.38 kg (5 lb 4 oz). The provider schedules a follow-up visit for 2 weeks later, and the nurse explains Hilary's nutritional requirements. When Hilary returns, she has lost 1 oz in weight.

1. Does Hilary qualify as having FTT? Explain your answer.

2. Do you suspect an organic or inorganic cause of her failure to gain weight?
3. Develop a nursing plan of care for Hilary.

REFLECT Apply Your Knowledge

Tom and Jenny Fordham, both in their 70s, have lived in the same home for more than 20 years. Mr. Fordham is a retired media professional; Mrs. Fordham a retired interior designer. In the past 3 years, both of them have experienced a decline in health. Mr. Fordham is now in the middle stages of Alzheimer disease. He is no longer able to drive and frequently needs to be reminded to do things like take a shower or take his medicine. Mrs. Fordham developed chronic obstructive pulmonary disease (COPD) several years ago. She now requires oxygen via cannula 24/7, and she uses her tiotropium bromide (Spiriva) and fluticasone (Flovent) inhalers daily as prescribed. She also takes calcium and vitamin D daily and ibandronate sodium (Boniva) once a month for osteoporosis. She continues to drive, although she finds it frustrating and does not like to go out often.

You are the nurse at Mrs. Fordham's primary care provider's office. When Mrs. Fordham comes for a routine checkup, you take her height and weight and find that she has lost 5 lb since she was in 3 months ago with acute bronchitis. She complains that Mr. Fordham is in the waiting room because she is too scared to leave him home alone. She relates that she has very little energy these days, and that taking care of him is "wearing me out."

1. What risk factors does Mr. Fordham have for GFTT? Mrs. Fordham?
2. What are your primary concerns about Mrs. Fordham at this time? Why?
3. What additional assessment data do you need to gather? Why?

Module 26

Family

Module Outline and Learning Outcomes

The Concept of Family

Normal Presentation

26.1 Outline the makeup of the family structure.

Factors That Shape Family Development

26.2 Summarize the factors that shape family development.

Influence of Parenting on the Family System

26.3 Contrast how differences in parenting styles and strategies affect the family system.

Alterations in Family Function

26.4 Differentiate alterations in family.

Concepts Related to Family

26.5 Outline the relationship between family and other concepts.

Health Promotion

26.6 Explain family health promotion.

Nursing Assessment

26.7 Differentiate common assessment procedures and tests used to examine family.

Independent Interventions

26.8 Analyze independent interventions nurses can implement for patients with alterations in family.

Discipline, 1859			Limit setting, 1858	Two-career family, 1853
Ecomap, 1867				

For most individuals, family serves as a primary developmental influence. Numerous family structures exist, from single-parent families to families headed by two mothers or two fathers. Regardless of structural variations, every family is subject to the challenges of life, including economic hardship, illness, and stress. This concept explores the role of the family in terms of development, childrearing, health promotion, and response to alterations in health status. In addition, the nurse's role in caring for the family unit is examined.

Normal Presentation

The Merriam-Webster dictionary gives no fewer than eight definitions of the word *family* (Merriam-Webster Dictionary,

2016). The basic unit of society, family can be defined as a group of people related to each other, by birth, by marriage, or by choice, who may or may not live together in the same household. The head of a family may be a single individual—for example, a grandfather or elder, or a single mother—or a couple who may or may not be married and who may or may not live under the same roof with all members of the family. The U.S. Census Bureau (2012) defines a **family** as two or more individuals who are joined together by marriage, birth, or adoption and are residing in the same household. More broadly, families are generally characterized by bonds of emotional closeness, sharing, and support. Beyond the Census Bureau's definition, there are legal, social, and psychologic definitions that also are commonly recognized.

Regardless of the definition, it is clear that there is no such thing as a *typical* family.

The Family as a Functional System

As with any unit or organization, the family is more than the sum of its parts or members. Genetic and cultural influences (including beliefs and values systems) and the interactions among its members inform the family's functional ability as well as how each member interacts with others outside the family. In other words, within a family, each individual is interconnected with and interdependent on the other members, both as individuals and as a group (Mellins et al., 2015). This is the heart of *family systems theory*. A *system* can be described as a set of parts or elements (or in the case of a family, individuals) that interact purposefully or orderly rather than randomly with each other (von Bertalanffy, 1981). Like any system, the family's purpose or goals are to maintain functioning—a steady state—and to adapt or respond successfully to change. Families that operate as *open systems* are able to exchange information (for example, by discussing and modeling acceptable behaviors) and resources (such as personal energy necessary to accomplish tasks) to meet problems and find solutions. Families that operate as *closed systems* often view change as a threat and have difficulty adapting to or overcoming change (Mellins et al., 2015; Kaakinen & Hanson, 2015).

Precisely because family members are so interconnected and interdependent, when nurses encounter any individual in need of care, they should approach the patient holistically, viewing the patient as part of a whole, as part of the family unit, and not simply as an individual. Consider the following examples:

- Parents caring for a toddler with a chronic illness. What hurdles might the child's parents face? What thoughts or feelings might they have? How might these impact care of other children? Their relationship as parents?
- A family whose oldest child has a serious mental illness, such as schizophrenia or bipolar disorder.
- A family whose main provider is in a motor vehicle crash and sustains significant head trauma.
- A woman who comes for a simple procedure (say, a mammogram or DEXA scan) at 3:30 and is still in the waiting room at 4:30 and must pick up her father from eldercare by 5:00 before picking up her teenager from soccer practice by 5:30.

Consider how even small issues can have a large impact and how the nurse and staff may view the issue differently from the patient, as in the last example provided. These and myriad other issues can impact functioning of the entire family system.

A family generally provides an environment for its members to learn group values, norms, and acceptable behaviors. Support and communication provide a way for families to maintain optimal health and functioning. In a healthy, functional family unit, roles include the following:

- Caring, nurturing, and educating children; teaching children how to get along in the world
- Maintaining the continuity of society by transmitting the family's knowledge, customs, traditions, values, and beliefs to children

- Receiving and giving love
- Preparing children to become productive members of society
- Meeting the needs of its members, including protection and economic support
- Serving as a buffer between family members and environmental and societal demands while advocating or addressing the interests and needs of the individual family members.

Individual family members take on certain social and gender roles and hold a designated status within the family based on the values and beliefs that bind the family together. These values and beliefs may evolve from the family's religious or cultural values and practices, social norms, education, and other influences to which parents were exposed during their childhood, adolescence, and early adult years. Parental roles, including childrearing practices and beliefs, are usually learned through a socialization process that occurs during childhood and adolescence.

Ideally, the family is a child's source of strength and support, the major constant in the child's life. Families are intimately involved in their children's physical and psychologic well-being, and they play a vital role in the health promotion and health maintenance of their children. Parents and children learn specific roles through a socialization process. By respecting the family's role, strengths, and experiences with the healthcare system, nurses have an opportunity to develop an effective partnership with the child and family as they make healthcare decisions that promote the child's health. This partnership between nurses and families is known as **family-centered care**. More recently, recognition of the advantages of involving patient and families across the lifespan directly in their care has resulted in patient- and family-centered care (PFCC). This concept identifies that the healthcare team needs to involve both the patient and the family in making mutually beneficial partnerships for the planning and implementation of healthcare in a variety of settings (Institute for Patient- and Family-Centered Care [IPFCC], 2015). Nursing care of the patient and family is core to nursing practice, and as such necessitates viewing this as a partnership in a comprehensive, holistic manner.

For many families, providing family-centered care also means providing culturally competent care. Families from different cultures are an integral part of North America's rich heritage. Each family has values and beliefs that are unique to its culture of origin and shape the family's structure, methods of interaction, healthcare practices, and coping mechanisms. These factors interact to influence the health of families. Families of a particular culture may cluster to form mutual support systems and to preserve their heritage; however, this practice may isolate them from the larger society (see **Figure 26-1** »).

Diversity in Family Structures and Roles

Families consist of individuals (structure) and their responsibilities within the family (roles). Governmental data are grouped by types of *households*: married couples with children, married couples without children, other family households (single-parent families), men living alone, women living alone, lesbian and gay family households, and other

Figure 26-1 » An example of cultural clustering can be seen in New York's Chinatown in Manhattan.

nonfamily households. Some families live in houses, some in apartments; some live in urban areas, some in rural towns, and some are homeless.

The family protects the physical health of its members by providing adequate nutrition and healthcare services. Family nutritional and lifestyle practices directly affect the developing health attitudes and lifestyle practices of the children. In most cases, the family's economic resources are secured by adult members.

When considering families from the standpoint of the tasks associated with functioning as a unit, many families are similar. However, family units in the United States are diverse in terms of structure and with regard to which family member assumes a given role.

Nuclear Family

A family structure of a mother and father and their offspring is known as the **nuclear family**. In 2014, 64% of children under the age of 18 lived in the same household with two married parents (Federal Interagency Forum on Child and Family Statistics, 2015).

When two biological parents divorce but continue to raise their children in partnership with one another, the family may be referred to as **binuclear**. Children in a binuclear family spend significant time with both parents, often going from one house to the other on a mutually agreed-upon schedule. In **joint custody**, both parents have equal legal rights and responsibility regardless of where the children live. The binuclear family model enables both parents to be involved in the children's upbringing and provides additional support and role models in the form of extended family members. Special nursing considerations in this family type involve ensuring that health promotion guidance and education for care of the child with an acute or chronic condition are communicated effectively to both biological parents.

Extended Family

The relatives of nuclear families, such as grandparents or aunts and uncles, compose the **extended family**. In some families, members of the extended family live with the family (see **Figure 26-2** »). Although members of the extended

Figure 26-2 » Three generations of a family enjoying a day in the park.

family may live in different areas, they may be a source of emotional or financial support for the family. An extended family may share household and childrearing responsibilities with parents, siblings, or other relatives. In 2014, 1.6 million children in the United States lived with a grandparent (U.S. Census Bureau, 2015). Grandparents may raise children because the parents are unable to care for them. Grandparents endure emotional, physical, and financial stresses when taking on the childrearing role for one or more grandchildren.

One example of an extended family is the **extended-kin network family**. This is a specific form of an extended family in which two nuclear families of primary or unmarried kin live in proximity to each other. The family shares a social support network, chores, goods, and services. This type of family model is common in the Latino community. Multi-generational arrangements of this sort are more common in non-U.S. cultures and working-class families.

Two-Career Family

In **two-career families** (or dual-career families), both partners are employed by choice or by necessity. They may or may not have children. Two-career families have steadily increased since the 1960s because of increased career opportunities for women, a desire to increase the family's standard of living, and economic necessity. The U.S. Bureau of Labor Statistics (2012) reported that the percentage of married dual-career families rose to 58.5% in 2011. Two-career families have to address issues related to child care, household chores, and spending time together, with finding good-quality, affordable child care being one of the greatest stressors.

Single-Parent Family

In 2014, just over one-quarter of all children (28%) lived in a **single-parent family**, that is, a family with one parent only (Federal Interagency Forum on Child and Family Statistics, 2015). There are many reasons for single parenthood, including death of a spouse, separation, divorce, birth of a child to an unmarried woman (whether or not the pregnancy was planned), or adoption of a child by a single man

or woman. The stresses of single parenthood are many: child care concerns, financial concerns, role overload and fatigue from managing daily tasks, and social isolation. Single-parent families may face difficulties because the sole parent may need assistance with childrearing issues, lack social and emotional support, or have financial issues. Single-parent families experience higher rates of poverty, which has important implications for the children. Poverty is highest among single-parent families headed by women, with 46% living in poverty. Only some 10% of children in married households live in poverty (Federal Interagency Forum, 2015).

Single mothers are at risk for poverty because of lack of child support, unequal pay for work performed, and the high costs of child care. Additional risk factors may include work skill deficiencies and cutbacks in social welfare programs, such as child-care subsidy programs. Nurses working with single parents assess their strengths and needs in providing care to the child, such as after-school and backup child care arrangements that enable the parent to fulfill work commitments. Nurses also determine if the family has access to all resources available to support growth and development, such as school breakfast and lunch programs that provide nutritional support.

Adolescent Family

The birth rate among teenagers peaked in 1991 and has decreased progressively since then to 34.2 births per 1000 women age 15–19 in 2010. This is the lowest birth rate for teenagers reported in more than 70 years (Martin, 2012). Rates are highest among Hispanic and Black females (Hamilton, Mathews, & Ventura, 2013). The parents in **adolescent families** are often developmentally, physically, emotionally, and financially ill prepared to undertake the responsibility of parenthood. Adolescent pregnancies frequently interrupt or stop formal education. Children born to adolescents are often at greater risk for health and social problems.

Foster Family

Children who can no longer live with their birth parents may require placement with a family that has agreed to include them temporarily. The legal agreement between the **foster family** and the court to care for the child includes the expectations of the foster parents and the financial compensation they will receive. A family (with or without its own children) may house more than one foster child at a time or different children over many years. Ideally, at some time the fostered child can either return to the birth parent(s) or be legally and permanently adopted by other parents.

Childfree Family

Childfree families are a growing trend. In some cases a family has no children by choice; in other cases, a family has no children because of issues related to infertility or other medical conditions that present risks to the woman or fetus should the woman become pregnant. According to the U.S. Census Bureau (2015), in 2014, more women in the United States (47.6% of those age 15 to 44) did not have children than at any other time since the government started tracking childbearing.

Blended Family

A **blended family** consists of two parents with biological children from previous relationships. The parents may be married or may cohabit. This family structure has become increasingly common in the United States because of high rates of divorce and remarriage. In 2014, of the 51.06 million children living with two parents in the United States, 8% (4.08 million) lived with a stepparent (U.S. Census Bureau, 2015).

Blended family models have both strengths and challenges. Blended families may have fewer financial issues than single parent homes and may offer a child a new support person and role model. Remarriage also provides a new opportunity for a successful relationship for the parents; however, the relationship between stepparents and stepchildren can be strained. Stresses can include discipline issues, adjustment problems, role ambiguity, strain with the other biological parent, and communication issues. When blended families with children form after the divorce or death of a parent, adjustment can be particularly challenged by the normal processes of grief and loss. An important nursing consideration is to direct families to resources that may help reduce the potential conflicts associated with different parenting styles, discipline, and manipulative behaviors of children that can develop within a blended family.

Intergenerational Family

In some cultures, and as people live longer, more than two generations may live together in an **intergenerational family**. Children may continue to live with their parents even after having their own children, or the grandparents may move in with their grown children's families after some years of living apart. In other situations, a generation is skipped or missing; that is, grandparents live with and care for their grandchildren, but the children's parents are not a part of this family. Many life events and choices can result in this type of family structure.

Cohabiting Family

Cohabiting (or communal) families consist of unrelated individuals or families who live under one roof. This may include never-married individuals as well as divorced or widowed persons. In 2014, 4% of children age 0 to 17 in the United States lived with two unmarried cohabiting parents. Others live with a single parent and a cohabiting partner (Federal Interagency Forum, 2015). Biological children may result from the relationship, or in some cases children of one parent are present and help form a blended cohabiting family.

An important nursing consideration for children who live in informal cohabiting families is that the nonbiological parent has no legal authority to seek emergency medical care for the child. However, in the case of a true emergency that could result in loss of life or diminished functioning, health professionals are obligated to provide care and obtain consent as soon as possible afterward. The nonbiological parent also may not have any knowledge of the child's medical history.

Gay and Lesbian Families

Gay and lesbian families can have all of the structures outlined previously (e.g., married, single parent, blended, intergenerational, cohabitation). They differ in that these families

Source: © Dubova/Fotolia.

Figure 26-3 >> A lesbian couple and their daughter.

have two or more people who share a same-sex orientation (see **Figure 26-3** >>). Nearly 220,000 children in the United States live in a gay or lesbian household (Gates, 2013). Children in these families may be from a previous heterosexual union, or be born to or adopted by one or both member(s) of the same-sex couple. For example, a biological child may be born to one of the partners through artificial insemination or through a surrogate mother. Lesbian and gay couples function much like heterosexual couples, and children who are adopted or born into the family are highly valued. Although children raised in gay and lesbian families may face unique issues when interacting with peers and when revealing their parents' sexual orientation, they develop sex role orientations and behaviors similar to those of children in the general population.

These children have been found to have the same advantages and expectations for health, adjustment, and development as children born into heterosexual families. Lesbian and gay parents are believed to be as effective as heterosexual couples in providing a supportive and healthy environment for their children (American Academy of Pediatrics, 2013). In addition, Prickett, Martin-Storey, and Crosnoe (2015) reported that fathers of heterosexual marriages spent less time in child-focused activities than fathers of gay marriages. On average, same-sex parents spent 3.5 hours with their children, compared to 2.5 hours in households with a mother and a father.

SAFETY ALERT When obtaining consent to provide healthcare and medical treatments to children and adolescents, the healthcare provider should identify the biological or adoptive parent or confirm a caregiver's possession of legal documentation proving the right to make medical decisions on the child's behalf.

Children in these families typically have only one biological or adoptive legal parent even if they are legally married. In many states, the other partner is the coparent and has no legal parental status. Various states have now taken legislative action to ensure the security of children whose parents are gay or lesbian by guaranteeing access by the second parent to joint adoption rights. Coparent adoption provides for

either parent to give consent for healthcare and make other important decisions on behalf of the child. It also has implications for child custody and financial support in the event the parents separate or a death occurs, ensuring the child's right to a continuing relationship with and financial support from both parents. Nursing considerations for individuals in gay and lesbian families emphasize respect for the relationship between partners and recognition of the nurturing capacity in these families.

Legal issues for same-sex couples are significant and constantly changing. Many, but by no means all, companies and municipalities offer domestic partner benefits to employees. Domestic partner policies extend the same rights and privileges to the partner of a nonmarried employee of the same or opposite gender as would be offered to spouses. Health insurance is an example of a benefit that often is offered under domestic partner policies. California Family Code Section 297–297.5 defines *domestic partners* as “two adults who have chosen to share one another's lives in an intimate and committed relationship of mutual caring” (State of California Franchise Tax Board, 2013). Although numerous state and federal laws have been introduced in the United States to allow or prohibit same-sex marriages or civil unions, same-sex marriages have been legal nationwide since June 26, 2015. The nurse may find it challenging to keep current on how such legislation affects healthcare issues such as insurance coverage and the right to consent for healthcare.

Single Adults Living Alone

Individuals who live by themselves represent a significant portion of today's society. According to the U.S. Census, in 2013, 27% of adults lived alone (U.S. Census Bureau, 2013). Singles include young self-supporting adults who have recently left their family of origin as well as older adults living alone. Young adults typically move in and out of living situations and may have membership in the family, nonfamily-household, and living-alone categories at different times. Older adults may find themselves single through divorce, separation, or the death of a spouse, but generally remain living alone for the remainder of their lives, especially women.

Stages of Family Development

Family development refers to the dynamics or changes that a family experiences over time, including changes in relationships, communication patterns, roles, and interactions. Although each family is unique, the members go through a set of fairly predictable changes. For example, Duvall (1977) developed an eight-stage family life cycle that describes the developmental process each family encounters. This model is based on the nuclear family (see **Table 26-1** >>). The oldest child serves as a marker for the family's developmental stages except in the last two stages, when children are no longer present. Couples with more than one child may find themselves in overlapping stages, with developmental advances occurring simultaneously.

TABLE 26–1 Eight-Stage Family Life Cycle

Stage	Characteristics
Stage I	Beginning family, newly married couples*
Stage II	Childbearing family (oldest child is an infant through 30 months of age)
Stage III	Families with preschool children (oldest child is between 2.5 and 6 years of age)
Stage IV	Families with schoolchildren (oldest child is between 6 and 13 years of age)
Stage V	Families with teenagers (oldest child is between 13 and 20 years of age)
Stage VI	Families launching young adults (all children leave home)
Stage VII	Middle-aged parents (empty nest through retirement)
Stage VIII	Family in retirement and old age (retirement to death of both spouses)

*Keep in mind that this was the norm at the time the model was developed, but today families form through many different types of relationships.

Hanson (Eds.), *Family health care nursing: Theory, practice, and research* (5th ed., pp. 387–432). Philadelphia, PA: F. A. Davis.

Other family development models have been developed to address the stages and developmental tasks facing the unattached young adult, the gay and lesbian family, those who divorce, and those who remarry.

Choosing to become a parent is a major life change for adults. Beginning when they first learn they are expecting a child (whether through pregnancy or adoption), parents experience stresses and challenges along with feelings of pride and excitement. Mothers and fathers adjust their lifestyles to give priority to parenting. Babies and very young children are dependent for total care 24 hours a day, and this often results in sleep deprivation, irritability, less personal time, and less time for the couple's relationship. In addition, the family with a new baby often experiences a change in financial status. Families progress in their development. Children grow up and, in many cases, initiate new generations of the family. Parents grow older, seeing their children leave the "nest" and progressing toward retirement. Factors that affect how families adjust to each stage include family communication patterns, resiliency, and parenting styles. These and other factors are outlined later in this module.

The family, like the individual, has developmental stages and tasks. Each new stage brings change, requiring adaptation; each stage also brings family-related risk factors for alterations in health and wellness. The nurse must consider the patient's needs both at specific developmental stages and within a family with specific developmental tasks.

Factors That Shape Family Development

Changes in the family structure, function, and processes can alter family development. These changes generally occur over time and may be planned or unplanned.

Cultural Practices

Family assessment requires consideration of the ages of all family members, as well as the cultural practices of the family. The age of the child or children will influence the family dynamic; for example, tasks associated with raising a toddler are vastly different from those pertinent to raising a teenager. Family activities and interaction will also vary depending on the age of the child. For example, when raising a toddler, a majority of the parents' focus may be on meeting the child's developmental and social needs, whereas a teenager will generally work to meet these needs on his own, and the parental roles incorporate guiding the teenager in making life choices.

Cultural practices may influence the child's diet, behavior, and even sleep patterns. Some cultural and religious traditions may involve vegetarianism (see **Figure 26–4** »), while others may involve periods of fasting. The manner in which a child is expected to behave in public and at home can be impacted by culture, as can the child's degree of respect for older adults. Culture can also affect the behavior of the entire family unit depending on matriarchal or patriarchal views. For example, in a matriarchal structure, the mother may be expected to take responsibility for making family healthcare decisions, to the near exclusion of the father and children. Although it is neither realistic nor necessary for the nurse to be an expert on each culture's beliefs, through open and

Figure 26–4 » This extended family of Indian Americans are vegetarians. In keeping with their Hindu religion's concept of nonviolence against all life forms.

nonjudgmental communication, the nurse can ascertain a great deal about the family's cultural influences.

Emotional Availability

Healthy coping among family members occurs when all members feel safe expressing their feelings—positive and negative—and the emotional environment of the family is one of respect, closeness, and predictability. Predictability refers to the inclusion of family routines on which family members can depend and in which they find comfort. Examples include a reasonably regular schedule of activities (e.g., reading before bed and a consistent bedtime). In a family with healthy coping, members are emotionally available to each other—that is, they have healthy emotional connections (Saunders, Kraus, Barone, & Biringen, 2015). Emotional availability is correlated to parenting ability (Yousafzai et al., 2015). Emotionally available parents are sensitive to their children's needs without being intrusive, provide structure for learning and exploration without exceeding the child's abilities, and are available but not interfering or hostile. These behaviors encourage child responsiveness, respect, and willingness to interact with parents and other family members (Biringen et al., 2014).

Family Communication Patterns

Family communication is a key factor in family development. Clear communication, problem solving, and sharing feelings associated with events within the family can help families achieve a high level of functioning and increase resilience (Walsh, 2016).

The effectiveness of family communication determines the family's ability to function as a cooperative, growth-producing unit. Messages are constantly being communicated among family members, both verbally and nonverbally. The information transmitted influences how members work together, fulfill their assigned roles in the family, incorporate family values, and develop skills to function in society. Intra-family communication plays a significant role in the development of self-esteem, which is necessary for the growth of personality.

Family Cohesion

Family cohesion is defined as the emotional bonding between family members. Cohesion among family members can be visualized on a continuum from disengaged (very low cohesion and independence) to enmeshed (very high cohesion and dependence). A family unit may be very cohesive. In addition, there may be very cohesive or very disengaged dyadic or triadic relationships within the family. *Dyadic* refers to the dynamics in a relationship between two people; *triadic* to the dynamics among three people. For example, a dynamic triad may develop between one parent and two children when the other parent is called out of town for work and therefore absent on a regular basis.

Family Coping Mechanisms

Family coping mechanisms are the behaviors families use to deal with stress or changes imposed from either within or without the family. Coping mechanisms can be viewed as an active method of problem solving developed to meet life's challenges. The coping mechanisms families and family

members develop reflect their individual resourcefulness. Families may use coping patterns rather consistently over time or may change their coping strategies when new demands are made on the family. The success of a family largely depends on how well it copes with the stresses it experiences.

Nurses working with families realize the importance of assessing coping mechanisms as a way of determining how families relate to stress. The resources available to the family also are important. Internal resources, such as knowledge, skills, effective communication patterns, and a sense of mutuality and purpose within the family, assist in the problem-solving process. In addition, external support systems promote coping and adaptation. These external systems may be extended family, friends, religious affiliations, healthcare professionals, or social service agencies. The development of social support systems is particularly valuable today because many families, because of stress, mobility, or poverty, are isolated from the resources that would traditionally have helped them cope with stress.

Family Size

The size of the family may influence the amount of attention parents are able to give individual children. In small families, parents often have more time to give attention to the children, encourage achievement, meet family expectations, and support involvement in community activities. In larger families, children may receive less personal attention from parents and turn to others in the family for needed support. Family finances may be more limited, which may help children learn about budgeting. Children may adopt a specialized family role to gain recognition, such as "the responsible one," "the clown," or "the black sheep." Children in larger families are encouraged to be cooperative to support family functioning.

Parent–Child Interaction

The qualities of family relationships and behaviors are important aspects of family strengths and functioning. Positive family relationships are characterized by parent–child warmth and supportiveness. Warm parent–child relationships can buffer children from stress and promote positive cognitive and social outcomes. Parents who are warm and place high demands on their children for appropriate behavior have children who tend to be content, self-reliant, self-controlled, and open to learning in school.

Mothers and fathers both contribute to the psychologic, emotional, and social health and development of their children. Both parents provide affection, nurturing, and comfort. They teach children life skills and healthy lifestyles. Both mothers and fathers promote the social competence, academic achievement, and problem-solving abilities of their children. More information on how parenting influences family development can be found later in this module.

Resiliency

Another factor important in shaping a family is the amount of **resiliency** the family has. Having resources and adaptive abilities increases the resilience of a family, thus helping them to overcome adversity, heal from adverse experiences, and progress beyond adversity to fulfillment (Walsh, 2016).

Life crises and developmental transitions can stimulate family growth and transformation. Resilient families make it through crises such as disability and death with a renewed sense of confidence and purpose. A qualitative study conducted by Ellis, Gergen, and Wohlgemuth (2016) found three factors that enhanced resilience in families who were dealing with long-term surgical stays: communication, expectations, and support. In addition, routine and consistent communication between all members of the healthcare team with all family members was one of the most prominent factors that enhanced resiliency. Allowing the family to support their family members through providing basic care or through identifying unique needs of their family member was seen as a supportive action to increase resilience.

Sibling Relationships

Siblings are a child's first peers, and siblings often have a lifelong relationship. Siblings, especially those of the same gender or who are close in age, tend to have a close relationship because they often share many common experiences through childhood and adolescence (see **Figure 26-5** »).

Sibling rivalry between children exists at times in all families. Within the family, children learn to share, compete, and compromise with siblings. Some siblings take on roles such as protector, problem solver, friend, and supporter for dealing with issues in the family and in the environment. Some siblings learn to work well together to maintain privacy or to form a coalition for negotiating with the parents. An older sibling helps reinforce rules and roles in the family by prompting and inhibiting certain patterns of behavior in the younger siblings. However, one sibling may test the waters by breaking a previously implicit rule to determine what rule flexibility is allowed in the family.

Studies indicate that birth order may have an impact on intelligence, but it does not have an impact on personality. Using a within-family study design, Bleske-Rechek and Kelley (2013) identified that when evaluating five areas (openness, conscientiousness, extraversion, agreeableness, and neuroticism), parents did not see any difference in these traits

between their first- and last-born children as a function of their birth order. These authors conclude that the differences in personality may be due to genetic predispositions of the child and differences in environments that siblings do not necessarily share, such as peer groups. In a large study conducted on databases from Germany, Great Britain, and the United States ($N = 20,186$) using a within-family and between-family design, Rohrer, Egloff, and Schmukle (2015) found no differences in birth order in the following traits: extraversion, emotional stability, agreeableness, conscientiousness, and imagination. However, there was a small difference in self-reported intellect in this study.

Influence of Parenting on the Family System

Raising a family can be a difficult task. Every day, parents must balance change within the family, their role as parents, and the delicate nature of reward and stress when dealing with their children. Being flexible within the context of parenting is referred to as parenting flexibility (Moyer & Sandoz, 2014). Being able to deal with stressful issues without the need to control psychologic experiences can help the child to learn to cope and can provide the necessary structure for the parent-child relationship and the family unit to thrive.

Parenting Styles

Parents have responsibility for providing children stability through nurturance, safety, and structure in a family that undergoes frequent changes over time. The child needs to have physical and emotional space to grow and develop. Parents also provide their children with the values, beliefs, rituals, and behaviors learned and transmitted across family generations.

To be successful, parents should implement reasonable, consistent **limit setting** (established rules or guidelines for behavior) on children's autonomy while the children are still learning values and self-control. At the same time, parents need to foster their children's curiosity, initiative, and sense of competence. Parents use different styles to parent their children. Parental warmth and control are two major factors that are important in children's development. Parental warmth refers to the amount of affection and approval displayed. Parental control refers to how restrictive the parents are regarding rules. See **Table 26-2** » for the characteristics associated with parental warmth and control.

Hughes (2013) identified four parenting styles. These include authoritarian, authoritative, permissive, and neglectful. Although families generally tend to use one style, they may vary their style for certain situations. Although helicopter parenting has not been identified as a specific and separate parenting style, research in this area is increasing. An overview of helicopter parenting can be found in **Box 26-1** ».

Authoritarian Parents

Authoritarian parents tend to be punitive and adhere to rigid rules, or to be more dictatorial. This style sets firm limits, and those limits or rules are not negotiable or open to any discussion. Parents expect family beliefs and principles to be accepted without question. Children have no opportunity to

Figure 26-5 » Same-gender siblings who are close in age tend to have close, lifelong relationships.

TABLE 26–2 Characteristics of Significant Parenting Attributes

Parenting Attribute	Parental Warmth	Parental Control
High level	<ul style="list-style-type: none"> ■ Warm, nurturing ■ Expressing affection and smiling at children frequently ■ Limiting criticism, punishment ■ Expressing approval of child 	<ul style="list-style-type: none"> ■ Restrictive control of behavior ■ Surveying and enforcing compliance with rules ■ Encouraging children to fulfill their responsibilities ■ Sometimes limiting freedom of expression
Low level	<ul style="list-style-type: none"> ■ Cool, hostile ■ Quick to criticize or punish ■ Ignoring children ■ Rarely expressing affection or approval ■ Sometimes rejecting children 	<ul style="list-style-type: none"> ■ Permissive, minimally controlling ■ Making fewer demands ■ Making fewer restrictions on behavior or expression of emotion ■ Permitting freedom in exploring environment

participate in the family decision-making process. Children with authoritarian parents do not develop the skills to examine why a certain behavior is desirable or how their actions might influence others.

Authoritative Parents

Authoritative parents use firm control to set limits, but they establish an atmosphere with open discussion or are more democratic than authoritarian parents. Limits for behavior are clear, consistent, and reasonable, but the children are encouraged to talk about why certain behaviors occurred and how the situations might be handled differently another time. Parents set and stick to established routines, so children have clear expectations of appropriate behavior. Authoritative parents provide explanations about inappropriate behaviors at a child's level of understanding. Children are allowed to express their opinions and objections, and some flexibility is permitted when appropriate. However, parents make it clear that they are the ultimate authority for

decisions. Children with authoritative parents develop a sense of social responsibility because they converse about their responsibilities and approaches.

Permissive Parents

Permissive parents show a great deal of warmth, but set few controls or restraints on the children's behavior. Parents are so intent on showing unconditional love that they fail to perform some important parenting functions. Children are allowed to regulate their own behavior. Discipline is inconsistent, and parents may threaten punishment but not follow through. Because the parents do not impose any controls on the children, the children end up controlling the parents.

Neglectful Parents

Neglectful parents do not display much interest in their children or in their roles as parents. They do not demonstrate affection or approval of their children, and they do not set limits or controls on them. This may occur because they do not care, or because their lives are so stressed that they have no time or energy left for the children.

Box 26–1

Helicopter Parenting

Overparenting, often referred to as helicopter parenting, refers to the overinvolvement of parents in their children's lives. A survey of 128 school counselors, teachers, and mental health professionals (Locke, Campbell, & Kavanagh, 2012) elicited a number of examples of overparenting behaviors, such as:

- Low expectations and demands for children to develop independence, proceed along developmental milestones, or accept consequences for their actions
- Constant monitoring, phoning, and intrusiveness in the child's life
- A perception that their child is always right
- Constant instruction regarding behavior, an intense focus on academics, and restriction of experiences with peers.

Although the effects of overparenting are still being studied and may vary from one child to the next, overparenting has been positively associated with increased parental anxiety. Among young adults and adults who experienced overparenting growing up, the overinvolvement of their parents was associated with an increase in ineffective coping skills, which in turn was associated with greater anxiety (Segrin et al., 2013).

Discipline and Limit Setting

Discipline is a method for teaching children the rules for how to behave in society and what is expected in different circumstances. **Punishment** is the action taken to enforce the rules when the child misbehaves. Parenting styles play an important role in the type of discipline and punishment parents use with children. When clear limits are set and consistently maintained, as with authoritative parenting, punishment may be needed less often. Limit setting and firm control of those limits are important discipline methods that allow children to learn to what extent they can safely and independently operate within the environment. Firm limits also help children feel secure; they are reassured by consistency and the sense of protection the limits are perceived to provide. Punishment helps children learn that misbehavior has consequences and may affect other individuals. This helps children develop a sense of responsibility for their behavior.

Alterations in Family Function

Any number of situations or factors can cause short- or long-term alterations in family function. Trauma, abuse, neglect, addiction, criminal activity, and military deployment are

Patient Teaching

Guidelines for Promoting Acceptable Behavior in Children

The nurse can assist parents in handling their child's misbehavior by helping them to:

- Set realistic expectations and directions for behavior based on the child's age and understanding; consistently enforce the expected directions and behaviors.
- Focus on promoting appropriate and desirable behaviors in the child.
- Model or suggest appropriate behavior.
- Review expected behavior for special situations, such as a family party, going to the movies, or other social event.
- Praise or reward the child using appropriate behaviors.
- Tell the child about his or her inappropriate behavior as soon as it begins, and offer guidelines for changing behavior or provide a distraction.
- When reprimanding the child, focus on the behavior rather than stating that the child is bad. Explain how the behavior is

inappropriate and how it makes you, as the parent, and any other person involved feel. Avoid ridicule or accusation that can take the form of shame or criticism, because these actions can affect the child's self-esteem if repeated often enough. Stay calm.

- Remember that loud volume (yelling) is meant to warn of danger. Parents who discipline kindly have more success than those who discipline in anger or frustration.
- Be alert for situations when the child could misbehave, such as when tired or overexcited. Use a distraction to persuade or calm the child.
- Help children gain self-control with friendly reminders (e.g., count to 3, as soon as the clothes are on the doll, as soon as you finish the game) regarding the timing for transition to the next event of the day, such as bedtime, putting the toys away, or washing hands before dinner.

just a few of these situations. Resilient families may overcome such situations with time, patience, and understanding, and family and social support. Whenever a family experiences some kind of upheaval or alteration to family functioning, nurses assess for safety, coping mechanisms, and immediate and long-term needs, as well as providing support and making referrals as appropriate.

Abuse

Interpersonal (domestic) violence and child abuse and neglect have long-term implications for children and families. In addition to the risks of physical injury and even death, children who grow up with violence or neglect are at greater risk for delinquency, substance abuse, mental illness, and lower school achievement (Federal Interagency Forum, 2015). More information on the effects of abuse on children and families can be found in the module on Trauma.

Death of a Family Member

Death of an immediate family member can interrupt and even permanently alter family functioning and processes in a number of ways. The death of a parent brings both financial and practical concerns to the family as well as profound emotional loss. Loss of income and loss of another adult to assist with transportation to child care, school, doctor's appointments, and extracurricular activities combine to create new burdens for the remaining parent. In divorced families, death of a custodial parent can result in children relocating to new homes and schools. Death of a child has been identified as one of the most stressful events in an adult's life. For adults, death of a parent can result in an array of emotions and may also result in an adult child finding himself caring for the remaining parent, if the parent who died was a caregiver to the other parent.

Divorce

Nearly half of all children in the United States will experience the divorce of their parents (Anthony, DiPerna, &

Amato, 2014). When the divorce is preceded by long periods of stress and tension between the parents, the family may experience some level of disruption or dysfunction well in advance of the actual divorce. Children may experience guilt in the form of feeling they did something that caused the divorce. If the divorce results in the children seeing significantly less of one parent, one or more of the children may experience feelings of abandonment. Young children especially may fear abandonment by the remaining parent. Divorce can bring disruption to daily schedules and even result in children changing schools or moving to another city or state. Children who lived in a stable household with both parents may find themselves moving in with grandparents or moving to another house or apartment. Disruptions associated with divorce can result in child adjustment, academic, or behavior problems (Arkes, 2015).

Effects of Stigma on Gay and Lesbian Families

In *Accelerating Acceptance 2016*, conducted by GLAAD, the authors report their findings of surveys conducted among non-LGBTQ Americans on their degree of acceptance of LGBTQ individuals. Between 27 and 32% of Americans reported they would feel either somewhat uncomfortable or very uncomfortable on learning a family member was LGBTQ. The stigma and discrimination that LGBTQ individuals in Americans feel is real, and it affects both LGBTQ individuals and their families.

Family Rejection of LGBTQ Youth

LGBTQ youth experience disparities in both physical and mental health compared to their heterosexual peers. This has significant implications for both the medical and the larger community, because some 3.2 million American youth age 8 to 18 identify as LGBTQ (Mallory et al., 2014). Factors cited as contributing to the increased risk of physical and mental illness among LGBTQ youth include rejection

by families and peers and inadequate school and community supports (Mallory et al., 2014).

The significance of the role of the family in the health of the LGBTQ child or adolescent cannot be overstated. Compared with LGBTQ youth whose families were more accepting, youth who were rejected by their families were more than 8 times as likely to attempt suicide, almost 6 times as likely to report high levels of depression, more than 3 times as likely to report illegal drug use, and at much greater risk for acquiring HIV/AIDS and other sexually transmitted illnesses (Anonymous, n.d.).

Nurses working with families with an LGBTQ child or adolescent can support both the youth and the family by:

- Providing information on LGBTQ resources in the area
- Encouraging open, respectful communication among all family members
- Encouraging parents to allow their child access to LGBTQ friends and resources
- Helping the family understand that the young person is not to blame for any stigma the family experiences
- Encouraging the parents to talk with their child about her identity in an affirming manner
- Advocating in their communities for increased resources and support for LGBTQ children and adolescents.

LGBTQ Parents

Among the American media, there is an increased focus on LGBTQ parenting and on the specific question of whether children are worse off being raised by same-sex parents than by two heterosexual parents. A team of researchers reviewed the results of the 2011–2012 National Survey of Children's Health. They reviewed the responses of 95 female same-sex parent households with the responses of 95 different-sex parent households, with all households having children between 6 and 17 years old. No differences were observed in family relationships or child health outcomes, although the same-sex parents reported experiencing higher levels of parenting stress (Bos et al., 2016). As outlined earlier, parenting style and involvement, not the sexual attraction of the parents, seems to be the most important for child outcomes. However, children in gay and lesbian families may be at risk because of how they are treated by those in their communities. Nurses should be aware of support groups or other services to assist children in LGBTQ families who are misunderstood in their community.

Incarcerated Parents

The United States has 707 incarcerated people per 100,000 citizens and is the world leader in incarceration (American Psychological Association [APA], 2014). Children of incarcerated parents face many disadvantages that affect their emotional, physical, and mental health. Lee, Fang, and Luo (2013) identified that depression, anxiety, cholesterol, overall poor health, asthma, posttraumatic stress disorder (PTSD), migraines, and HIV were significantly associated with parental incarceration. Turney and Wildeman (2013) found that having an incarcerated father negatively impacted the relationship between the children and the

Source: C_FOR/ iStock/Getty Images.

Figure 26-6 Visiting day in prison is difficult for the incarcerated partner and the one left behind to care for the family.

father, as well as between the mother and the father. Separation and divorce are not uncommon when the father of the family is incarcerated and the mother is left to care for the children and take on the role responsibilities of the father (see **Figure 26-6**). In addition, all family members may be affected if the mother finds a new partner (Turney & Wildeman, 2013).

Military Deployment

Since the terrorist attack on September 11, 2001, many families have experienced having their loved ones deployed to Iraq, Afghanistan, and elsewhere. According to the Department of Defense, nearly 2 million children have at least one parent in the military (Department of Defense [DoD], 2012). Trautman, Alhusen, and Gross (2015) indicate that parental deployment is associated with increases in depressive symptoms, increased levels of parental stress, poorer general well-being, and greater use of mental health services (see **Figure 26-7**). Children have been shown to be at increased

Source: Kali9/E+/Getty Images.

Figure 26-7 Parental military deployment puts children at increased risk for behavioral and emotional problems.

risk for behavioral and emotional problems and child maltreatment (Trautman et al., 2015).

Poverty

For 2013, the U.S. poverty threshold for a family of four with two children was \$23,624. That same year, 20% of children lived below this threshold. Nearly half of these lived in families with extreme poverty. Extreme poverty is defined as below 50% of the poverty threshold (Federal Interagency Forum, 2015).

Poverty is associated with poor outcomes for children and families. First, it is linked with substandard housing, homelessness, food insecurity and malnutrition, lack of access to healthcare, unsafe neighborhoods, and inadequate school environments. Consider the issue of access to healthcare. Some may dismiss that as a nonissue because of the existence of Medicaid and Child Health Insurance Programs. But what of the child who lives in a rural area whose parent or parents does not have a car? That family's ability to access healthcare and other resources will be limited.

In children, poverty is associated with an array of short- and long-term consequences. The chronic stress of living in poverty leads to impaired concentration and memory. Poverty is also associated with lower academic achievement, increased dropout rates, increased risk for behavioral and emotional problems, and increased risk for physical illness (American Psychological Association [APA], 2016).

Trauma

When one or more family members experiences a traumatic event, it can upset the rhythms and relationships in the whole household and deplete individual and family coping mechanisms (see **Figure 26-8** >>). Coping with

Source: Marvi Lacar/Getty Images News/Getty Images.

Figure 26-8 >> This 12-year-old boy sits at the site of his home in Biloxi, Mississippi, that was destroyed in Hurricane Katrina. In the year after Katrina struck, it is estimated that tens of thousands of children missed weeks, months, or even a full year of school. Many moved away from home never to return. Children from more fragile families are more likely to be traumatized and are more likely to recover slowly (Reckdahl, 2015).

trauma and its aftermath can leave little time and energy for the parents to initiate normal family activities or to provide comfort to children and other family members. Children who experience trauma are at risk for trauma-related problems and disorders that disrupt functioning (National Child Traumatic Stress Network, 2011; American Psychiatric Association, 2013).

Case Study >> Part 1

Maria Rodriguez, age 30, and her wife Daniella Marshall, age 32, were recently married and decided to start a family. Following donor insemination, Mrs. Rodriguez became pregnant. The couple arrives at the obstetrician's office for Mrs. Rodriguez's routine health exam. You are familiar with the couple and have provided care to them in the past. Today, you are assigned to care for Mrs. Rodriguez, who is now at 7 months' gestation. After talking to the couple for a few minutes, you notice that Mrs. Rodriguez is more reserved than usual and seems a bit depressed. When you ask how things are coming along with planning for the new arrival, both women are silent. Finally, Mrs. Marshall explains that they are struggling to cope with reactions from other participants of the birthing classes they have been attending, and it is making them both more stressed. Mrs. Rodriguez then tells you that she no longer wishes to attend the birthing classes, even though Mrs. Marshall wishes to complete the course.

Clinical Reasoning Questions Level I

1. What additional information would be useful in assessing the challenges faced by Mrs. Rodriguez and Mrs. Marshall?
2. Which characteristics of communication would best promote open discussion between you and this couple?
3. What are some societal challenges that same-sex couples face?

Clinical Reasoning Questions Level II

4. Describe two nursing diagnoses that may be applicable in the care of Mrs. Rodriguez and Mrs. Marshall.
5. What are some of the dangers of stress at this stage in Mrs. Rodriguez's pregnancy?
6. Explain some of the benefits of birthing classes in terms of both safe delivery of the child and family planning.

Concepts Related to Family

Any number of concepts can influence family dynamics. For example, when an individual suffers from addiction to illegal substances or alcohol, his addictive behaviors are likely to affect close family members in a number of ways. Life-threatening health conditions can result in anticipatory grieving, loss of financial security, and caregiver burden, increasing the stresses with which families cope on a daily basis. Alternatively, the birth of a child can result in the strengthening or weakening of bonds and relationships within the family. Family members may be drawn closer through shared interests in the welfare of the child. Conversely, the addition of a new family member can add financial and emotional stressors that strain familial relationships.

Culture and spirituality inform the lifestyles and decision-making process of many families. It is important to note, however, that even within a single family, individual members may engage in different beliefs and practices or

Alterations and Therapies

Family

ALTERATION	DESCRIPTION	MANIFESTATIONS	INTERVENTIONS AND THERAPIES
Abuse	Physical, emotional, or sexual abuse directed toward another individual	<ul style="list-style-type: none"> Withdrawn emotions and a decrease in communication and/or socialization with family and friends Behavioral changes, such as anger, depression, acting out in school or at home, and changes in appetite or sleep patterns Bruises, broken bones, concussion, and other physical markers Fear of a specific person or situation (e.g., family events, arguments, school dances) 	<ul style="list-style-type: none"> Follow state laws and agency policies and procedures regarding the reporting of abuse and neglect. Treat physical injuries (e.g., broken bones, cuts, concussions) and emphasize the importance of follow-up care. Offer resources for emotional manifestations, for example, counseling or therapy. Provide proficient, nonjudgmental patient care.
Divorce	The separation of a couple from a marital bond with or without children	<ul style="list-style-type: none"> Anxiety Depression Stress and resulting manifestations such as restlessness, weight loss, headaches, and sleeplessness Behavioral modifications in children (e.g., acting out in school, withdrawal, anger, confusion, nightmares) 	<ul style="list-style-type: none"> Provide information about counseling, therapy, and support groups. Advise about healthy coping mechanisms for stress—for example, exercise, new hobbies, and writing. Educate about the importance of health maintenance and nutrition even during times of high stress and anxiety.
Death of family member	The loss of a spouse, child, parent, or other family member	<ul style="list-style-type: none"> Grief as evidenced by sadness, anger, denial, and pain associated with the loss Depression manifested in a lack of enjoyment of normal activities, intense feelings of sadness, and changes in appetite Sleeplessness Weight loss or weight gain Anxiety 	<ul style="list-style-type: none"> Provide information about therapy and support groups. Teach about healthy coping strategies. Assess for signs of complicated or traumatic grief. Facilitate referrals to grief counselors and other professional resources.
LGBTQ family member	Some 3.2 million children and youth identify as LGBTQ. Some 220,000 children live in households with same-sex parents.	<ul style="list-style-type: none"> Shame, fear, anxiety, isolation associated with stigma and discrimination Homelessness Suicide 	<ul style="list-style-type: none"> Assess for safety and shelter, other supports. Honor preferences regarding names and titles. Promote family communication.
Incarceration	One or both parents are in jail for varying lengths of time	<ul style="list-style-type: none"> Separation from one or both parents Possibility of repartnering of parent who is left to raise children Increase in physical and emotional concerns 	<ul style="list-style-type: none"> Facilitate communication with family counselor. Recognize changes in child's behavior indicating they are not coping with the situation. Provide nonjudgmental care and assistance.
Military deployment	Family with one or more members deployed from home (domestic or overseas deployment)	<ul style="list-style-type: none"> Frequent separations and reunions Frequent family relocations Social considerations related to rank Lack of control over progress in employment, promotion 	<ul style="list-style-type: none"> Encourage and promote open family communication, use of alternative communication methods (e.g., video messaging, email). Assist family to identify previously helpful coping strategies. Encourage participation in social and community supports and activities. Assist family members in mutual goal setting.
Poverty	Individuals and families living near or below the federally designated poverty threshold.	<ul style="list-style-type: none"> Overall poor health Increased stress Altered child development Increased risk for chronic illness 	<ul style="list-style-type: none"> Provide and encourage use of available resources. Identify support groups. Monitor child growth and development.

Concepts Related to Family

CONCEPT	RELATIONSHIP TO FAMILY	NURSING IMPLICATIONS
Addiction	Substance and/or alcohol abuse can affect individual family members as well as the family unit as a whole. Potential stressors may be psychosocial, physiologic, financial, or spiritual in nature.	<ul style="list-style-type: none"> ■ Be alert to the signs of addiction. ■ Propose interventions appropriate to addiction behavior. ■ Evaluate the individual's potential for being a danger to herself or others. ■ Recommend community resources to family members to help them process and cope with resultant complications.
Culture and Diversity	Cultural beliefs and practices may vary even among generations of the same family. They may impact decision-making processes, how patients and families view procedures, and day-to-day patient and family needs.	<ul style="list-style-type: none"> ■ Explore meaning of culture and diversity as it impacts each family. ■ Identify resources available for families who are diverse or from a different culture.
Grief and Loss	Grief and loss may result in alterations in family dynamics, particularly if the deceased individual was in a position of family leadership or was the primary source of financial support. Grief reactions can also affect how family members relate to one another.	<ul style="list-style-type: none"> ■ Be alert to the signs of intense grief reactions, such as lasting depression, anger, or denial. ■ Consider the nature of the loss and its possible ramifications. ■ Offer appropriate support and referral, such as therapy or grief counseling.
Reproduction	Addition of a family member may strengthen familial bonds through shared interests in the child's welfare or may instead strain relationships in terms of increased physical, emotional, and financial demands.	<ul style="list-style-type: none"> ■ Teach about prenatal care and maternal health. ■ Encourage all family members to engage in educational activities. ■ Assess the involved individuals' responses to pregnancy and sensitively address potentially harmful issues, such as ineffective communication patterns. ■ Be alert to signs of postpartum depression. ■ Advise parents of potential jealousies and complications with toddlers and new infants.
Stress and Coping	Family stressors are many and may increase risks for physical and mental illness, caregiver burden, and successful family functioning.	<ul style="list-style-type: none"> ■ Encourage open dialog among all family members. ■ Discuss what the issue means to family members. ■ Identify past coping mechanisms used by individual family members. ■ Help family members identify ways to find strength in the change. ■ Allow individuals to grieve. ■ Identify resources available.
Trauma	Trauma may be caused by physical abuse, or by emotional/verbal abuse or neglect. Trauma may also result from unintentional injuries. See the module on trauma for more information.	<ul style="list-style-type: none"> ■ Identify and document physical findings associated with physical abuse/neglect. ■ Enlist the aid of counselors/clergy. ■ Provide support to all family members. ■ Encourage open communication.

experience different degrees of devotion to the culture, religion, or spiritual practices of the family. Generally speaking, the more recently a family has immigrated to this country, the more likely the family is to continue to practice traditional cultural and religious beliefs and practices (Spector, 2017). Culturally competent nursing practice is a critical part of nursing care for children and families. The Concepts Related to Family feature links some, but not all, of the concepts integral to family. They are presented in alphabetical order.

Health Promotion

Health and wellness promotion is an essential aspect of family health and focuses on increasing healthy behaviors and optimizing lifestyle choices. Educating patients and facilitating appropriate referrals (e.g., to nutritionists, educational programs, and community service providers) will not only improve the family's quality of life, but also reduce the risk of illness. Depending on the needs of the patient, nurses

may collaborate with a variety of healthcare providers and professionals, including physicians, counselors, social workers, and mental health specialists.

Families may be most in need of health promotion and patient teaching during times of transition into new developmental or life stages. From teaching new parents the importance of skin-to-skin contact in the first hours after delivery to helping parents of teenagers identify signs of depression or addiction, nurses are uniquely placed to help parents parent their children successfully and to help families obtain optimal wellness and functioning. Settings in which nurses provide health promotion for patients and families include hospitals, physicians' offices and clinics, local health departments, and public schools.

Establishing a therapeutic relationship with the family is important in order to develop a rapport with the family that is characterized by empathy and trust. Having a trusting relationship also helps in development of mutually identified goals for the family's needs. The nurse provides information in a clear, timely, and sensitive manner. The nurse works with families by teaching them to identify solutions until they are able to problem solve independently. The family's ethnic and religious background needs to be considered in developing intervention recommendations.

When working with families, the nurse considers health and wellness not only from an individual perspective, but also in terms of the family unit. Family wellness promotion emphasizes addressing each individual family member's contribution to the health and well-being of the family and recognizing that if one member is affected, the entire family is affected. For example, any number of occupational or environmental problems could alter the individual's physical and emotional wellness. A physical ailment—such as a broken leg or lead poisoning—can be treated, but if occupational (e.g., physically demanding and personally unsatisfying hard labor) and environmental (e.g., house with lead-based paint in a dangerous neighborhood) aspects are not addressed, the health of the individual and the family remain at risk.

Family wellness and health promotion strategies involve empowering patients to make beneficial changes in their lives (Strout, 2012). Some common health promotion strategies include encouraging tobacco cessation, increased exercise, healthy eating habits, and use of stress reduction techniques. Each individual will have different needs and circumstances, requiring nurses to modify health promotion suggestions. For example, consider a stay-at-home mother of three who is seeking stress relief. For this patient, the nurse might suggest a community activity that promotes exercise (for stress relief) and a chance to connect with others in the community (for social wellness). Patients may decline to follow the nurse's suggestion; however, the nurse's role is to offer health- and wellness-promoting options without judgment and then allow the patient to decide.

Empowering patients requires nurses to help patients set goals for their own personal wellness and the wellness of their families. The choice of goals is dependent on the family's needs, both as individual members and as a unit. One family may set the goal of participating in a family game night once

a week to promote emotional, social, and intellectual wellness, whereas another family could set the goal of going hiking or biking every 2 weeks as a family to promote physical and even spiritual wellness. Nurses can help families set goals by working to understand the needs and wants of the family (Strout, 2012).

Health promotion within the family unit can be challenging. In some cases, family members will respond positively to nursing suggestions and interventions; in other cases, patients may feel they are unable to change their lifestyle because of socioeconomic conditions, stress, or other factors. Individuals also may interpret health promotion as an attempt to control their behaviors. The nurse approaches families on a case-by-case basis, recognizing that each family unit will need different forms of care and different nursing approaches.

Risk and Protective Factors

Risk factors for family dysfunction may not always be evident. At times, the risk factors are masked by the absence of obvious problems. Stress, for example, can lead to many problems within a family, as the effects of unmanaged and unresolved stress can impact normal family functioning. Parental coping methods can also determine how children will learn to handle stress, because children often model the actions of their parents (APA, 2013). The response to stressors can be exacerbated by a real or perceived sense of powerlessness over circumstances, such as poverty, unemployment, or abuse. Other risk factors for family dysfunction include family separation, forced migration, and cultural and social isolation.

Protective factors for family health and function include stable living environments, healthy and consistent parenting and supervision, healthy family coping, social and community supports, and financial stability (e.g., adequate shelter, food and nutrition, and access to healthcare).

Recognition and awareness of risk and protective factors and knowledge of community supports can help the nurse identify and plan health and wellness promotion activities for families at risk of alterations in family coping, physical health, and mental health (see **Table 26-3** »).

Care in the Community

Nurses encounter families experiencing stress, trauma, poverty, acute health conditions, and chronic illnesses in all settings. Many times nurses are called on to assist families in finding resources to alleviate financial burdens or to help them access social supports. Although the names of local resource agencies may vary from one location to another, both public and private resources are available in most communities. Public resources include departments of social services, local health departments, departments of aging, and public schools. Private resources are often available through nonprofit organizations such as literacy centers, homeless and transition shelters, and nonprofits that serve the aging and the disabled. Nurses should be aware of the resources in their community that support the populations with which they work.

» **Stay Current:** The organization 2-1-1 is a free and confidential service that helps individuals find local resources: www.211.org

TABLE 26–3 Health and Wellness Promotion for the Family at Risk for Health Alterations

Developmental Stage and Associated Risk Factors	Potential Health Consequences	Health and Wellness Promotion Strategies
Individual, Couple, or Family with Infants and Preschoolers <ul style="list-style-type: none"> ■ Lack of knowledge about family planning, contraception, and sexual and marital roles ■ Inadequate prenatal care ■ Altered nutrition: inadequate nutrition, overweight, underweight ■ Smoking, alcohol/drug abuse ■ Lack of knowledge about child health and safety ■ Low socioeconomic status ■ First pregnancy before age 16 or after age 35 	<ul style="list-style-type: none"> ■ Premature pregnancy ■ Low-birth-weight infant ■ Birth defects ■ Injury to infant or child ■ Accidents 	<ul style="list-style-type: none"> ■ Promote preconception/prenatal care if applicable. ■ Obtain detailed history to uncover environmental issues and lifestyle practices that may impact health of individuals and family. ■ Provide education related to contraception and sexually transmitted infection (STI) prevention. ■ Facilitate nutritional assessment and counseling. ■ Offer referrals to appropriate resources for smoking cessation programs and alcohol/drug abuse counseling. ■ Educate about basic child health and safety protocols. ■ Identify resources for financial assistance and facilitate appropriate referrals. ■ Advocate for safe care of infants and their families.
Family with School-age Children <ul style="list-style-type: none"> ■ Unsafe home environment ■ Working parents with inappropriate or inadequate resources for child care ■ Low socioeconomic status ■ Child abuse or neglect ■ Multiple, closely spaced children ■ Repeated infections, accidents, and hospitalizations ■ Unrecognized and unattended health problems ■ Poor or inappropriate nutrition ■ Toxic substances in the home 	<ul style="list-style-type: none"> ■ Behavior problems ■ Speech and vision problems ■ Learning disabilities ■ Communicable diseases ■ Physical abuse ■ Developmental delay ■ Obesity, underweight 	<ul style="list-style-type: none"> ■ Educate about preventive healthcare measures. ■ Provide information about community assistance and healthcare programs. ■ Educate about contraception. ■ Provide information about adequate nutrition. ■ Provide education to children and families regarding risk of certain environmental hazards (i.e., risk of carbon monoxide [CO] poisoning and need for CO monitors in home).
Family with Adolescents and Young Adults <ul style="list-style-type: none"> ■ Family values of aggressiveness and competition ■ Lifestyle and behaviors that lead to chronic illness (substance abuse, inadequate diet) ■ Lack of problem-solving skills ■ Conflicts between parents and children 	<ul style="list-style-type: none"> ■ Violent death and injury ■ Alcohol/drug abuse ■ Unwanted pregnancy ■ Suicide ■ STIs ■ Domestic abuse 	<ul style="list-style-type: none"> ■ Promote healthy problem-solving skills. ■ Educate about healthy anger and emotion management techniques. ■ Provide information about healthcare resources. ■ Teach about contraception. ■ Facilitate learning about substance and alcohol abuse prevention.
Family with Middle-aged Adults <ul style="list-style-type: none"> ■ High-cholesterol diet ■ Obesity ■ Hypertension ■ Smoking, alcohol abuse ■ Physical inactivity ■ Personality patterns related to stress ■ Exposure to environment: sunlight, radiation, asbestos, or water or air pollution ■ Depression 	<ul style="list-style-type: none"> ■ Cardiovascular disease (coronary artery disease, cerebrovascular disease) ■ Cancer ■ Accidents ■ Suicide ■ Mental illness 	<ul style="list-style-type: none"> ■ Educate about nutrition and exercise and its relationship to cardiovascular disease, diabetes and certain forms of cancer. ■ Educate regarding changes in relationships, careers, and biologic changes that occur during this time. ■ Provide information about mental health counseling and facilitate referrals. ■ Suggest screening for hypertension, cardiac disease, osteoporosis, colon cancer, breast cancer. ■ Educate regarding occupational safety hazards and risk for exposure to potential carcinogens and risk of accidents (if applicable).
Family with Older Adults <ul style="list-style-type: none"> ■ Depression ■ Drug interactions ■ Chronic illness ■ Reduced income ■ Poor nutrition ■ Lack of exercise ■ Past environmental exposure to toxins and adverse lifestyle choices 	<ul style="list-style-type: none"> ■ Impaired vision and hearing ■ Hypertension ■ Acute illness ■ Chronic illness ■ Infectious diseases (influenza, pneumonia) ■ Injuries from burns and falls ■ Depression ■ Alcohol abuse ■ Adjusting to retirement, losses 	<ul style="list-style-type: none"> ■ Educate about nutrition and exercise. ■ Provide information about community-based programs for healthcare. ■ Facilitate mental health counseling. ■ Educate about illness prevention and health promotion (i.e., use of prescription medications with herbal remedies). ■ Encourage ways to stay involved and productive (i.e., volunteering, assisting with community projects). ■ Provide referrals regarding wills, advance directive, power of attorney.

Nursing Assessment

The purpose of family assessment is to determine the level of family functioning, clarify family interaction patterns, identify family strengths and weaknesses, and describe the health status of the family and its individual members. Also important are family living patterns, including communication, childrearing, coping strategies, and health practices. Family assessment gives an overview of the family process and helps the nurse identify areas that need further investigation. As the nurse becomes more acquainted with the family, the assessment continues in more targeted areas to further develop the nursing care plan.

Observation and Family Interview

To obtain an accurate and concise family assessment, the nurse needs to establish a trusting relationship with the parent(s) and the family. Data are best collected in a comfortable, private environment, free from interruptions. Typically this occurs in the family's home, but it may also occur in the clinic, hospital, or other similar setting.

Key to any good assessment and health history is observation of how family members interact with and respond to each other, what types of communication patterns they use, the amount of support they provide to one another, and the closeness/distance of each family member as they relate to one another. Interviewing family members individually or as a group, depending on the situation, provides additional valuable information about their knowledge regarding health promotion and illness prevention. The amount of cooperation, identification of norms within the family, and assessing for the potential for the family to engage in positive change are all other important aspects of observation and the interview (Rentfro, 2014). This information should be documented clearly on the electronic health record (EHR), whether the nurse is working with the family in the community or inpatient setting.

The family assessment provides important information about family structure and function, including which individuals are responsible for making healthcare decisions for specific family members. The following data may be useful in informing planning and care:

Family Structure

- Which adults spend the most time with the children? What is the nature of sibling relationships?
- Who has legal custody—that is, who is able to make healthcare decisions for the child?
- For older adults or those living with serious illness, has a family member been legally designated as having a healthcare power of attorney?

Family Roles/Functions/Resources

- Who provides for the child or family financially? Does the child/patient/family have health insurance?
- Who else helps the parent(s) care for the children? What other support systems does the family have in place?

Physical Health Status

- What is the health status of each member of the family? How do family members perceive their own health?

- What preventive practices does the family use (e.g., status of immunizations, oral hygiene practices, regularity of vision examinations)?
- To what extent do family members receive routine health-care?

Mental Health Status

- What is the mental health status of each member of the family? How do family members perceive their own health?
- What protective factors are in place? What kind of family or community supports do family members access or participate in?
- What kind of coping mechanisms do individual members use? How does the family cope with stresses together?

Family Interactions and Values

- How do family members express feelings? Communicate with each other?
- What cultural and religious practices does the family observe? What relationship do these practices have to family health and well-being?
- What type of parenting style is preferred by the parent(s)? Do parents share caregiving responsibilities?
- What are the family's health values? How much emphasis is put on exercise, diet, and preventive healthcare? Are complementary health approaches included in their daily activities? Are they used to promote health and prevent illness?

Family Assessment Tools

In the context of wellness promotion, nursing assessment includes identifying and optimizing current positive behaviors and lifestyle choices, as well as recognizing the family's needs for disease prevention. In addition to patient interviews and observation of family processes, several tools are available for completing a multifaceted family assessment that takes into consideration a number of factors, including physiologic, psychosocial, spiritual, and environmental components. Presented are some of the more common tools that can be used by nurses to identify strengths and areas where families may need more support, education, or resources in order to strengthen the family unit.

Family Ecomap

How a family interacts within the community can provide useful information, especially when trying to determine how to support families who are having difficulty coping. **Ecomaps** are an assessment tool that can help nurses visualize how the family unit interacts with the external community environment, including schools, religious commitments, occupational duties, and recreational pursuits (see **Figure 26-9** >>>). The ecomap provides an opportunity to identify the organizational patterns of the family and the status of relationships within the family and community, as well as the community resources the family might access. As part of the assessment, the nurse observes intrafamily communication patterns closely, paying special attention to who does the talking for the family, which members are silent, how disagreements are handled, and how well the members listen to one another and encourage the participation of others. Nonverbal communication is important because it gives valuable clues about what people are feeling.

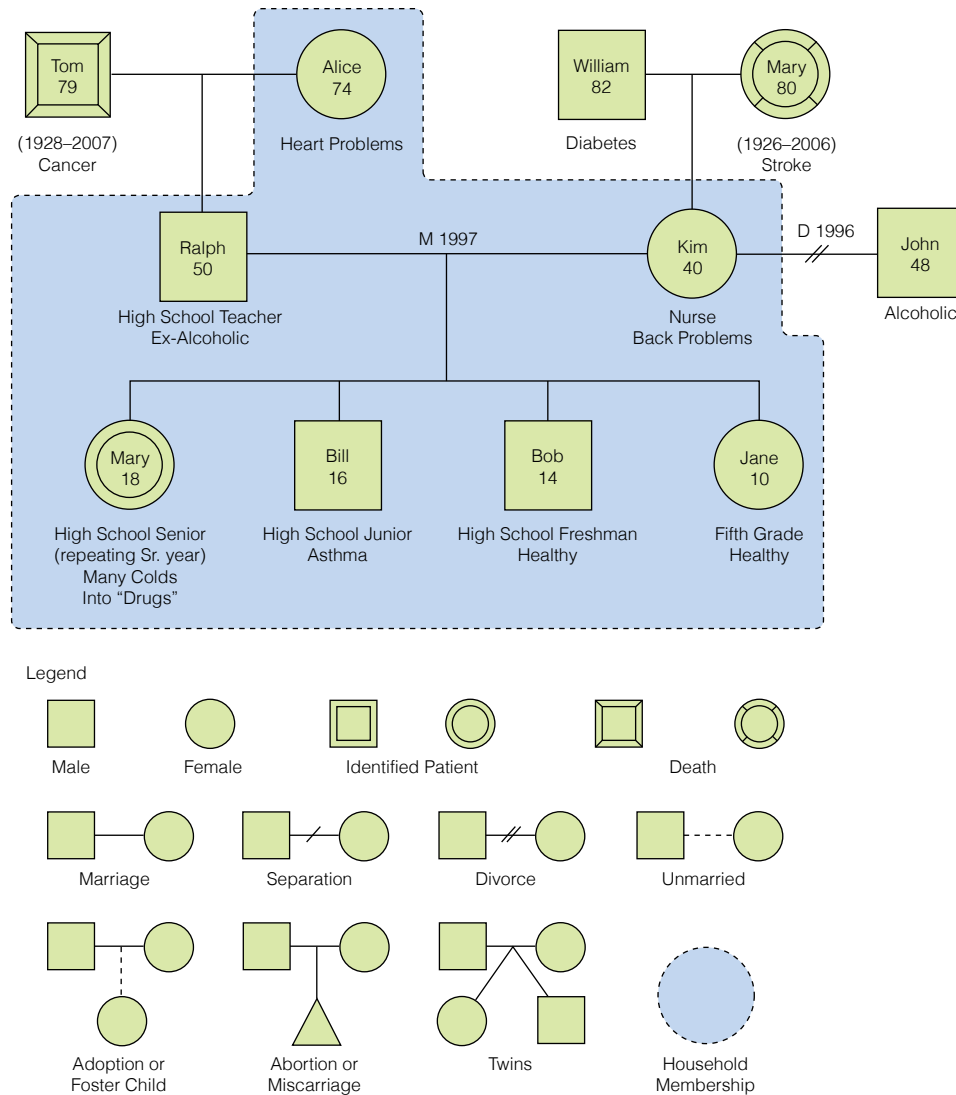

Figure 26-9 » Example of a family genogram.

Family Genogram

Using a genogram assists the nurse to visualize familial relationships and patterns of chronic conditions occurring within the family unit. **Genograms** consist of visual representations of gender showing lines of birth descent through the generations (see **Figure 26-10** »).

Family APGAR

The Family APGAR is a quick, five-item questionnaire that may be used as an initial screening tool for family assessment. The five family concepts measured are family adaptability, partnership, growth, affection, and resolve (see **Table 26-4** »). This five-item questionnaire can be administered quickly to each family member over 10 years of age. Be concerned if the majority of responses fall in the “hardly ever” category or if responses vary a lot among family members. This may indicate a family that needs much more support to cope with the demands of daily life and may also provide insight into health maintenance and health promotion needs.

Home Observation for Measurement of the Environment

The HOME Inventory is an assessment tool developed to measure the quality and quantity of stimulation and support available in the home environment (Caldwell & Bradley, 1984). Four age-specific scales are available (birth to 3 years, 3 to 6 years, 6 to 10 years, and 10 to 15 years). Examples of subscales within each age-specific scale are parental responsiveness, acceptance of child, the physical environment, learning materials, variety in experience, and parental involvement. Data are collected during an informal, low-stress interview and observation over 45 to 90 minutes in the home setting. The child and his or her primary caregiver must be present and awake during the interview. Observation of the parent-child interaction is an essential part of the assessment. The intent is to allow family members to act normally. Assessment of the home environment will help to identify factors that promote the child's growth and development. Nursing interventions that could result from the HOME assessment include recommending items that can be

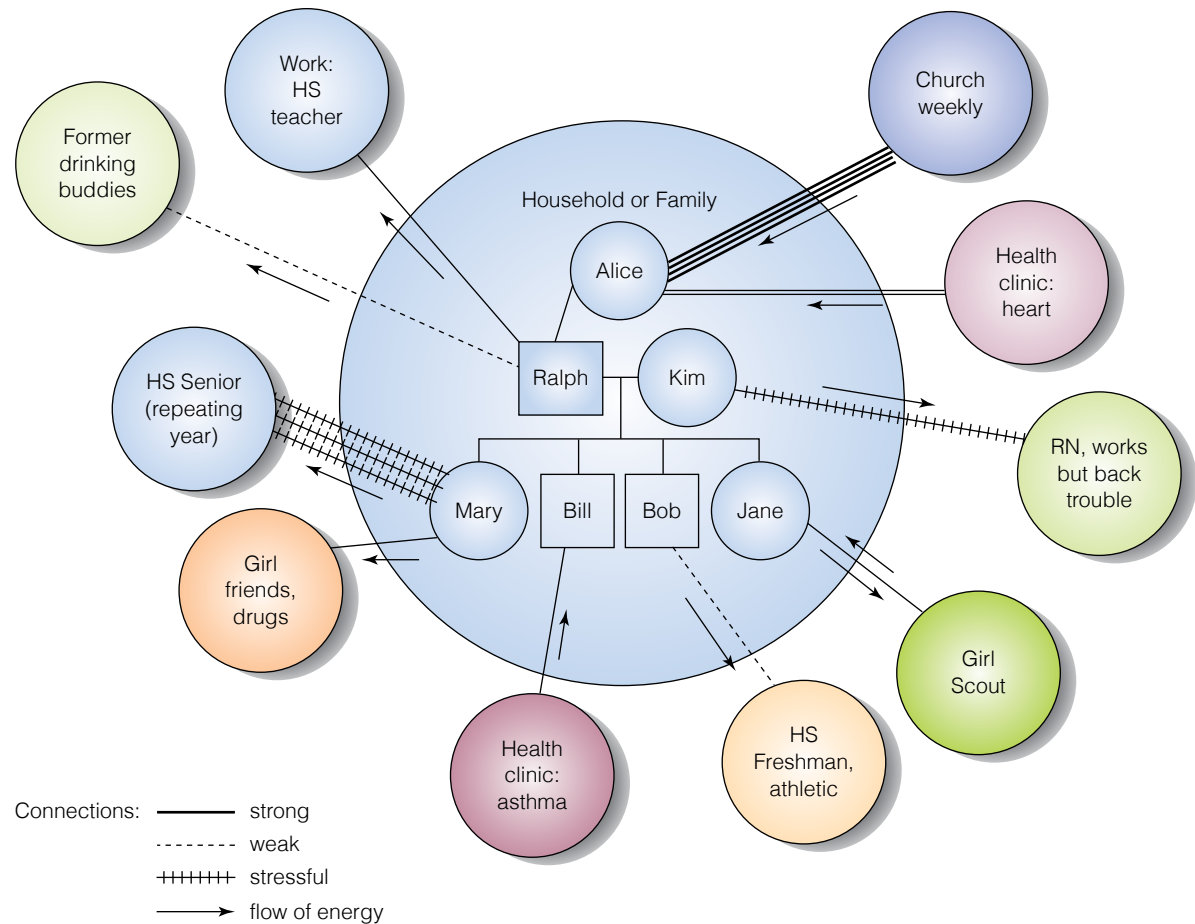

Figure 26-10 » Example of a family ecomap. Many more components may be added to the map.

used in the home for toys and suggesting strategies for interacting with the child to promote learning.

The Friedman Family Assessment Tool

The Friedman Family Assessment Tool (FFAM), developed by Marilyn Friedman, was designed to assist nurses with family assessment. This tool provides a method for examining the whole family in the context of the larger community where the family resides. The interview collects information about a family's relationships, functioning, strengths, and problems.

» Go to **Pearson MyLab Nursing and eText** to see a shortened version of the Friedman Family Assessment Tool.

Case Study » Part 2

After expressing concern for Mrs. Rodriguez and Mrs. Marshall, you begin to explore their birthing class experiences in greater detail. Mrs. Rodriguez explains that many of the other couples in the class are rude to her and her wife, and that the woman conducting the class is cold to them as well. The couple continues to tell you about similarly negative reactions they have experienced while searching for a birthing center. During the discussion, you notice that Mrs. Rodriguez becomes increasingly upset. When Mrs. Marshall asks for a few moments alone with Mrs. Rodriguez, you step out of the room. Upon your return, Mrs. Rodriguez apologizes for "losing control of my emotions." You assure her that she is welcome to express her emotions and that you are committed to providing her with the best possible

care, including recommending some potential alternatives to her current birthing classes. You continue your physical assessment of Mrs. Rodriguez. Her vital signs are T 98.8°F oral, P 86 bpm, R 24/min, and BP 168/90 mmHg. Mrs. Rodriguez denies any physical complaints or unusual changes in her condition. You leave the room to talk with the physician. The physician comes in to examine Mrs. Rodriguez and notes that everything appears to be fine but expresses concern about Mrs. Rodriguez's elevated blood pressure.

Clinical Reasoning Questions Level I

1. Presuming that Mrs. Rodriguez has no other health issues and no pregnancy-related complications, why might her blood pressure be elevated?
2. Identify three nursing actions described in this scenario that reflect respect and nonjudgmental care of this couple.

Clinical Reasoning Questions Level II

3. Describe two nursing interventions appropriate for inclusion in the care of this couple.
4. What steps might you take to assist Mrs. Rodriguez with identifying alternative providers of birthing classes?
5. What are some concerns associated with hypertension during the third trimester of pregnancy?

Independent Interventions

Families are shaped by multiple factors, including life experiences, current and past challenges, coping abilities, cultural

TABLE 26–4 The Family APGAR Questionnaire

Directions: The following questions have been designed to help us better understand you and your family. You should feel free to ask questions about any item in the questionnaire. The space for comments should be used when you wish to give additional information or if you wish to discuss how the question is applied to your family. Please try to answer all questions. Family is defined as the individual(s) with whom you usually live. If you live alone, your “family” consists of persons with whom you now have the strongest emotional ties.*

For each question, check only one box.

	Almost Always 2	Some of the Time 1	Hardly Ever 0
I am satisfied that I can turn to my family for help when something is troubling me. Comments: _____			
I am satisfied with the way my family talks over things with me and shares problems with me. Comments: _____			
I am satisfied that my family accepts and supports my wishes to take on new activities or directions. Comments: _____			
I am satisfied with the way my family expresses affection and responds to my emotions, such as anger, sorrow, and love. Comments: _____			
I am satisfied with the way my family and I share time together. Comments: _____			

*Note: Depending on which member of the family is being interviewed, the interviewer may substitute for the word *family* either *spouse*, *significant other*, *parents*, or *children*. Responses are scored 2, 1, 0 and totaled. The total score ranges from 0 to 10. The higher the score, the greater amount of satisfaction that family member has with family functioning.

Source: Adapted from Smilkstein, G. (1978). The family APGAR: A proposal for a family function test and its use by physicians. *Journal of Family Practice*, 6, 1231–1239. Reprinted with permission from Frontline Medical Communications, Inc.

diversity, individual personalities, and the age of the family members. Nurses can employ numerous interventions to assist families with navigating through challenges or difficult circumstances, as well as to promote the optimal use of each individual’s strengths.

Explore Health Beliefs

Families have different and varying beliefs about health, illness, and ways and methods of treating illness. In some cases, these beliefs may be based in cultural or religious practices. As part of the assessment, the nurse asks open-ended questions in a nonjudgmental manner in an attempt to learn about the family’s health beliefs, including the use of herbs and supplements and the use of home remedies. By exploring the family’s health beliefs, nurses show respect for cultural and religious values and practice and can identify practices that may have a bearing on healthcare and family functioning. For example, consider the Muslim patient who has come in for assessment prior to scheduling a procedure. The nurse recognizes that the holy period of Ramadan is coming up and knows that observances for Ramadan include a month-long period of fasting from sunrise to sunset. One of the medications the patient will have to take during the postoperative period must be taken 4 times a day with food. Although the Muslim faith respects the need of those who are sick to abstain from fasting, the nurse consults with both the patient and the physician about whether or not the procedure may be scheduled after Ramadan.

Identify Resources

The nurse working with a family to develop a care plan identifies potential resources in the community that match the child’s and the family’s needs for support. The nurse will collaborate with the family to discuss those resources and to select the ones that are acceptable to the family, to increase the likelihood that the family will follow through with the plan. In some cases it may be necessary to collaborate with a multidisciplinary team, including social workers, to help the family obtain assistance to overcome, for example, transportation or financial problems or any others that interfere family functioning. The nurse may also assist the family in obtaining resources by such actions as role rehearsal, providing instructions and support when making an initial call, or connecting with another family support person who can help with resource linkage. The nurse will refer families with moderate or severe dysfunction to community resources for social support and counseling as appropriate.

Provide Patient and Family Education

Family members may have a lack of information or misinformation about health or disease. Because of the many advances in medicine and healthcare during the past few decades, patients may have outdated information about health, illness, treatment, and prevention. The addition of internet access has also caused a dramatic increase in the information available to families regarding health and illness (Hebda & Czar, 2014). The nurse is frequently in a position to give information or

Nursing Care Plan

A Single-Parent Family with Child Care Issues

ASSESSMENT	DIAGNOSES	PLANNING
Ms. Wilson, a newly divorced single mother, brings her 3-year-old son in for routine immunizations. After he has received his immunizations, while waiting the required 20 minutes before leaving, Ms. Wilson reveals that she recently lost her job because her company was bought by another. She says that she has found a new job, and that the salary is much higher, but the only available shift is from midnight to 7:00 a.m. She asks if there are any certified child-care providers who provide services during nighttime hours. She notes that her parents have offered to keep her son while she is at work, but she is worried about burdening her parents and being viewed as incapable of taking care of her child independently.	<ul style="list-style-type: none"> ■ <i>Parenting, Readiness for Enhanced</i> ■ <i>Knowledge, Readiness for Enhanced</i> ■ <i>Decision Making, Readiness for Enhanced</i> (NANDA-I © 2014)	<ul style="list-style-type: none"> ■ Ms. Wilson will be able to state the risks related to leaving a child home alone. ■ Ms. Wilson will learn of other resources available to help her care for her child in a safe environment. ■ Ms. Wilson will discuss available choices she has without risking her child's safety.
IMPLEMENTATION		
<ul style="list-style-type: none"> ■ Explore patient's reluctance to accept her parents' offer to assist her. ■ Assist with identifying additional sources of support, including support groups and classes geared toward meeting the needs of single parents. ■ Reinforce and support the patient's concern for her child's well-being, including his physiologic and psychosocial wellness. 	<ul style="list-style-type: none"> ■ Provide referrals to social services to help meet financial needs. ■ Encourage and support patient's desire to be financially self-sufficient. ■ Assess patient's knowledge of pediatric vaccination schedules and provide appropriate teaching, including in written form. 	
EVALUATION		
Ms. Wilson agrees to explore the option of accepting her parents' offer to care for her child while she is at work. She also agrees to	attend classes designed to educate and assist individuals with overcoming challenges that accompany single parenting.	
CRITICAL THINKING		
<ol style="list-style-type: none"> 1. Is the nursing diagnosis of Readiness for Enhanced Parenting appropriate? Why or why not? 2. In what ways might Ms. Wilson's recent divorce have affected her family's level of wellness? 	<ol style="list-style-type: none"> 3. How might Ms. Wilson's fear of appearing dependent negatively impact her level of personal and family wellness? 	

correct misconceptions. This function is an important component of the nursing care plan. Referrals to other healthcare team members offer the nurse the ability to collaborate with others in providing the necessary care to families.

Collaborative Practices

The interconnectedness and interdependence that are inherent in each family underscore the importance of collaboration as part of family-centered nursing care. Armed with the information from the family assessment, the nurse advocates within the interprofessional care team on behalf of the family and helps family members learn how to advocate for themselves and each other. At all times, the nurse remembers that family members may perceive some needs, issues, and situations differently than the nurse or other members of the healthcare team. **Box 26-2** illustrates this aspect of family-centered care.

When working with families, nurses will often need to collaborate with other healthcare professionals. In some cases, collaboration may include working with experts who specialize in social work, psychology, or mental healthcare.

For families in need of counseling, financial assistance may be available. Generally, community-funded organizations offer free or discounted services. When making these recommendations, nurses should be aware of some stigmas surrounding therapy and counseling, and work to assure families of the potential benefits of these modes of care. For new or expectant parents, referral to parenting classes may be valuable. Families facing economic challenges should be made aware of community resources, including wellness clinics and food banks. Additional assistance and collaboration with the school nurse may also help those families whose children requires special care during the school day.

Family responsibilities for children do not necessarily end on the child's 18th birthday. This is particularly true for families with children with disability and families with children with *serious mental illness (SMI)*. Serious mental illnesses are those that create significant disability in an individual's ability to function and reach life goals. Many community and social supports for individuals with disability or mental illness end when the individual turns 18 or graduates from high school. Parents may find themselves at a loss to cope with an adult child who needs continued support and care. In particular,

Box 26–2

Family-Centered Collaborative Care

Kayla Harrison is a public health nurse who is part of the early childhood collaborative assessment and referral team in her community. The team also includes a child psychologist, a pediatrician, a speech and language therapist, and an early childhood specialist from the local public schools. The team is meeting with Coretta Simons, the grandmother and foster parent of Alex Simons, a 3-year-old who was referred for evaluation based on an obvious speech deficit and behavior problems reported by his preschool teacher. During the meeting, the team shares the results of Alex's evaluation and listens to Ms. Simon's concerns about her grandson. Ms. Simon is the foster parent for Alex and his two older siblings. She works 40 hours a week driving the van for the local eldercare center, taking older adults to and from the center for the day while their caregivers go to work. Ms. Simon reports that Alex is the youngest, and his behavioral problems are exhausting the entire family. Team members advise her that they would like for Alex to be enrolled in a part-day program offered by the school system. The program specializes in offering services for children based on an individual education plan. The team is also recommending that Alex see a child psychologist to begin to learn some coping skills and for Ms. Simon to participate in therapy as well. Ms. Simon shares she cannot take any more time off for work to attend to Alex's needs, in part because of the number of times she got calls at work from the preschool asking her to come to the

center to help intervene with Alex's troublesome behaviors. She also says that she does not think a part-day program is best for Alex. That would mean he would have to be shuttled to and from his current preschool to the public school because she works all day. Ms. Simon does not see this as being appropriate for a 3-year-old.

Ms. Harrison, the nurse at the table, hears Ms. Simon's frustrations and recognizes quickly that Ms. Simon understands her needs, Alex's needs, and the needs of their family unit. The early childhood specialist, however, is pushing for Ms. Simon to make the therapy appointments happen, on the argument that this will help her learn to manage Alex's behaviors and help Alex learn some coping mechanisms as well. Ms. Harrison knows that the local preschool developmental day center has some grant funding to provide outreach mental health services to children in other preschool settings. Ms. Harrison suggests that the team begin Alex's treatment plan by starting with speech therapy and by signing Alex up for the outreach services so that a behavioral therapist can work with Alex at school. When possible, Ms. Simon can join in those sessions or observe and work with the therapist to find what works for Alex. Ms. Harrison suggests that the team try these options and meet again after a few weeks to see how the plan is working. Ms. Simon replies that this sounds feasible, that she would find it more helpful to meet with a therapist Ms. Harrison recommends at Alex's preschool instead of having to take him to and from appointments.

older adults who have been caring for adult children with disability or serious mental illness may experience increased distress as they plan for the care of their child beyond their own lives (Potter & Moller, 2016). Nurses may find themselves collaborating with these parents to help them find and access services for adult children. One advocacy organization, the Center for Parent Information and Resources, provides information for parents of individuals with disabilities.

» **Stay Current:** The Center for Parent Information and Resources provides a list of organizations that offer resources or support for adults with disabilities. See <http://www.parentcenterhub.org/repository/foradults/>

Case Study » Part 3

The physician requests that Mrs. Rodriguez remain at the office so that her blood pressure can be reassessed. While Mrs. Rodriguez is relaxing, you check with some of the staff and learn that a newly hired certified nurse midwife (CNM) offers a birthing class once per week. The CNM reports that two of her patients are a lesbian couple and that they are warmly welcomed by the other patients. You also consult with two of the physicians and compile a list of three birthing centers in the area that they prefer.

Upon return to Mrs. Rodriguez's room, you reassess her blood pressure, which is now 122/82 mmHg. You provide the couple with the information you have gathered about the birthing class and the three birthing centers. Both Mrs. Rodriguez and her wife express gratitude for your compassion and efforts to assist them. Mrs. Rodriguez is scheduled to return for a follow-up appointment in 2 weeks. She reports that she has a blood pressure monitor at home and tells you she'll check her blood pressure at least once daily. Mrs. Rodriguez agrees to contact the clinic if her blood pressure is elevated or if she has any unusual changes.

Clinical Reasoning Questions Level I

1. Do you think Mrs. Rodriguez and Mrs. Marshall are wellness oriented? Explain your answer.
2. What recommendations would you provide to help Mrs. Rodriguez keep her stress level down during her pregnancy?

Clinical Reasoning Questions Level II

3. What are some of the negative effects of stress on families?
4. According to the laws of your state, when the couple in this case study has their child, who will have parental rights?
5. If Mrs. Rodriguez's blood pressure had not decreased, what interventions could have been proposed?

REVIEW The Concept of Family

RELATE Link the Concepts

Linking the concept of family with the concept of culture:

1. Explain how culture influences the family unit. What are three values or beliefs that could impact how a family functions?
2. What impact does stereotyping have on family? Describe at least two negative effects stereotyping can have on the family unit.

3. How does the nurse incorporate the family's cultural beliefs into health promotion teaching?
4. How might the family's cultural beliefs impact their health behaviors?

Linking the concept of family with the concept of self:

5. What are two measures that could be implemented for a teenager you suspect is experiencing anorexia nervosa?

6. While you are providing care to a family of four (two parents, two children), the parents ask for advice on helping their daughter, who they believe has become bulimic. What suggestions do you provide the parents? Explain your answers.

Linking the concept of family with the concept of advocacy:

7. How can the nurse advocate for families from vulnerable populations in the community?
8. What responsibilities does the nurse have to advocate for families?

REFLECT Apply Your Knowledge

The home health nurse has been visiting a 90-year-old woman and her younger sister who live together in a large farmhouse. The women have been active in caring for each other and their residence. During one of the home visits, they confide that the farm is too much for them, but they admit that they do not want to tell their families because they are afraid that they will be put into a nursing home.

1. What community resources are available to assist the sisters to live independently?
2. How should the family be involved in the decision making?
3. What signs can alert the nurse that the sisters are unable to care for themselves?
4. Should the nurse contact the family without the sisters' knowledge? Why or why not?

Exemplar 26.A Family Response to Health Alterations

Exemplar Learning Outcomes

26.A Analyze family response to health alterations.

- Describe the impact of illness on the family system.
- Identify the clinical manifestations of family response to health alterations.
- Outline aspects of collaboration necessary to the care of families experiencing health alterations.
- Apply the nursing process in providing culturally competent care to families with health alterations.

Overview

Although some patients are totally alone in the world, most have one or more people who are significant in their lives. These significant others may be related or bonded to the patient by birth, adoption, marriage, or friendship. Although not always meeting traditional definitions, people (or even pets) significant to the patient are the patient's family. The nurse includes the family as an integral component of care in all healthcare settings.

The Impact of Illness on the Family System

Illness of a family member is a crisis that affects the entire family system. The family is disrupted as members abandon their usual activities and focus their energy on restoring family equilibrium. Roles and responsibilities of the ill family member are delegated to other family members, or those functions remain undone for the duration of the illness. Family members experience anxiety about the sick individual and the resolution of the illness. This anxiety is compounded by additional responsibilities that leave less time or motivation to complete the normal tasks of daily living.

Exemplar Key Terms

Family burden, 1874
Objective family burden, 1874
Stigma, 1875
Subjective family burden, 1874

See **Box 26-3** for some factors that determine the impact of illness on the family unit.

The family's ability to deal with the stress of illness depends on the members' coping skills. Families with good communication skills are better able to discuss how they feel

Box 26-3

Factors Determining the Impact of Illness on the Family

- The nature of the illness, which can range from minor to life threatening
- The duration of the illness
- The residual effects of the illness, ranging from none to permanent disability
- The meaning of the illness to the family and its significance to family systems
- The financial impact of the illness, which is influenced by factors such as insurance and ability of the ill family member to return to work
- The effect of the illness on future family functioning (for instance, previous patterns may be restored or new patterns may be established).

about the illness and how it affects family functioning. They can plan for the future and are flexible in adapting these plans as the situation changes. An established social support network provides strength, encouragement, and services to the family during the illness. During health crises, families must realize that turning to others for support is a sign of strength rather than weakness. Nurses can be part of the support system for families, or they can identify other sources of support in the community.

During a crisis, families are often drawn together by a common purpose. In this time of closeness, family members have the opportunity to reaffirm personal and family values and their commitment to one another. Indeed, illness may provide a unique opportunity for family growth.

Nurses committed to family-centered care involve both the patient and the patient's family in the nursing process. Through their interaction with families, nurses can give support and information, although the patient needs to give permission regarding what information can be shared with family members. Nurses make sure that not only the patient but also each family member understands the disease, its management, and the effect of these two factors on family functioning.

The interconnected and interdependence of the family have considerable impact on patient care beyond the acute care setting. For example, changes in the dietary needs of one member may impact all family members. Nurses must assess the implications of treatment management on all members of the household, including siblings. Nurses must also be attuned to how family members are responding.

Nurses also support families as they try to find solutions, providing patient education about community resources and the Family Medical Leave Act (**Box 26-4**)).

Chronic Illness and the Family

Chronic illness has increased dramatically so much that nearly one half of the U.S. population experience a chronic

condition, and more than one in four Americans have multiple chronic conditions (Murray & Lopez, 2013). The patient with a chronic illness may be hospitalized when experiencing an acute exacerbation, but the care of the patient is primarily and usually provided at home. Chronic illness in a family member is a major stressor that may cause changes in family structure and function, as well as in how family developmental tasks are performed.

Many different factors affect family responses to chronic illness; family responses in turn affect the patient's response to and perception of the illness. Factors influencing response to chronic illness include personal, social, and economic resources; the nature and course of the disease; and demands of the illness as perceived by family members. In a systematic review, Cousino and Hazen (2013) found that significantly greater parenting stress of caregivers of children with chronic illness was associated with greater caregiver responsibility for treatment management. Interestingly, duration and severity of illness were not found to be correlated with greater caregiver stress.

Patients with chronic illness, and their families, may be at risk for depression. Caregiver burden, loss of role function, and financial burden are just some of the factors that increase risk for depression in patients with chronic illness and their families. Nursing considerations for a patient with a chronic illness include being alert to symptoms of depression, both in the patient and in his or her close family members.

Serious Mental Illness and the Family

Caring for a family member with a mental illness can result in overwhelming emotional and economic stress on the family system, particularly if caregiver role strain becomes a contributing factor. Symptoms associated with SMI can significantly impair daily functioning, requiring a great deal of time and energy from family members who live with or care for the individual. Thus, it is common for the individual with SMI to become a large focus within the family dynamic, causing other members of the family to feel neglected or even ignored. In some situations this can cause a strain on the family unit as a whole (Mental Health America, 2013). In addition, a qualitative analysis by van der Sanden et al. (2015) found that family members of those who experienced mental illness were also stigmatized, increasing the stress felt by the family.

Family burden is the overall level of distress experienced as a result of the mental illness (Biegel & Schultz, 1999; Schene, 1990). **Objective burdens** are those that are measurable, such as disruption of family functioning and routines and financial costs of care. **Subjective burden** refers to the family or caregiver's perception of what is burdensome. Significantly higher family burden is associated with a number of variables. For example, the relapsing nature of schizophrenia has been associated with greater family burden than the more chronic, but perhaps more stable, symptoms of depression (Koujalgi & Patil, 2013). Acuity of patient symptoms is highly associated with caregiver burden, with sleep disturbances, lack of motivation, poor hygiene, acting out, and violent behaviors among a number of behaviors that increase family burden. Koutra et al. (2014) found that in families who have a member with psychosis, neither family cohesion nor flexibility was found to have significant direct

Box 26-4

Family and Medical Leave Act

Eligible parents of newborns and adopted children are entitled to 12 weeks of unpaid leave during any 12-month period, as initially authorized by the federal Family and Medical Leave Act of 1993. Vacation or sick leave may be used to pay for time away from work, depending on the employer's leave policies. This act also applies if a child, spouse, or parent of the employee develops a serious health condition. The employee is entitled to return to the previous position or an equivalent position with all the same pay, benefits, and other conditions. The act carries some additional conditions and requirements, including that employees are only eligible if they have worked for a covered employer for 1250 hours over the previous 12 months.

» **Stay Current:** More information on the Family and Medical Leave Act can be found at <http://www.dol.gov/whd/fmla/employeeguide.htm>

Source: Based on the Family and Medical Leave Act, Public Law 103-3, February 5, 1999. 5 U.S.C. 6381-6387; 5 CFR part 630, subpart L. Retrieved from <http://www.opm.gov/pca/leave/HTMS/fmlafac2.asp>.

effects on caregivers' psychologic distress; rather, this was mediated by family burden and caregivers' criticism.

The caregiving process itself can be stressful. Often community resources are not available, not satisfactory, or have long waiting lists. Insufficiency of these resources nationwide has resulted in high rates of homelessness, incarceration, and hospitalization of individuals with mental illness (Smith & Sederer, 2015). Some 40% of psychiatric patients have a history of criminal justice involvement related to decreased access to care, and rates of incarceration are high for individuals experiencing their first episode of mental illness, especially if it manifests as mania (Prince, Akincigil, & Bromet, 2007; Steadman et al., 2009). Families of the seriously mentally ill often find themselves negotiating the criminal justice system. Many times, the crimes are misdemeanors related to symptoms, such as disorderly conduct and intoxication.

Stigma describes patterns of negative attitudes that lead people to fear and discriminate against individuals with mental illness and their families. Because mental illness is so widely misunderstood, family members may isolate themselves from others who they feel are unsupportive or critical. Inability of some family members and friends to learn about and accept mental illness may lead to rejection. Further, discrimination resulting from stigma often extends to the family and caregivers (Pescosolido et al., 2013).

Feelings associated with subjective family burden include frustration, anxiety, hopelessness, and helplessness. Feelings of depression and/or grief and loss may also be present. Chronic sorrow may take hold as family members experience the relapsing nature of the illness.

Families with healthy coping strategies are more likely to experience better outcomes and reduced caregiver burden. Healthy coping strategies when caring for a loved one with SMI include focusing on the positive response of the relationship, seeking social and community supports, reducing sources of conflict, and expressing affection. Moral support, practical support, and motivation to help the loved one improve in functional ability are essential to helping family members with SMI lower their symptom burdens and increase daily functioning (Aldersey, 2015). Families who act as stressors, increase or create conflict, display stigma and discrimination, or force treatment choices can impede the recovery of their loved one.

Pediatric Illness and the Family

Collaborating with families in providing healthcare is essential to promoting the best outcome when caring for children. Families have important knowledge to share about their child, their child's health condition, and how their child responds to various actions and events. They also need access to information that will make it possible for them to fully participate in planning and decision making.

Elements of family-centered care are outlined in **Table 26-5** ».

Parents often need to assess their strengths in managing their ongoing family and caregiving responsibilities before planning how to add more caregiving responsibilities to their routine. Individuals who become family caregivers are at risk for considerable strain and stress, especially if they are unable to balance their own needs with those of the

Box 26-5

Guidelines for Effective Parent-Provider Collaboration

Parents have a role in developing an effective collaborative relationship with nurses and other health professionals. Parents often become experts in their child's health condition and learn to advocate for their child. They also must learn to communicate effectively with the health professionals caring for their child, and in the process develop a trusting relationship.

Tips for parents for improved communication are as follows:

- Keep a journal that includes your observations about your child's behavior, eating habits, illness, temperature, or anything else that might be helpful to the healthcare providers caring for your child.
- Keep a copy of your child's medical records, including test and procedure results.
- Write out questions or email healthcare providers, and do not hesitate to ask for clarification if you do not understand an answer provided.
- Be realistic about what you can expect from your child's nurses and doctors. They may not have all of the answers to your questions right away, but if you give them time, they will answer your questions. Try to let your healthcare providers know you appreciate their time and efforts on behalf of your child.

Communication tips for nurses include the following:

- Provide information and honestly discuss issues of concern to both the family and healthcare providers.
- Engage in creative problem solving and identify options for needed care that conform to the family's values and functioning.
- Demonstrate respect for the family's choices and methods for providing needed care.
- Continue to collaborate with the child and family and be willing to continue problem solving as new issues arise.

child. The nurse and parents should collaborate in developing the plan for the child's care, so as not to conflict with the family's cultural and ethnic illness-related behaviors, experiences, and beliefs. The child's opinions should also be integrated in the strategies for care. In almost all cases, the child leaves the healthcare setting and the family assumes responsibility for providing needed care in the home. The family caregivers must not feel alienated from a healthcare system they need for continuing assistance. See **Box 26-5** » for guidelines for effective collaboration.

Family involvement is also valuable in the development of policies and guidelines for family-centered care in all types of healthcare settings. A family's experiences while receiving care may reveal valuable insights, perspectives, and realities that could lead to improved quality of care and satisfaction with care. Feedback could be provided on such issues as how comfortable they felt in the setting, their understanding of information provided to them, and the attitudes they sensed from health professionals. Parents who have been supported in developing leadership skills can be empowered to serve on advisory boards or councils representing the family and community perspectives (Warren, 2012).

TABLE 26–5 Elements of Family-Centered Care and Recommendations for Nursing Practice

Elements	Nursing Practice Recommendations
Family at the Center: <ul style="list-style-type: none"> ■ Incorporate into policy and practice the recognition that the family is the constant in a child's life, while the service systems and support personnel within those systems fluctuate, and that the illness or injury of a child affects all members of the family system. 	<ul style="list-style-type: none"> ■ Establish a therapeutic relationship with the family. ■ Perform a comprehensive family assessment in collaboration with the family, identifying both strengths and needs. ■ Use the family assessment when working with the family to plan, implement, and evaluate care, considering the impact of the child's illness or injury on the entire family, with special attention to the siblings. ■ Provide siblings with information about their sibling's illness/injury at an appropriate developmental level and answer questions honestly. ■ Promote sibling visitation in hospital settings and participation in home care activities. ■ Identify extended family members who should receive information and be included in the educational process.
Family–professional Collaboration: <ul style="list-style-type: none"> ■ Facilitate family–professional collaboration at all levels of hospital, home, and community care. 	<ul style="list-style-type: none"> ■ Develop provider–family relationships that are guided by the goals and expectations of both the family and the provider. ■ Ensure that parents are integral and critical collaborators in the decision-making process about their child's care. Involve children and adolescents in the decision-making process as appropriate for their cognitive and emotional development. ■ Ensure that parents have 24-hour access to their child, and facilitate their participation in the child's care. ■ Provide parents with the option to stay with their child during procedures and tests, and provide ways for parents to support the child during the procedure. ■ Provide comfort and hygiene facilities for families who spend long hours at the facility or travel great distances. ■ Promote the family's development of expertise in the special care of their child, fostering family independence and empowerment. ■ Incorporate parents and children into the quality assessment/improvement process. ■ Integrate family members into institutional and community advisory groups and involve them in policy development.
Family–professional Communication: <ul style="list-style-type: none"> ■ Exchange complete and unbiased information between families and professionals in a supportive manner at all times. 	<ul style="list-style-type: none"> ■ Provide information about the child's problem, prognosis, and needs in a manner that respects the child and family as individuals and promotes two-way dialogue. ■ Encourage the family to share information about the child and the illness/injury so that care planning and decisions are made in the most informed and collaborative manner.
Cultural Diversity of Families: <ul style="list-style-type: none"> ■ Incorporate into policy and practice the recognition and honoring of cultural diversity, strengths, and individuality within and across all families, including ethnic, racial, gender, spiritual, social, economic, educational, and geographic diversity. 	<ul style="list-style-type: none"> ■ Practice family-centered care in a culturally competent manner with respect and sensitivity for the wide range of families with diverse values and beliefs. ■ Seek to understand the family's beliefs and practices related to race, culture, gender, and ethnicity when developing relationships and collaborating in the child's healthcare. ■ Seek to understand and respect the family's religious/spiritual beliefs and practices and integrate these into the child's care, as the family desires. ■ Assist the family to address care issues related to socioeconomic status, insurance status, geography, and access to healthcare. ■ Integrate training programs on diversity, cultural understanding, and culturally competent care into staff development programs.
Coping Differences and Support: <ul style="list-style-type: none"> ■ Recognize and respect different methods of coping. Implement comprehensive policies and programs that provide families with the developmental, educational, emotional, spiritual, environmental, and financial support needed to meet their diverse needs. 	<ul style="list-style-type: none"> ■ Assess the strengths and weaknesses of the family's coping strategies and its resiliency factors and characteristics. Identify maladaptive coping mechanisms and help the family to augment its coping efforts. ■ Assess and support the family's needs and desires for support and assist the family in accessing and accepting assistance from support networks as needed or desired.
Family-centered Peer Support: <ul style="list-style-type: none"> ■ Encourage and facilitate family-to-family support and networking. 	<ul style="list-style-type: none"> ■ Educate parents about parent-to-parent and family support resources and help them to access such resources in the institution and community. ■ Provide access to psychoeducational groups that might be useful to parents, siblings, or ill/injured children.
Specialized Service and Support Systems: <ul style="list-style-type: none"> ■ Ensure that hospital, home, and community service and support systems for children needing specialized health and developmental care and their families are flexible, accessible, and comprehensive in responding to diverse family-identified needs. 	<ul style="list-style-type: none"> ■ Provide collaborative, flexible, accessible, comprehensive, and coordinated services to children and their families. ■ Provide comprehensive case management/care coordination for children and families with ongoing care needs. ■ Along with families, take an active role in advocating for the needs of ill and injured children.
Holistic Perspective of Family-centered Care: <ul style="list-style-type: none"> ■ Appreciate families as families and children as children, recognizing that they possess a wider range of strengths, concerns, emotions, and aspirations beyond their need for specialized health and developmental services and support. 	<ul style="list-style-type: none"> ■ Encourage attention to the normal developmental needs and developmental tasks of the entire family unit and individual family members. ■ Encourage and facilitate the development of individual and family identities beyond a focus on illness or injury. ■ Facilitate "normalization" as valued and desired by the family.

Focus on Diversity and Culture

Family-Centered Care

When working to establish a family-centered relationship with families of various ethnic groups, consider the possibility that an extended family may need to be consulted. For example, Native Americans may consult tribal elders (considered part of the extended family) before agreeing to healthcare for their child. In some Hispanic cultures, major decisions for the child's healthcare are made with input from grandparents and other extended family members. Nurses and other healthcare providers should work to determine the strengths of the family network to better assist the family in planning the child's care at home (Spector, 2017).

Some healthcare facilities are developing family resource centers to provide consumer information and support. In most cases, the resource center is a consumer-oriented health library with staffing, but peer support services may be coordinated through the center as well (Institute for Patient- and Family-Centered Care [IPFCC], 2016). Families can be supported in accessing useful information that helps them become informed decision makers about their child's care. Resources can often be provided in the preferred language and at an appropriate reading level.

When providing care to children, be aware that the family is central to all healthcare interventions with parents and child as the partners in care. It is important to consider how a healthcare setting's written policies, procedures, and literature for families refer to families and what attitudes these materials convey. Words like *policies*, *allowed*, and *not permitted* imply that hospital personnel have authority over families in matters concerning their children. Words like *guidelines*, *working together*, and *welcome* communicate an openness and appreciation for families in the care of their children.

Geriatric Illness and the Family

Adults who care for their own children and one or more of their own parents belong to a group that has come to be known as the "sandwich generation." This group of adults faces an incredible amount of stress trying to meet the diverse needs of young children and adolescents as well as aging parents. One of the chief sources of stress for these families is financial insecurity. A family with limited financial resources may face taking the aging parent into their own home or placing an aging parent who is no longer independent into a senior care facility that is below standard. If a family has very young children, taking an aging parent with dementia into the home can present either real or perceived hazards to the young children, increasing the stress level of the entire family. In addition, a member of the sandwich generation often faces additional stress addressing an older parent's needs while still trying to get children off to school and extracurricular activities and to maintain a full-time job. End-of-life issues can be a great source of stress and conflict for these families.

The needs of the family caring for an older adult who is ill will vary based on factors already detailed in this module.

In some cases, interventions needed are multiple and complex. But that should not stop nurses from helping family members identify needs that can be met in the short term with simple interventions. For example, caregivers may benefit from patient teaching regarding sleep hygiene to improve their own sleep or teaching about deep breathing and other relaxation techniques. Other nursing interventions may include referrals for respite care, hospice services, or counseling.

» **Stay Current:** Older adults with neurologic disorders often experience sleep disruption. Research and advocacy organizations such as the Michael J. Fox Foundation for Parkinson's Research and the Alzheimer's Association offer resources to help both professionals and caregivers learn how to help their loved ones. See www.michaeljfox.org for resources for caregivers of individuals with Parkinson disease.

Risk Factors

The physical or mental illness of one family member places the entire family unit at risk for alterations in function. Among families, coping with illness may lead to family disputes, financial difficulties, and caregiver strain, as well as a number of other challenges. Financial challenges associated with illness are multifactorial; however, two common sources include medical bills and a member of the family leaving employment to help take care of another family member. Illness alone adds a considerable amount of stress to each family member's life—financial strains further compound the stress (Wadsworth & Rienks, 2012). High stress levels, especially among family caregivers, have been linked to health problems and an increased risk for premature mortality. Similarly, for the caregiver, impaired or inadequate coping function may lead to unhealthy choices, such as using tobacco and/or alcohol to manage stress levels (APA, 2013).

Prevention

Families who are made aware of the challenges associated with illness early in the process may benefit from having additional time to consider and plan for some of the upcoming circumstances. Talking about the illness as a family can be extremely beneficial, as can family counseling. Family support for one another is essential to get through this difficult time (Mental Health America, 2013). Nurses can help families by advising them of the challenges they will face and connecting them with the appropriate supportive resources, including counselors and sources of financial assistance as indicated.

Clinical Manifestations

Each family's reaction to a particular illness will vary based on their previous experiences, personal opinions, and cultural influences. Nurses must be alert to manifestations that signal the family is having difficulty coping with managing the illness and be able to respond appropriately to help family members improve their coping skills and access helpful resources (see the Clinical Manifestations and Therapies feature). Primary caregivers may benefit from education about techniques to relieve stress, participation in support groups, and respite care.

Clinical Manifestations and Therapies

Family Stressors

ETIOLOGY (PRIMARY STRESSOR)	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Chronic illness in the family	<ul style="list-style-type: none"> Increased stress resulting in weight loss or gain, headaches, and anxiety Lifestyle changes (e.g., job loss and financial difficulties) Depression as evidenced by fatigue, lack of enjoyment, loss of interest in regular activities Decreased participation in social activities; withdrawal Unhealthy coping mechanisms (e.g., smoking, alcohol use, substance use) 	<ul style="list-style-type: none"> Teach about healthy forms of stress management. Provide resources for family counseling. Educate about healthy eating habits to reduce risk for further illness and increase nutrition. Discuss the benefits of exercise for stress relief and health.
Mental illness in the family	<ul style="list-style-type: none"> Confusion over changes occurring within the family unit Stress related to helping the family member experiencing mental illness (possibly financial stress) Anxiety Depression Feelings of loss related to changes in family member's behavior Fear over the changes that are occurring Changes in social activities, often resulting in decreased socialization 	<ul style="list-style-type: none"> Educate about the benefits of counseling for the family to help with the changes that are occurring. Advise about healthy stress management techniques. Provide resources for support groups involving other families in similar circumstances. Educate about the realities of the mental illness to dispel any misinformation and/or stigmas.
Illness of a child	<ul style="list-style-type: none"> Fear of death of the child Anxiety, stress, depression in accordance with the child's illness and its effect on the parents and family Decreased job performance, job loss, and financial difficulties resulting from taking the child to doctor appointments or spending time in the hospital Confusion and anger resulting from a lack of control over the child's illness and health 	<ul style="list-style-type: none"> Promote awareness of available counseling services. Emphasize the importance of healthy eating habits and exercise. Advise the primary caregivers to take time for themselves to avoid burnout. Teach about healthy coping mechanisms and stress management. Answer any questions the parents may have about their child's illness.
Caring for older parents	<ul style="list-style-type: none"> Criticism for not caring or not wanting to care for parent Feeling censured because of reasons for caring for parent Moral exclusion for not caring for parents 	<ul style="list-style-type: none"> Suggest counseling for adult children of older adult as well as family members. Provide resources such as respite care/day care for older adult and adult children.

Collaboration

Interventions vary based on the identified risks and actual or potential alterations in health. Nurses working with pediatric patients may collaborate with the school nurse, homebound teacher, guidance counselors, and other professionals. Collaboration with parents is key, because they often are the experts not only on their child but also on their child's illness, making them an extremely valuable member of the healthcare team. For older adults, nurses and other healthcare providers should continue to collaborate with the patient as long as the patient is able to participate in care.

However, the nurse and/or the healthcare team may increasingly collaborate with the older adult's primary caregiver in the event of progressive illness or deteriorating condition.

NURSING PROCESS

Nurses assess both the family and the patient when one family member is experiencing health problems. Families should be assessed for coping abilities, as well as possible complications that can arise from stress as a result of the family member's illness. Data from assessment of the patient and family will determine priorities for care.

Assessment

Assessment of the family facing challenges related to illness leads to the identification of family strengths and weaknesses. When indicated, the nurse also assesses the family's readiness and ability to provide continued care and supervision at home. Key components to consider when performing any family assessment and developing a patient's plan of care include the following:

- Cohesiveness and communication patterns within the family
- Family interactions that support self-care
- Number of friends and relatives available
- Family values and beliefs about health and illness
- Cultural and spiritual beliefs
- Developmental level of the patient and family.

Nursing assessment requires obtaining a complete family history, including genetic influences that may impact health. A family genogram (see Figure 26–9) may be helpful in collecting information, as detailed health histories should incorporate data regarding the patient's parents, siblings, grandparents, and even great-grandparents if information is available. If aunts, uncles, or cousins have had any health concerns, these should be noted as well. When assessing a family's history of mental illness, nurses should be aware that many individuals—especially from older generations—might not have volunteered knowledge about their mental illness. As a result, the patient may not know that a grandparent was diagnosed with a mental illness. Patients who were adopted and have no information about their birth parents will have no genetic health history to report, but information can be gathered about their health and environmental conditions during childhood, such as exposure to secondhand smoke, dietary patterns, or childhood illnesses.

Nurses are in a unique position to focus on care for an individual within the context of the family as partners. Being aware of issues that the family may face when one or more family members becomes ill can be helpful in guiding, teaching, and coordinating care for families. Being mindful of the impact of family function and structure in the particular family being cared for will provide a framework for identifying strengths of families as well as areas/resources needed by the family to recover and establish normal functioning patterns.

Diagnosis

Data gathered during a family assessment may lead to the following nursing diagnoses:

- *Family Processes, Interrupted*
- *Family Processes, Readiness for Enhanced*
- *Family Coping, Compromised*
- *Parenting, Impaired*
- *Parenting, Readiness for Enhanced*
- *Home Maintenance, Impaired*
- *Caregiver Role Strain.*

(NANDA-I © 2014)

Planning

Being sensitive to cultural differences is important in assessment and planning care. The nurse should determine who makes most of the decisions in the family, especially health-care decisions, so he knows whom to obtain information from and whom to instruct. The extended family unit is found in many cultures, and different health beliefs and health practices may exist within the family. Building a trusting relationship with these families by talking with them about their beliefs and practices is the first step toward planning more effective care.

Nursing care includes assisting the family with planning realistic goals/outcomes and strategies that enhance family functioning, such as improving communication skills, identifying and using support systems, and developing and rehearsing parenting skills. Anticipatory guidance may assist well-functioning families in preparing for predictable developmental transitions that occur in the life of families.

To help families reintegrate the patient into the home following hospitalization or rehabilitation, nurses use data gathered during family assessment to identify family resources and deficits. By formulating mutually acceptable goals for reintegration, nurses help families cope with the realities of the illness and the changes it may have brought about. Such changes may include new roles and functions of family members or the need to provide continued medical care to the patient. Working together, nurses and families can create environments that restore or reorganize family functioning during illness and throughout the recovery process.

Implementation

Although teaching is a core nursing intervention, it is important to remember that standardized teaching plans may not be effective for patients with chronic illness and their families. These patients and their families should be encouraged to choose appropriate literature and to find self-help or support groups so they can interact with others who have the same illness.

For families who will be providing care in the home setting, extensive teaching may be required. When the plan of care includes medication administration and equipment use, family members and caregivers may feel overwhelmed by the technical aspects of the patient's care. As much as possible, teaching sessions should be organized and divided into segmented presentations to avoid overloading the family and caregivers with information. Teaching sessions may include demonstration of the family's ability to provide care to their family member. In addition, the nurse assists in identifying available resources that are socially and financially acceptable.

Evaluation

In evaluating the efficacy of the family nursing care plan, the nurse identifies the degree to which the family members have achieved the identified outcomes relevant to each nursing diagnosis. During evaluation, the nurse also examines all aspects of the nursing care plan to determine the effectiveness of nursing interventions, as well as to evaluate the continued relevance of original nursing diagnoses. Based on

evaluation, the nursing care plan is modified to meet the family's current needs.

While the process of evaluation varies depending on the components of the family-specific nursing care plan, examples of criteria that may reflect successful achievement of identified outcomes include the following:

- Family members demonstrate the ability to identify realistic personal and family goals.

- Family members identify and demonstrate healthy coping strategies.
- Caregiver(s) demonstrate safe and effective implementation of care to their family member.
- Family members demonstrate support of the primary caregiver(s).

REVIEW Family Response to Health Alterations

RELATE Link the Concepts and Exemplars

Mrs. Ann Bell, an 82-year-old widow, was diagnosed with Alzheimer disease several years ago. She lives with her daughter and son-in-law and their two children, ages 16 and 10 years. Mrs. Bell has begun wandering, especially at night, and has started small fires when she attempts to cook and forgets about the pot on the stove. Mrs. Bell's daughter, Laura, accompanies her mother to her physician's appointment today and relates that the stress of caring for her mother, in addition to her other obligations to her husband and children, is becoming increasingly difficult.

Linking the exemplar of family response to health alterations with the concept of grief and loss:

1. How can the nurse help the family members to cope with the loss they feel related to Mrs. Bell's cognitive degeneration?
2. What strategies might help Mrs. Bell's grandchildren identify their feelings of grief and loss and work as a family to deal with these feelings?

Linking the exemplar of family response to health alterations with the concept of stress and coping:

3. What strategies can you suggest to help this family deal with the stress of Mrs. Bell's cognitive degeneration?
4. What referrals can you make to reduce Mrs. Bell's daughter's caregiver role strain?

REFLECT Apply Your Knowledge

Casey, a 16-year-old, is recuperating from injuries sustained in a motor vehicle crash in which he was the passenger. He was not wearing a seat belt and experienced a brain injury after striking the windshield. His cognitive and motor functions are impaired. After a 7-day acute care hospital stay, he was moved to an inpatient rehabilitation hospital, where he has been for the past 5 days. He is much more responsive to stimuli and to family members 12 days after his injury. Physical therapy is provided twice a day to promote range of motion and muscle tone and to prevent contractures. Plans are being made to discharge him home with outpatient rehabilitation care within the next 5 days. A case manager will be assigned to coordinate his healthcare services.

Casey lives with his mother, two half-brothers (10 and 6 years old), and stepfather. Both his mother and stepfather are employed full time and are trying to determine how to manage care for Casey once he returns home. Casey's father has not been actively involved in his life since his parents divorced 12 years ago. Casey's grandparents reside in the same town and may provide the family some support.

1. What family supports will Casey need as he continues his rehabilitation for the brain injury?
2. What family assessment information is needed to effectively plan nursing care for this adolescent and his family?
3. Identify two strengths and coping strategies that will help Casey's family members adapt to his disability.

Casey's family is coping with his initial survival of a serious brain injury and facing a long rehabilitation process. The family is just now recognizing that life as they have known it is changing. Casey is totally dependent for care, including bathing, toileting, feeding, and mobilizing. While he is expected to regain self-care abilities, the impact of the injury on his cognitive ability and future functioning is unknown.

Casey's extended family has provided support for the family during the past 12 days, but the level of support in the future weeks will decrease because of other family obligations. Casey's mother has already initiated a leave of absence from work so she can care for him when he returns home; however, this will mean the family has reduced income during that time period. Casey's younger brothers have been able to visit him, and they are very anxious because Casey cannot talk with them. They have been trying to avoid bothering their mother and father during this time, but they are wondering when life will be more normal and they can again participate in their usual afterschool activities.

4. What information about the family's strengths, needs, and resilience can be identified from the case study scenario?
5. What additional information would be helpful to know about family strengths and needs prior to developing a nursing care plan?
6. Based on your assessment of the family and challenges facing them, what is the priority nursing diagnosis for Casey and his family at this time? Why do you believe it is the priority?
7. Describe the use of family-centered care principles in planning Casey's nursing care in collaboration with the family.
8. What potential parenting issues could this family anticipate for Casey and his brothers?

Module 27

Grief and Loss

Module Outline and Learning Outcomes

The Concept of Grief and Loss

The Process of Grieving

27.1 Analyze the process of grieving.

Factors That Affect the Grieving Process

27.2 Analyze factors that affect the grieving process.

Concepts Related to Grief and Loss

27.3 Outline the relationship between grief and loss and other concepts.

Nursing Assessment

27.4 Differentiate common assessment procedures used to examine patients or families who are grieving.

Independent Interventions

27.5 Analyze independent interventions nurses can implement for patients who are grieving.

Collaborative Therapies

27.6 Summarize collaborative therapies used by interprofessional teams for patients experiencing grief and loss.

Children's Grief Responses

27.7 Differentiate considerations related to the assessment and care of children who are dying or experiencing significant loss.

Perinatal Loss

27.8 Differentiate considerations related to the assessment and care of a family who experiences a perinatal loss.

Older Adults' Responses to Loss

27.9 Differentiate considerations related to the assessment and care of older adults experiencing a significant loss.

>> The Concept of Grief and Loss

Concept Key Terms

Actual loss, 1884	Childhood traumatic grief, 1897	Disseminated intravascular coagulation (DIC), 1900	Intrauterine fetal death (IUFD), 1899	Perinatal loss, 1899
Ageism, 1904	Complicated grief, 1885	Fetal demise, 1899	Loss, 1883	Placental abruption, 1900
Anticipatory grief, 1884	Death anxiety, 1895	Grief, 1883	Miscarriage, 1899	Rh disease, 1900
Anticipatory loss, 1884	Disenfranchised grief, 1884	Hospice, 1893	Mourning, 1883	Spontaneous abortion, 1899
Bereavement, 1883			Perceived loss, 1884	Stillbirth, 1899
Blighted ovum, 1899				

Loss and grief are inherent in the human experience. Even so, reactions to loss and manifestations of grief vary widely. Each individual's methods of processing and coping with grief are influenced by numerous variables, including personality, age, culture, the nature of the loss, and the availability of a functional support system. **Loss** occurs when something or someone of value is rendered inaccessible or drastically changed. In addition to the loss of a loved one, numerous other sources of loss can also prompt grief reactions. Examples include the loss of a friend or relationship, loss of mobility, loss of independence, loss of a limb, and loss of hair from illness (**Figure 27-1 >>>**). By understanding the emotional and physical aspects associated with grief, nurses are better prepared to care for patients who have

experienced loss, as well as to support these patients during the grieving process.

The Process of Grieving

Grief is the combination of various psychologic, biological, and behavioral responses to a loss. Psychologic responses may include anger, denial, and depression. Biological responses to grief include sleep disturbances, decreased appetite, and weight loss. Behavioral responses include personality changes and decreased socialization. Bereavement and mourning can also accompany grief. **Bereavement** is the response to having lost another through death. **Mourning** involves the processing and resolution of grief,

Figure 27-1 » Loss of an aspect of self is common in those serving in the military, as loss of an appendage or a functional ability is one of the hazards of serving in combat.

generally through cultural and/or spiritual beliefs and practices. Grief can be triggered by any number of situations or occurrences, such as the loss of a loved one or acquaintance or being diagnosed with a terminal illness. Grief can also result from the end of a significant relationship with a partner or a close friend. In most cases, grief is a normal, healthy reaction to loss, as it helps the individual to process the situation. Grief should not be avoided, as avoidance often prolongs and intensifies the experience. For some individuals, the grieving process may also be prolonged by failure to mourn the loss according to an individual's cultural or spiritual practices.

The process of grieving is different for all who experience a loss. There is no correct way to grieve, nor is there a timetable for how long the grieving process should last. Manifestations associated with grief are highly individualized and depend on numerous factors such as the nature of the loss, the circumstances surrounding the loss, the developmental age and personality of the individual who is grieving, and the individual's history of grief and/or depression. Intense feelings of grief over the loss of a loved one are generally believed to lessen over a few months, and to resolve—or at least partly resolve—within 1–2 years (Walsh, 2012). This timetable does not apply in every case, and if the grief becomes complicated in any way—for example, when a loss is especially sudden or traumatic—resolution and acceptance take longer. Different types of grief should also be considered, as these often coincide with the type of loss experienced.

Types and Sources of Loss

Everyone experiences various types of loss over the course of a lifetime. The three main types of loss are **actual loss**, loss that is identified and recognized by others, such as the loss of a spouse; **anticipatory loss**, which occurs when an individual knows a loss is coming, such as the impending

death of a friend or family member from a fatal illness; and **perceived loss**, which is felt by an individual but cannot be verified as a loss from outside—for example, loss of control or loss of self-esteem.

The source of the loss may impact the range of an individual's emotional responses. For example, individuals who have lost a limb because of amputation lose an aspect of the self. They may experience disturbance of body image, depression, loss of independence, and frustration as they learn to live without use of the limb. Loss of an aspect of self can be very similar to loss of a loved one, in that the individual must learn to function despite the loss. Loss of independence itself is a serious loss, and it may occur with the loss of mobility due to injury or with debilitating illnesses such as dementia or multiple sclerosis.

Many individuals, families, and communities cope with grief and loss that is related to military conflicts. Examples include the loss and grief experienced by families who lost a loved one in the terror attacks of September 11, 2001, and loss and grief associated with military deployment. The deployment of military personnel carries a number of consequences that may result in grief responses. Long-term absence of a deployed parent creates additional responsibility for the parent remaining at home and a sense of loss for the entire family, as well as fear for the safety of the deployed family member. When both parents are deployed, children may be relocated away from their childhood home and support systems to live with other relatives. Personnel returning with traumatic physical and mental injuries may have difficulty rejoining the family unit. Finally, death of a family member overseas brings great loss to a family.

Types of Grief

Grief presents itself in many different forms, ranging from anticipatory grief to complicated grief. Similar to anticipatory loss, **anticipatory grief** is grief that is experienced before the event occurs. This can occur in anticipation of the death of a loved one, or in response to the diagnosis of an individual's own terminal illness. For example, a man's wife has a terminal illness and is expected to live only another 3 months. He may experience anticipatory grief in advance of his wife's death, grieving for her while she is still alive. Not all individuals experience anticipatory grief. Despite many debates on the subject, no conclusive studies have proven whether anticipatory grief actually lessens the grieving process after a loved one has died.

Disenfranchised grief occurs when individuals cannot acknowledge their loss to others, typically when the loss is not one that is socially recognized (sometimes referred to as an *ambiguous loss*). Disenfranchised grief may result from the loss of a partner in a socially unrecognized relationship, the loss of a child due to abortion, the loss of someone from suicide or a drug overdose, or even the loss of a pet. When a loss is considered socially unacceptable, the individual grieving the loss may experience not only intense grief but also feelings of isolation. Unable to participate in culturally appropriate expressions of mourning, the bereaved may find it very difficult to resolve their feelings and responses to the loss.

Individuals who are unable to process their grief to a point of resolution may experience **complicated grief**. Complicated grief is generally not diagnosed until 6 months after a loss. If at this time the grief has not diminished, has become debilitating, and makes daily activities difficult or impossible, the grief may be deemed complicated. Some have proposed renaming this type of grief *prolonged grief disorder (PGD)*. The two terms are sometimes used interchangeably (Robinaugh et al., 2012).

Theories of Grieving

Different theories have been proposed to explain the grieving process. Typically, these theories identify different stages of grief. Grief theorists include Elisabeth Kübler-Ross, George Engel, and Catherine Sanders.

Kübler-Ross and the Five Stages of Grief

One of the first grief theorists, Elisabeth Kübler-Ross (1969), proposed five stages of grief: denial, anger, bargaining, depression, and acceptance. A psychiatrist, Kübler-Ross based her theory on work she did with dying patients, so some criticism holds that these stages cannot, therefore, be ascribed to those mourning the loss of another. Other critics contend that the stages of grief do not always occur sequentially, as Kübler-Ross described them; stages can overlap or occur individually (Buglas, 2010, p. 45).

Denial, the first stage of grieving, may serve to soften the initial blow of the loss. A small amount of denial early in the grieving process is healthy, as it allows individuals who have undergone a loss to retreat into themselves so as to eventually accept the loss more fully. Nurses working with patients in denial should not force their patients to accept the loss; neither should they reinforce the denial. Denial generally occurs for only a short time, as most individuals eventually begin to accept the loss in their own way, so nurses should be understanding and supportive.

Anger is one of the most difficult stages for all those involved. During this stage, bereaved individuals direct their anger toward anyone who is around them, sometimes without even the slightest apology. Patients who are angry in their grief over a significant loss may direct their anger at staff, nurses, and doctors. This behavior should not be taken personally, as it usually has nothing to do with the actions of the nurse, doctor, or staff member.

The third stage is bargaining. Those who are in this phase of grieving try to make a bargain, generally with a higher power (such as God, Allah, or Mother Nature), or even with a doctor, for more time. Kübler-Ross found through interviews with patients that this stage sometimes results from the individual's guilt over something from the past. A nurse can help during this stage by listening sympathetically to the patient's expression of fears and guilt.

Depression follows the bargaining stage. Depression, a profound sense of deep and penetrating loss felt during the grieving period, is part of the normal work of loss. Nurses support patients during this phase by encouraging and allowing them to express their sadness and sometimes simply by sitting with them silently as they work through these emotions on their own.

After depression, the final stage of the grieving process is acceptance. During acceptance the patient is free from anger and depression; this is not a happy stage, but one almost lacking in emotions. Generally, during this time, a terminally ill patient's family needs more support and comfort than the patient, who often experiences a decreased desire for visits from family and loved ones. At this point, the dying individual has fully accepted the loss and gone through the various stages of grieving in order to arrive at acceptance.

Engel and Sanders

Other theories about the grieving process describe similar experiences with grief, but focus on the individual grieving for the loss of another as opposed to individuals grieving the loss of their own lives. George Engel's (1964) theory describes six stages of grief: shock, disbelief, awareness, restitution, idealization, and outcome. Shock and awareness are very similar to Kübler-Ross's stages of denial and anger, while restitution, idealization, and outcome deal primarily with the acceptance and understanding of the loss.

The work of Catherine Sanders (1998) focuses on the five distinct phases of grief: shock, awareness, conservation, healing, and renewal. The phases of shock and awareness resemble Kübler-Ross's stages of denial and anger, during which the patient is still working to come to terms with the loss. In the conservation/withdrawal phase, the individual begins to feel depressed and weakened from the loss, needing time to work through the emotions. Healing and renewal are the final stages, during which the emotions associated with grief begin to abate, and the individual is left with a feeling of acceptance.

Manifestations of Grief

Normal grief reactions are difficult to define, as all individuals grieve differently, but in general it is normal to experience sadness, anxiety, guilt, anger, confusion, sleep disturbances, and loss of appetite, among other reactions. The amount of time these emotions last varies. Typically, however, the intense feelings of grief begin to dissipate over the first 3–6 months following the loss, resurfacing on holidays, birthdays, and other important reminders of the loss. When grief becomes complicated, the intense emotions begin to impact the individual's ability to carry out daily activities. Similarly, these forms of grief may begin to affect the individual's health through loss of appetite, extreme depression, and sleeplessness. It is important for nurses to know the signs of different forms of grief reactions. Disenfranchised grief, described earlier, may result in a prolonged grief reaction, in part due to the individual's inability to mourn the loss in a socially acceptable way. Consider, for example, the case of a mother who gives up her child for adoption. Others do not know why she has made this decision, and individuals may assume that she did not want the child. Others are also likely to refrain from offering support or from asking questions, unsure how to treat the mother who is giving up her child. As a result, the birth mother may feel that society has told her she has no right to grieve the loss of this infant because she decided to give it up for adoption. Her grief may then become disenfranchised because

she cannot acknowledge her loss to others. It is critical that nurses provide both physical care and psychosocial support to patients experiencing disenfranchised grief. When a mother has released her child for adoption, the nurse might mention the adoption, letting the patient know she is free to talk if she chooses. Often, the nurse's willingness to listen without offering advice helps the patient greatly by allowing her a safe, nonjudgmental place to grieve. The nurse could also offer the birth mother an opportunity to hold the infant and say good-bye, thus allowing a sense of closure (Aloi, 2009, p. 30).

For the individual experiencing complicated grief, the grieving process does not progress. Instead, an overwhelming sense of grief persists and sometimes worsens over a period of months. The individual may experience profound emotions associated with memories of the deceased, along with an inability to accept the reality of the loss. Auditory and visual hallucinations are not uncommon for those experiencing this form of prolonged grief. In addition to these symptoms, bereaved individuals may become distrustful or uncaring toward others, forcing themselves into a form of self-imposed isolation. Complicated grief arises in approximately 6–25% of the bereaved, who still feel intense, disruptive grief for a prolonged period of many months, or even years, while typically grief begins to lessen in intensity within 3–6 months. In the first 6 months after a loss, an individual is expected to experience some of the same symptoms seen in individuals with complicated grief, such as extreme distress and an inability to function normally in day-to-day activities. However, if after 6 months these symptoms have not lessened and individual functioning is significantly impaired or the individual is at an increased risk for suicide, then complicated grief may be diagnosed. The earliest this diagnosis can be made is 6 months; however, many still debate about how much time must elapse before this diagnosis can be made (Robinaugh et al., 2012).

Factors That Affect the Grieving Process

When considering the process of grieving, it is important to take into account the nature of the individual's loss as well as the support system. The nature of the loss and the individual's current health and financial status affect the amount and type of support needed. A loss that impacts daily functioning, such as the death of an income-earning spouse or of a primary caregiver, results in a variety of consequences. Individuals experiencing this type of loss typically require greater support than those who experience the loss of, say, a distant relative or casual acquaintance. Similarly, individuals who experience ambiguous losses—such as perinatal loss, the death of a pet, or the death of an ex-spouse—require a wholly different form of support. In general, individuals seek support from those who were close to the deceased or from those who have experienced similar losses. Researchers have found that among participants in a study of the importance of social support during bereavement, the majority of respondents said it was

helpful to talk to others who had undergone similar experiences, or who could truly understand the feelings of the individual grieving. In the same study, many participants reported that whether or not they took advantage of professional support such as therapy, they were comforted by knowing it was available to them if needed (Benkel, Wijk, & Molander, 2009, pp. 144–145).

Cumulative loss is defined as several losses within a short period, one after another after another. The individual who experiences cumulative loss may not recover from the initial loss before the next loss occurs. Each loss has the potential to compound the grief of previous loss to the point where the individual becomes paralyzed with grief (Thompson, 2012). An example of a cumulative loss would be an individual who experiences the death of a friend, then a short time later experiences the death of a spouse, and soon after is diagnosed with a serious illness. The individual may not be able to fully grieve the loss of the friend when having to then cope with the loss of the spouse. The grief then could be compounded with the diagnosis of a serious illness when the individual is faced with his or her own mortality.

Age

Children who experience loss at an early age are at greater risk of an intense grieving period, especially children who lose a parent or primary caregiver. This risk increases further when the remaining parent or caregiver fails to recognize the child's grief and assumes that the child is too young to be affected by the loss. If children do not receive support and explanation after a substantial loss, they may view the loss as a betrayal, giving rise to feelings of guilt and anger. This reaction may result in the development of trust issues later in life (Walsh, 2012, p. 33). Children's grief responses can also be more complicated if the individual lost was physically or mentally abusive, or both. In such cases, especially young children may find it difficult to process the loss because, while there is a considerable amount of sadness, there might also be some relief that the abuse is over. The guilt that comes with relief at the death of a loved one is difficult to handle at any age, but particularly for a young child, especially if the child is unable to express these feelings.

Adults' reactions to grief and loss can become abnormal if the loss cannot be, or is not, acknowledged by others, or if extreme grief responses do not lessen after a substantial amount of time. The complicated or disenfranchised grief responses in adults have more to do with personality, circumstance, support systems, and other factors. By middle adulthood, loss and grief begin to be expected and accepted as a normal occurrence. Although losses are certainly not easy, they typically are processed in a healthy manner. Older adults may be at greater risk for a complicated grief reaction because their support system may have become limited as a result of past losses, including the death of close family members and friends and even children and grandchildren (Walsh, 2012, p. 72). For example, an older adult who has already lost her husband may be more likely to experience complicated grief if her child dies, as she finds

Source: KatarzynaBialasiewicz/iStock/Getty Images.

Figure 27-2 » An elderly widower mourns the loss of his wife and needs to learn to cook for himself and clean the house, tasks his wife handled during their 60 years of marriage.

herself without her partner to help her mourn the loss of their child. As described earlier, these cumulative, substantial losses may result in complicated grieving. Having a past history of numerous losses may make the grieving process harder for older adults, as a new loss may serve as a reminder of past losses.

Symbolic losses are also more prevalent among older adults; for example, older adults are more at risk than other age groups of losing their independence, their memory, and their mobility, as well as other significant assets. Symbolic losses may occur as a consequence of the death of a spouse or caregiver. For example, a husband with limited mobility may rely on his wife for transportation, cooking, and assistance with daily living. If she dies, the husband faces a number of losses in addition to mourning her death (**Figure 27-2 »**).

Gender

Gender often is a factor in grief when society or culture influences how individuals perceive the grieving process. In some cultures, men cannot show sadness or tears, whereas women are expected to do so. In other cultures, only men can attend funerals, while women must stay at home and grieve privately (Purnell, 2014). Grief reactions in general, though, cannot truly be understood or analyzed

based on the individual's gender alone. Factors such as age, personality, culture, family dynamics, and the nature of the loss must also be taken into account when assessing grief reactions.

Substance and Alcohol Abuse

Periods of grief and loss are very vulnerable times. Grief can have devastating effects that, if not acknowledged and dealt with, can result in various forms of self-medicating. Nurses encourage healthy coping mechanisms such as seeking counsel from support systems, seeking comfort from religious practices, going to support groups, and doing therapeutic writing. Unhealthy coping mechanisms can complicate grief, resulting in alcohol or drug use as a way to numb the pain of loss. The use of unhealthy coping mechanisms, including drugs or alcohol, can further prolong the grieving process. Because substance use only masks the pain and delays the work of grief, addiction may result quickly.

The signs of substance or alcohol abuse are not always easy to spot, especially in a patient who is going through a period of heightened grief. Some drugs used over a long period, or used in excess, can present in physical ways such as weight loss and a general physical deterioration. In situations where the nurse suspects alcohol or substance abuse, the nurse remains nonjudgmental and uses a therapeutic approach to ask how the patient has been handling the grief and adjusting to the loss. If patients admit to depending on alcohol or substances, the nurse can provide support and referral for the dependency and can also provide patient teaching related to healthy coping responses.

Resilience

Experiencing a loss, or many losses, can be a challenge for the individual to cope and recover. Resilience, in this case, is how quickly the individual can return to his or her normal state of being. Individual resilience depends on many factors. One impact on resilience is the cause of the loss. Those who experience loss unexpectedly or through trauma or violence may have more difficulty returning to normal than those who anticipate a loss due to illness (Boerner & Jopp, 2010). For example, a patient who must have an amputation because of a prolonged struggle with a non-healing wound will be more likely to cope than a patient who loses a limb in a car accident. Similarly, in the case of loss due to death, the relationship between the deceased and the bereaved can also be a factor in the individual's resilience in the situation.

The physical health of the individual at the time of loss can also affect resilience. A study found that bereaved spouses who were in good physical health were less likely to report somatic symptoms and/or depression after the loss of a spouse compared to those who were not in good health at the time of their spouse's death (Utz, Caserta, & Lund, 2012). Other factors that can influence an individual's resilience in the time of loss include mental and cognitive state, support systems, and spiritual strength.

Alterations and Therapies

Grief

ALTERATION	DESCRIPTION/DEFINITION	MANIFESTATIONS	INTERVENTIONS AND THERAPIES
Disenfranchised grief	The result of being unable to acknowledge a loss to others, generally because the grief is not socially recognized	<ul style="list-style-type: none"> ■ Hiding grief from others as opposed to allowing support from friends and family ■ Not seeking support after a loss because of feelings of shame, guilt, or lack of recognition of the loss ■ Intensified emotions associated with grief as opposed to those found in a normal grief reaction ■ More pronounced feelings of anger and depression due to resentment over the unacknowledged loss 	<ul style="list-style-type: none"> ■ Refer the patient to support groups that acknowledge the loss and feelings of grief. ■ Recognize and support the patient's right to grieve the loss. ■ Facilitate the patient's spiritual and cultural needs.
Complicated grief	Prolonged or intensified grief causing an individual to be unable to proceed with the grieving process	<ul style="list-style-type: none"> ■ Intense grieving for 6 months or more with little to no indication of grief resolution ■ Inability to proceed with daily activities after the loss ■ Visual and/or auditory hallucinations of the individual who has died ■ Growing distrust of friends and family members, making the individual seem cold or uncaring ■ Avoidance of places associated with memories of the deceased ■ Intense feelings of depression, at times accompanied by suicidal thoughts or tendencies 	<ul style="list-style-type: none"> ■ Psychotherapy ■ Monitoring for suicidal behaviors ■ Assessment for signs of alcohol and/or substance abuse ■ Appropriate referrals when signs of suicidal ideation and drug/alcohol abuse are present

Asking for Help

Depending on an individual's paradigm, as well as the views of society or an individual's culture, grief may carry a stigma. Neglecting to grieve or being unable to seek comfort and strength from support systems can lead to feelings of isolation. Nurses encourage patients to ask for help if they feel that the effects of loss are becoming overwhelming. Nurses also provide information about support systems and services available in the community. A strong support system can positively impact the grieving process.

vital signs, weight, and temperature, you notice that Mrs. Duncan has lost 15 pounds since her last visit 6 months ago. Her blood pressure and temperature are both normal. You observe that she looks exhausted and has deep circles under her eyes; the clothes she is wearing are at least a size too large. She also seems to be very distracted.

Clinical Reasoning Questions Level I

1. Why might Mrs. Duncan be having trouble sleeping?
2. What are some factors that influence an individual's grief response?
3. What additional questions would you want to ask Mrs. Duncan? Why?

Clinical Reasoning Questions Level II

4. Is Mrs. Duncan at risk for a complicated grief reaction? Explain your answer.
5. Do you think the doctor will prescribe medication for Mrs. Duncan's sleeplessness? What other interventions could be performed?

Case Study » Part 1

Josie Duncan is a 32-year-old woman whose 7-year-old daughter, Tasha, died 3 months ago after fighting leukemia. Mrs. Duncan took a week off from work after her daughter died and then returned to her job. She visits her primary care physician's office complaining of difficulty falling asleep over the past 2 weeks. After checking her

Concepts Related to Grief and Loss

Grief is an important consideration when working with end-of-life patients. Not only are these patients learning how to come to terms with the loss of their own lives, but also their families experience a variety of hardships during this time, from the financial burden of caring for the dying to anticipatory grieving. Nurses need to understand the grieving process in order to help end-of-life patients and their families work through grief. When working with grieving patients, it is equally important to obtain a full history in order to determine if those patients have a history of anxiety or depression, as these conditions can complicate or elongate the grieving

process. Patients who have experienced a traumatic loss, such as a perinatal loss or a death due to violence, or who have witnessed a death are at risk for developing posttraumatic stress disorder (PTSD) and should be made aware of the signs. Similarly, patients who have a history of PTSD have a higher risk of developing a complicated grief reaction later in life. When grief becomes overwhelming, some individuals turn to alcohol or other substances to numb their emotions. Masking the impact of a loss only serves to prolong the grieving process.

The Concepts Related to Grief and Loss feature links some, but not all, of the concepts integral to grief and loss. They are presented in alphabetical order.

Concepts Related to Grief and Loss

CONCEPT	RELATIONSHIP TO GRIEF AND LOSS	NURSING IMPLICATIONS
Addiction	Alcohol and substance abuse can mask the emotions associated with grief and cause a longer and sometimes more intensified grief reaction	<ul style="list-style-type: none"> Look for signs of alcohol or substance use as an unhealthy coping mechanism for grief. Teach the patient about health coping mechanisms. Maintain a nonjudgmental attitude. Refer to a specialist.
Comfort	Palliative care can help further the grieving process for both patients and their families, providing both physical and psychologic comfort.	<ul style="list-style-type: none"> Help dying patients to grieve for their own loss of life. Assist family members in understanding the signs of grief and acceptance of death. Provide referral to such assistance as hospice, support groups, and spiritual resources.
Culture and Diversity	Response to loss and the display of grief will be different from culture to culture. Culture also dictates how different family members, including males and females, are to respond to loss.	<ul style="list-style-type: none"> Be aware that grief and loss response is culturally influenced. Ask the patient how his or her cultural needs can be met during the time of loss and grief.
Mood and Affect	Situational depression is common in those who experience loss. Those effects may include feelings of extreme sadness, guilt, worthlessness, and other such emotions. Physically the individual may complain of fatigue, lack of appetite, and sleep pattern disruption.	<ul style="list-style-type: none"> Assess for suicidal ideation. Engage the patient in therapeutic communication. Provide resources for support groups. Refer the patient to a medical provider for evaluation and potential medications.
Nutrition	Those who are grieving often do not enjoy eating as they did previously. They are more likely to eat alone and eat less. Along with decreased caloric intake, bereaved people tend to have nutritional deficits as well.	<ul style="list-style-type: none"> Assess the patient for signs of malnutrition. Monitor the patient's weight. Obtain a 24-hour food diary and make recommendations based on the findings. Provide and teach a nutrition plan based on the patient's needs. Suggest nutritionally dense, small meals to help promote weight stability and to meet nutritional needs.
Spirituality	Grief and loss can have either a positive or negative impact on the patient's spiritual foundation.	<ul style="list-style-type: none"> Assess the patient's attitude and current state of spirituality. Refer the patient to a rabbi, priest, pastor, imam, or other spiritual counselor.
Stress and Coping	Existing anxiety disorders and PTSD can prolong or intensify the effects of grief.	<ul style="list-style-type: none"> Assess patient's anxiety level and trauma history. Assess history of losses and level of current functioning. Encourage patients who are already in treatment to continue their treatment plan and to communicate their loss to their provider.

Nursing Assessment

Assessment related to grief and loss should include exploration of the patient's current grief, as well as interviewing the patient regarding any past significant losses. Obtaining a complete history of any medical conditions is also necessary. A mental health assessment and information about current coping abilities should also be obtained. A complete nursing assessment also includes identifying the patient's cultural and spiritual needs.

Observation and Patient Interview

Assessment of the patient who has experienced a loss includes assessing the many factors that contribute to an individual's grief reaction, such as the patient's age, coping mechanisms, support system, history of previous losses, history of depression, culture, and personality. When conducting an assessment, be attentive to the patient's needs and maintain a nonjudgmental attitude. If the patient has an extensive history of loss, ascertain how the patient dealt with those losses and whether the patient has achieved resolution or acceptance of them. A sensitive and thorough assessment promotes openness and creates an environment in which the patient can feel safe in discussing emotions. The following questions may be included in the patient interview.

Current Loss

- When did the loss occur?
- What was the nature of the loss?
- Are you having trouble carrying on with your normal activities?
- Have you experienced any trouble sleeping or eating?
- Have you talked to anyone about the loss (for example, a spouse, friends, family, or counselor)?
- Are you taking any medications and/or antidepressants?

History of Loss and Grief Reactions

- Have you experienced similar losses in the past?
- Did your grief manifest in ways similar to those for your grief for this loss?
- Are you experiencing any unresolved grief?

Lifestyle

- Do you have an active support system?
- Do you drink alcohol on a regular basis?
- What types of coping mechanisms have you employed to work through your grief?

Physical Examination

Physical examination of the grieving patient should include a complete physical assessment. Patients may have somatic complaints, such as abdominal pain or headaches, that will need focused assessments. Other focused assessments include looking for signs of self-harm, self-neglect, and nutritional status. Evaluate the patient's hair, skin, and nails

for signs of malnutrition and wounds. Evaluate energy level, functional status, and mental status.

Assessing Family Functioning

Family bonds are often challenged when coping with loss. Some families are able to come together and grow stronger; other families become distant and detached. Assessment of the family unit is primarily an interview process. Questions to ask of family members include:

- What impact is the loss having on the family?
- What are the strengths of the family?
- What are the support systems of the family?
- What needs does the family have?
- How does the family perceive how they are coping?
- How are family members expressing their feelings?
- How is each family member's current health status?

» See the module on Family for more information regarding assessment of the family.

Spiritual and Cultural Considerations

Accurate assessment of the grieving process requires awareness of an individual's cultural influences. While it would be unreasonable to expect nurses and other medical professionals to know the practices and beliefs of every culture, in many cases valuable information can be gleaned during a simple patient interview. Understanding the patient's culture may also give meaning to her or his reaction toward professionals who offer assistance, particularly as certain cultural or religious practices view seeking help as undesirable. The nurse should avoid the tendency to view individual behaviors and cultural practices through a personal, ethnocentric lens. By not understanding other cultures, the nurse is at risk of deeming the traditions and practices of others as odd because they do not fit into the nurse's own expectations and experiences. In most settings, patient populations offer a diversity of cultural backgrounds. Respect for the practices of others is essential to building trust, establishing a relationship, and, ultimately, providing effective patient care.

Awareness of the patient's cultural beliefs and values can prevent miscommunication and conflict. For example, some cultures see death as a beginning rather than an end and choose to celebrate the individual's life on earth and the movement to the next life. Misinterpretation of cultural belief may lead clinicians to try to promote coping mechanisms that may not have meaning to the individual patient. It is important to understand that patients view death and grief from their own perspective.

Mourning practices vary widely among cultures and religions. Some mourn openly and in public, while others mourn at home for a set period before moving back into society. In the Jewish faith, for example, followers practice the tradition of shivah, a 7-day mourning period during which the closest family members—such as parents, siblings, and spouse—stay together to mourn their loss and

Grief and Loss Assessment

ASSESSMENT/METHOD	NORMAL FINDINGS	ABNORMAL FINDINGS	LIFESPAN OR DEVELOPMENTAL CONSIDERATIONS
Loss Assessment			
Ask about previous losses. Discover the different types of losses, as well as their frequency.	Experiencing a number of losses is normal at almost any age. In the first few months after the loss, sadness, sleep disturbance, loneliness, and intermittent periods of decreased motivation or activity are to be expected.	<ul style="list-style-type: none"> ■ Inability or unwillingness to process the loss ■ Denial of the loss for a prolonged time ■ Inability or unwillingness to discuss the loss ■ Accumulation of losses with little to no resolution ■ Grief that interferes with daily functioning and lasts 6 months or longer should trigger additional assessment. 	<ul style="list-style-type: none"> ■ Children are likely to process losses differently from adults; it should not be assumed that they do not understand loss because of their age. ■ Older adults are likely to develop numerous losses over their lifetime, and these can begin to have a cumulative effect.
Grief Assessment			
Assess patient's current and past grief reaction. Determine the nature of the loss causing the grief.	Grief is intense over the first 2–6 months after the loss and then begins to lessen. Resolution/acceptance generally occurs within 1–2 years after the loss.	<ul style="list-style-type: none"> ■ <i>Complicated Grieving</i> ■ <i>Grief related to traumatic loss</i> ■ <i>Grief related to disenfranchised loss</i> ■ <i>Post-Trauma Syndrome</i> 	<ul style="list-style-type: none"> ■ Children and older adults are at a high risk for complicated grief. ■ Older adults are at high risk for depression. Loss of a spouse or caregiver may impact independence and requires additional assessment and referral.

receive visitors. Other cultures may emphasize the need to continue with normal activities, such as school or work, during the mourning period, in place of taking time away to mourn privately.

Similarly, cultural and religious practices are important to a patient who is dying. If a patient has specific spiritual or religious requests, such as seeing a priest or a rabbi or having ceremonial traditions performed by an elder of the religion, nurses and other staff should facilitate these requests whenever possible. Those who practice Catholicism, for example, believe the dying person should receive the Sacrament of the Sick (sometimes referred to as Last Rites) in order to receive God's grace before death. Some requests have greater impact on nursing and clinical staff than others. As part of Jewish practice, if the person dies on the Sabbath, the body cannot be removed from the place of death. This means the body cannot be removed from a hospital room until Sabbath is over. Some cultures and religions have ritualistic cleaning of the deceased by same-gender attendants. In those cases, opposite-gender nurses should not prepare a body for the morgue. Even more so, some faiths do not want those who are not of the faith to touch the deceased. When a Muslim person dies, the body is typically prepared for burial by Muslims of the same gender (Purnell, 2014), and nurses should limit the amount of contact with the deceased.

Case Study » Part 2

Mrs. Duncan tells you that she has been working a lot since her daughter died because she needs something to occupy her mind. For the last year of Tasha's life, Mrs. Duncan spent all of her free time taking Tasha to doctor appointments and treatments; now that Tasha is gone, Mrs. Duncan does not know what to do with her spare time. She reports that her appetite decreased before her daughter died, and she has not really had any desire to eat since then. Lately Mrs. Duncan has not wanted to see any of her friends because they act differently around her; they also have children, and Mrs. Duncan admits she does not want to be around children right now. She reports her sleeplessness started 2 weeks ago, shortly after the Christmas holiday. She and her husband tried to celebrate, but they felt it was not the same without their daughter. Mrs. Duncan admitted that she does not think her husband understands how upset she is over their loss.

Clinical Reasoning Questions Level I

1. Why was Mrs. Duncan's appetite poor before her daughter died?
2. What are two nursing diagnoses that apply to Mrs. Duncan?

Clinical Reasoning Questions Level II

3. Based on what you know about grief and loss, why do you think Mrs. Duncan began to experience sleep disturbances after Christmas?

4. How would you characterize Mrs. Duncan's support system? Is it strong, moderate, or weak? Explain your answer.
5. Do you think Mrs. Duncan is working through the grieving process, avoiding grief, or both? Justify your answer using data from the case study.

Independent Interventions

When an individual is grieving, it is sometimes hard to know what to say or do, and nurses may find themselves reluctant to pose questions that patients may see as an invasion of their privacy. It is important to know that there are many ways to offer a patient support and a forum to discuss any difficulties (**Figure 27-3** »). Open-ended questions, such as asking how the patient has been doing since the loss or what challenges the patient is facing, may be effective for engaging the patient in discussion. Once the patient begins to speak, the nurse should use active listening techniques to show full engagement in the interaction. Body language also conveys the nurse's engagement in the conversation. A nurse's body language should be open and attentive, and when possible, both individuals should be positioned so they are at eye level with one another. (See the exemplar on Therapeutic Communication in the Communication module for a discussion of active listening techniques.)

Implementation of the patient's care depends on a number of factors, including the nature of the loss, the patient's health, the patient's use of coping mechanisms, and the patient's personality. Interventions helpful in working with adults and older adults who are grieving include:

- Teach the patient about the grieving process and its general progression.
- Discuss the benefits of different forms of therapy, as well as the differences between modes of therapy such as group therapy, psychotherapy, and one-on-one therapy.
- Inform the patient about the warning signs of intense depression and/or suicidal thoughts.

Source: KatarzynaBialasiewicz/iStock/Getty Images.

Figure 27-3 » Finding the time to talk with patients and actively listening to their concerns is an important component of nursing.

- Teach the patient about healthy coping mechanisms as opposed to unhealthy coping mechanisms.
- Provide a judgment-free area for the patient to discuss experiences and fears about grief.
- Encourage the patient to share emotions and fears with close family members or friends.
- Provide referral to resources that can assist the patient to maintain as much independence as possible.

Anticipatory Grief

With anticipatory grief, the individual begins to grieve before the actual loss occurs. For example, a family member may start the mourning process when given the news that another family member has a terminal condition. Sometimes, individuals complete the grieving process before the loss occurs and, as a result, become detached. As in the previous example, the family member of the individual who is diagnosed with the terminal illness may complete mourning for the individual before he or she has died. The family member may seem distant to the dying individual, causing isolation and loneliness for the terminally ill individual. The nurse can help both the family member and the dying individual with coping strategies for anticipatory grief. It is important for the nurse to educate those close to someone dying about the dying process. Likewise, the nurse can also promote healthy relationships between the dying and family members.

Helping the Patient to Cope with Death

The dying individual can be a hallmark example of someone experiencing anticipatory grief. Just as others will, the dying patient will experience stages of grief. The nurse can apply techniques and strategies for those experiencing the loss of their life just as others will be experiencing the loss of a loved one.

Preparing for one's own death is certainly a process that will be as unique as the individual. Some patients will embrace death as relief from their pain and find peace in death; others will be fearful of death and find despair. The nurse working with dying patients has a primary goal of providing comfort. This comfort is not exclusive to physical comfort: the nurse should help the patient cope in a holistic manner. Patients might feel a variety of things, including social distress, psychologic distress, and/or spiritual distress, along with physical distress (Hospice and Palliative Nurses Association, n.d.).

Some might find talking with a dying person awkward or uncomfortable. Acknowledging these feelings is important for the nurse to address. From there, the nurse should let the dying patient lead the conversation (Canadian Virtual Hospice, 2015). The nurse can offer support and provide care that the patient directs. If the patient expresses spiritual distress, the nurse can collaborate with a spiritual counselor; if the patient requests to relief from pain, the nurse can provide comfort measures. During these conversations with the dying patient, the nurse should always be honest regarding the patient's health status unless this is not culturally acceptable (some cultures do not believe in telling a person he or she is dying).

Coping with the Loss of a Patient

All nurses will encounter death of a patient at some point in their practice, although nurses in care settings such as oncology, hospice, the emergency department, and intensive care units will experience patient deaths with some frequency. Nurses are not immune to the effects of grief over the death of a patient. All nurses, but especially those who work with terminally ill patients, should assess their own needs to grieve and process a loss. If they do not, they could easily experience compassion fatigue, a type of burnout that occurs with emotional draining from caring for others, particularly dying, traumatized, and vulnerable patients (Boyle, 2011).

Nurses not accustomed to working with dying patients should also assess their own feelings regarding death. Peters et al. (2013) found that nurses who have strong anxiety regarding death tend to be more uncomfortable with caring for the dying patient. Nurses who are not comfortable with the topic of dying may not be prepared when confronted by a patient who is dying and in need of support. When this happens, nurses may cope by encouraging the patient or family member to talk about something else. While this may seem more conducive to the patient's happiness, it can be detrimental to the patient's overall well-being. Similarly, the nurse who is uncomfortable with the topic of death may try to avoid the topic by providing the patient with false hope, saying things such as "You are going to be fine; don't worry." This type of false reassurance is not beneficial to either the patient or the family (Berman & Snyder, 2016). Nurses need to honestly assess their own feelings about death and handle them properly so as not to impose these feelings on the patient. For example, a nurse who is obviously anxious about and fearful of death can make a patient more fearful of death.

When working with a patient who has a terminal illness, or a patient who has been fatally injured, it is easy for a nurse to form a bond with this individual. These bonds can result not only in normal feelings of grief, such as sorrow, but also in feelings of guilt, as nurses sometimes wonder if they could have done more to help their patients. In such cases, it is important that nurses acknowledge and process their feelings of guilt rather than ignore them. Similarly, nurses should seek support for any grief they may feel at the loss of a patient (**Figure 27-4**)). Resources for support may include coworkers, professional therapists or social workers, and grief counseling resources offered through employers. It is important that nurses make time to seek and find the support they need to process their own grief in a healthy manner. In acknowledging and processing their grief over a patient's death, nurses will be better able to help future patients and their families through the processes of death and grief.

Collaborative Therapies

Collaboration may include facilitating meetings between the hospital chaplain and the patient or the family, or requesting a referral to a social worker who can provide expert guidance about coping with loss or assist with linking patients with additional resources. Group therapy, bereavement

Figure 27-4 » Nurses need to express their own grief in a supportive environment after a child's death. Sharing with colleagues the sadness and grief or futility of resuscitation efforts often helps nurses provide supportive care to the next family who needs it.

groups, and grief therapists can all be resources for patients who have experienced a loss. **Hospice** is an organization that provides end-of-life care for patients either in their homes or in a hospital setting. Area hospice programs also provide an array of other services, depending on the community resources available.

Treatment of complicated grief is often in the form of psychotherapy targeting specific symptoms related to the disorder. Physician Katherine Shear (Shear et al., 2005) developed Complicated Grief Treatment (CGT), a form of psychotherapy administered over 16 sessions in accordance with a published manual that describes this treatment. According to Shear, healing from a loss is composed of a loss-oriented process and a restoration-oriented process. During the first process, the individual accepts the loss; during the restoration process, the individual begins to move on to a life without the deceased (Robinaugh et al., 2012, p. 32). CGT has been shown to be helpful to patients on its own, but some have used it in combination with antidepressants. While recent studies have shown that antidepressants may be helpful to those with depression related to grief, they do not appear to be as effective for patients with complicated grief. However, combining the use of antidepressants with CGT has proved to be quite effective in helping patients to work through their grief.

Medications

Antidepressants

CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION	NURSING CONSIDERATIONS
Antidepressants <ul style="list-style-type: none"> ■ Selective serotonin reuptake inhibitors (SSRIs) ■ Serotonin and norepinephrine reuptake inhibitors (SNRIs) ■ Tricyclic and tetracyclic antidepressants <p>Drug examples: Escitalopram, fluoxetine, sertraline, duloxetine, doxepin</p>	<p>May be used to treat the symptoms of moderate or severe depression as the result of grief or loss.</p> <p>May also be used for:</p> <ul style="list-style-type: none"> ■ Treatment of complicated grief in conjunction with psychotherapy 	<ul style="list-style-type: none"> ■ Monitor for signs of suicidal thoughts. ■ Teach patients about risks associated with specific antidepressants. ■ Monitor for signs of allergic reaction. ■ Monitor for signs of drug interactions.

Pharmacologic Therapy

If pharmacologic interventions are appropriate, antidepressant medications may be prescribed. Although impaired sleep patterns may be associated with grieving, medications to promote sleep usually are not indicated for these patients. In addition to the addictive potential of certain pharmacologic sleeping aids, these medications may be used to mask the patient's grief response, which can prolong the process. If these medications are prescribed, the patient should be carefully monitored for signs and symptoms that they are being used to blunt the emotional impact of grieving.

Nonpharmacologic Therapy

Finding support sources is one of the primary ways that the nurse can provide nonpharmacologic therapy for the person experiencing loss. Support can come in many forms, including support groups, family support, community support, faith community support, and individual counseling. The nurse can also provide support to the individual.

Complementary health approaches, including stress management techniques may be helpful. Those grieving might find comfort in gentle exercise, such as yoga and tai chi. Others might find massage and healing touch helpful. Aromatherapy might also be a useful tool to use for coping.

Case Study » Part 3

Before the doctor talks with Mrs. Duncan, you discuss her complaints of sleeplessness and weight loss with him. You also inform him of Mrs. Duncan's difficulties since her daughter has died. After the doctor talks to Mrs. Duncan, he recommends that she consider talking with a grief counselor about the loss of her daughter. He also recommends that she try to eat more, and that she begin exercising at least three times a week—even if she only goes for a 10-minute walk. Mrs. Duncan and the doctor agree that she should try a combination of counseling, a healthy diet, and exercise before they consider the possibility of pharmacotherapy. Mrs. Duncan schedules a follow-up appointment for next month.

Clinical Reasoning Questions Level I

1. Why do you think the doctor recommended exercise?
2. What are some of the benefits of grief counseling?

Clinical Reasoning Questions Level II

3. Do you think Mrs. Duncan's grief reaction is normal after the loss of a child? Explain your answer.

4. Why did the doctor not prescribe pharmaceutical sleep aids immediately? What are some risk factors associated with taking controlled substances while grieving?
5. Do you think Mrs. Duncan has demonstrated healthy coping mechanisms for dealing with her grief?

Children's Grief Responses

Children and adults experience grief differently, and manifestations of grief vary across the lifespan (**Figure 27-5** »). Children do not generally show or express their emotions regarding loss as openly as adults. Because young children may not express their grief in a way that is expected by an adult, they are sometimes believed to be too young to fully recognize the loss. However, this is not always the case. The child may be grieving in his or her own way and sometimes expresses this grief after the loss through art, imaginary games, playing, or behavioral changes. Behavioral changes, such as decreased socialization, irritability, and confusion, may occur more frequently in adolescents than in very young children (Walsh, 2012). Losses experienced by

Figure 27-5 » Children who experience the death of a parent may be concerned about losing their other parent as well. Nurses can help by inviting children to talk about their grief and answering questions they may have.

children that may result in grieving include any of the following: loss of parent, grandparent, or sibling; loss of a pet; loss of a relationship with a parent due to divorce; loss of a childhood friend or mentor; and loss of support systems if the family relocates to another city or country.

Children's grief responses vary depending on a number of factors, most notably the child's developmental stage and the significance of the loss. When caring for a grieving child, it is important to remember that cognitive development greatly influences grief response. While young children have the capacity to understand loss to some degree, their grief is displayed in ways that differ from grief reactions seen in other age groups. Children also experience **death anxiety**, which manifests as feelings of fear and/or apprehension connected with death.

Developmental Stage

Children grieve differently at different stages of development. Quite a few similarities exist as well. Grief responses in children across the developmental stages are often behavioral: The child acts out emotionally or physically in one way or another.

Worden and Silverman (1996) proposed four tasks that help children adapt to loss:

1. Accept the loss and its permanence.
2. Experience the emotions associated with grief, such as anger, fear, sadness, guilt, and loneliness.
3. Adjust to daily life without the individual who has been lost.
4. Come to see the relationship with the deceased as one based on memories in place of continuing experience.

During the first task, the child must come to understand the loss. In the case of a death, the child must understand that the one who has been lost will not return. Many childhood movies, television shows, and books involve storylines in which an important character dies but is then magically brought back to life. Although a child may intellectually understand that this is not possible, the desire for the return of the individual who has been lost may be so great that it is easier for the child to believe that the individual will come back in some way. Although the child should not be forced to accept the death, nurses and other caregivers can explain and reinforce the reality that the beloved individual is not returning. During the second task, children experience emotions similarly to those of adults as they grieve loss. Nurses support children in this task by encouraging emotional expression and by helping parents to understand that these expressions are normal and appropriate. It also is helpful for adults to recognize that emotions can be triggered long after the loss by holidays, birthdays, or other special events. The third and fourth tasks of this model take time to process and accept (Howarth, 2011, pp. 23–24). Adults can help children in these tasks by listening, by helping children adjust to changes in routines, and by encouraging activities that promote new memories.

Age 2–4

Children age 2–4 cannot yet fully comprehend or express the ideas associated with loss. At this stage, they also see death

as temporary or even reversible, believing that the individual or pet who has been lost will come home again. Reaction to grief at this age can also result in changes to sleeping and eating habits, as well as regression in the area of toilet training. Other habits also may change in reaction to loss; for example, the child may lose interest in normal activities or may crave more attention and affection. This type of behavior often manifests as the child becoming clingy or screaming when not being held. When dealing with loss at this age, it is best for caregivers to respond to the child's changes from grief by trying to maintain as normal a routine as possible. Similarly, providing extra reassurance and attention can also be helpful. It is easy to believe that children at such a young age do not understand the concept of loss or death, but they most certainly do notice and understand when change occurs. Therefore, it is important for parents to provide honest answers to questions about grief when they are asked.

Age 5–7

At this stage, children still view death as reversible. It is common during this age span for children to think of death as another place; according to this thinking, the loved one is still alive but has moved to a place the child cannot reach. Other common thought processes at this age revolve around feelings of guilt or blame. In the case of the death of a loved one, a child may fear having caused the death, especially as a result of negative thoughts about the individual or engaging in some type of misbehavior just before the death. Feelings of responsibility such as these are referred to as *magical thinking* and are quite normal in this stage of development. Children at this age may or may not verbalize these feelings, so parents or caregivers are advised to discuss the loss honestly and help the child realize the loss is not the child's fault. A child experiencing grief at this age may also act as though nothing has changed—this is a common reaction for children at this stage and is not by itself cause for alarm.

Grief responses for children age 5–7 may include changes in eating and sleeping patterns, as well as an increase in nightmares. It is also quite normal for the child to be concerned that other important individuals may die as well. Some children express these fears verbally, while others express them through artwork or even writing. Parents and caregivers can help children with reassurances about their safety and well-being, and also by inviting children to talk about their grief or ask any questions. It is best for adults to answer questions simply and honestly, providing the child with further explanations when needed.

Age 8–11

From around age 8 to age 11, children begin to understand that death means the individual is gone and will not be coming back. During this developmental stage, children become more curious about death and what happens after people (or pets) die. As in the previous developmental stage, children in this age group also tend to believe their thoughts or misbehaviors could be the cause of a loved one's death. It is common for a child to feel that the death of a loved one is a form of punishment for some misbehavior. Grief responses

Figure 27-6 » Teenagers lay flowers on the casket of the victim of a drive-by shooting.

at this stage are typically behavioral and may involve becoming more aggressive, acting out in school, or misbehaving at home, or the child may respond by becoming more withdrawn and engaging in solitary activities.

Age 12–18

By the time children reach adolescence, they are more capable of understanding the abstract idea of death. During this time, children stop believing that their thoughts or behaviors can result in the death of others. Adolescent grief responses are very similar to those of most adults, and they may display a wide range of emotions, including depression, denial, and anger. It is very common for individuals in this age group to direct grief-related anger toward their parents. Adolescents should be encouraged, but not forced, to voice their feelings about the loss. Sometimes individuals in this age group feel more comfortable talking to peers or those outside the family (**Figure 27-6** »).

Significance of the Loss

The significance of a loss impacts the child's grief experience. For many children, their first encounter with loss is the death of a pet; regardless of the type of pet (fish or dog, cat or hamster), the loss carries meaning for the child. With the death of a pet, the child may react with an abbreviated grief response and, depending on age, ask a number of questions. For more significant losses, though, such as the death of a parent, grandparent, sibling, or friend, a child's grief response is likely to be much more developed.

Death of a Parent

Approximately 2.5 million children in the United States lose a parent before the age of 18 (Howarth, 2011, p. 21). In many ways the death of a parent, especially for a young child, is one of the most devastating losses the child will experience. The death of a parent is not only the loss of an important person; for many children the death results in the loss of an entire way of life. Children depend on their

parents or caregivers for almost everything, from their home, meals, and security to their sense of love and belonging. When a parent dies, children sense that all of those things are threatened. Children are very habit oriented, and a parent's death brings chaos and confusion to their daily routine. The death of one parent also puts numerous different stresses on the other parent, and the child may not receive as much attention or discipline as before. Depending on the developmental stage of the child, the death of one parent could also introduce profound fear that the other parent will die soon as well. This sense of impending loss can stimulate a great deal of anxiety for the child. How the surviving parent or guardian handles the adjustment period after the death has a large impact on how the child copes with the loss. Many children are said to adjust to a parent's death after about a year, but a large percentage still experience changes in behavior, such as social withdrawal and problems with schoolwork, well beyond the first year.

Death of a Grandparent

The death of a grandparent generally is one of the first significant losses children experience. How a child handles the death depends on the child's relationship with that grandparent. For example, if the child has met her grandfather only once because he lives in another state and does not visit often, the impact of the loss will be far less than if the grandparent has lived with and helped raise the child. In this case, the impact of the grandparent's death is similar to that of a parent dying. Children who realize the significance of the grandparent's relationship to their own parent may become concerned about the possibility of losing their parents.

Death of a Sibling

In many ways, the loss of a sibling can be as traumatic as losing a parent or primary caregiver. Siblings often spend much of their childhood together, and they share experiences and relationships with loved ones. For siblings who share a bedroom, the connection is intensified. At a minimum, the death of a sibling generates questions about mortality; related concerns may lead to fear and worry. If unaddressed, fear and worry may cause behavioral problems, developmental regression, and a heightened fear of anything the child believes may be harmful. Depending on the developmental stage of the child, feelings of guilt and confusion may also be associated with the death of a sibling. Children from ages 2 to 11 (and especially ages 2 to 7) often indulge in a certain amount of magical thinking, believing that their negative thoughts or wishes could be the cause of another's death. This type of thinking is particularly difficult in connection with siblings, as most siblings fight from time to time—so if a child's sister dies, he may believe that his mean thoughts toward her were the cause of her death.

Death of a Friend

Similar to the death of a sibling, the loss of a friend causes difficulties for children because it is the death of someone

their own age. When a parent or grandparent dies, children often fear for the surviving adults; however, when another child dies, children fear for themselves and their friends. This fear can affect the child's sense of security in the world. If a child becomes friends with a schoolmate who is terminally ill, parents can work to prepare the child for the loss. If the death occurs suddenly, however, there is no time to prepare, and parents and caregivers should work to assure children of their safety.

Other Losses

Like adults, children experience losses other than death that can trigger a grief response. Parental divorce alone can be a significant loss, but it is further complicated if the divorce results in the child's separation from the noncustodial parent by a great distance. Similarly, deployment of a parent serving in the military or other parental absence creates a loss for the child and other family members. Moving can result in loss of school friends, teachers, and other support systems. Long-term or severe acute or chronic illness or injury may result in lifestyle modifications, loss of a limb or body part, or loss of independence. Children experiencing these losses need as much support as, and sometimes more support than, children who experience the death of a loved one.

Complications

Children can experience complications in the grief process as the result of circumstances surrounding the loss, or the significance of the loss. When children experience a significant or traumatic loss, they need a very strong support system to help them work through their feelings of grief, which are most likely difficult for them to understand. Children who do not receive the support they need are at an increased risk for developing a grief reaction that has been complicated in some way.

Children and adolescents who lose a parent are also at risk for premature death. A European study found that parental death, particularly those parents who die of traumatic or unexpected causes, was associated with early death of the child in young adulthood (Li et al., 2014). This may be attributed to genetic predisposition, impact on health caused by loss of a parent, and social well-being.

Complicated Grief Reactions

Loss of an abuser can lead to development of a complicated grief reaction. In such circumstances, feelings of grief are mixed with a sense of relief at knowing the abuse has ended. Regardless of age, coping with mixed emotions related to the death of an abuser presents serious challenges. For children, who lack the cognitive ability to fully understand death, the impact is even more complex. Furthermore, if the abuse has been hidden, the child's experience can be even more confusing. The child who is grappling with mixed emotions observes the others involved in mourning the loss. With no confidantes, the child has no one with whom to discuss the conflicted feelings. This need to hide emotions related to grief due to feelings of guilt or shame can result in a complicated grief reaction.

Box 27-1

Childhood Exposure to Trauma and Violence

Unfortunately, children are witnesses to trauma and violence on a frequent basis. Approximately 39% of children age 1–17 have witnessed violence, with 48% of those having multiple exposures to violence (Finkelhor et al., 2013). These violent events include bullying, assault, sexual assault, and maltreatment. Children are also witnesses to traumatic events such as accidents and fires. For more information on child and adolescent responses to trauma, see the module on Trauma.

Childhood Traumatic Grief

Childhood traumatic grief is a grief reaction to the traumatic death of an individual who is important in a child's life or to witnessing a traumatic event (**Box 27-1** >>). In addition, the child may find it traumatic to see a beloved individual's body after death. The child may associate thoughts of the beloved with the circumstances of the death and be unable to separate the beloved from the event (Finkelhor et al., 2013; Mannario & Cohen, 2011). This type of grief reaction results in both trauma and grief symptoms for the child. The child may begin to avoid activities that the child associates with the trauma. For example, if the child's mother died in an accident on the way to the grocery store, the child may associate riding in the car or going to the grocery store with death. Furthermore, the child may experience learning difficulties, behavioral issues, and mental health difficulties (Child Traumatic Stress Network, n.d.).

Not all children who witness trauma or violence, or lose a loved one to accidental death, develop traumatic grief. In fact, the majority of children recuperate from the loss with no lasting effects (Mannario & Cohen, 2011). However, those who do develop traumatic grief also often develop other mental health issues, including PTSD, depression, anxiety, and/or behavioral problems (Mannario & Cohen, 2011).

Clinical Manifestations

When children encounter death, they often do not grasp the idea entirely. As a result, their minds often work to protect them from the overwhelming feelings caused by grief. In some cases, children may not even react to loss outwardly. There is nothing wrong with this reaction: Their minds may act to protect them from experiencing emotions for which they have no point of reference. When children do react, though, their reactions often revolve around behavioral changes, which may include emotional and behavioral regression.

Behavioral Responses to Grief

Behavioral responses to grief vary depending on developmental age, temperament, and other factors already mentioned. Behavioral changes following loss may be immediate or may occur over an extended period of time. A child's behavior change often presents in one of two ways: withdrawal or acting out. Some children are more withdrawn at home but act out more frequently at school. The responses depend on the child. Some who withdraw will be quieter

than usual and seem shy around others. Their primary method of play may be in activities they can do alone, such as drawing, reading, or simply engaging in solitary play. In rare cases, a school-age child may revert to total silence, refusing to speak to anyone. If this behavior goes on for an extended period, a doctor or therapist should be consulted.

Some children may respond to grief with anger and aggression. Anger typically is directed toward the individual who has passed away or at the loss itself but often is taken out on family, friends, or teachers. Other responses may involve trouble eating and sleeping or an overall feeling of anxiety. Adolescents who are grieving may turn to alcohol, tobacco, or drugs as a method of coping with the loss.

Watching a child's behavior change drastically after an individual has died can be terrifying for a parent or guardian. Nurses work to assure parents that the changes they are seeing in their children are a normal response to the loss and that each individual grieves differently. Nurses and other clinicians encourage parents to allow children to express their grief, either verbally or artistically, and provide parents with information about warning signs of unhealthy coping. For example, preoccupation with thoughts of death, engaging in dangerous activities, and drug or alcohol use are considered unhealthy coping mechanisms.

Cultural Considerations

How children handle their grief at the loss of a loved one is greatly influenced by the cultural or spiritual practices of the child's immediate family. For example, children may be raised to believe that someone who dies goes on to an afterlife. Other cultural traditions believe that an individual's soul is reincarnated in a new body after death. Some practices teach that no existence of any sort continues after death, and that death is simply the end of life (Spector, 2017). Nurses take the cultural and spiritual traditions of patients into consideration, especially when speaking to children about grief. For example, if a child's father has told her that the individual who has died will now be reincarnated in a new existence, and another individual who is not familiar with the family's culture tells the child that this individual is now in heaven, the child will most likely be very confused. The nurse who is unaware of a family's beliefs should avoid inadvertently imposing his own belief system on the child. Similarly, if the family has decided not to offer any explanation of an afterlife or lack thereof to the child, that is the parents' decision, and the nurse should not use spiritual beliefs to help the child work through her grief.

Collaboration

In most cases, childhood grief progresses naturally and in a healthy manner with the help of supportive family members and friends. Young children's minds are equipped to protect them from experiencing the full range of grief all at once and for prolonged periods. This is one of the many reasons children grieve differently from adults. When faced with a challenge that is beyond their emotional capacity, young children have defense mechanisms that allow them to compartmentalize the event. As a result, the child can focus on play or daily activities, as opposed to being overwhelmed.

Young children experience intense grief for short periods before their mind moves on to another focus (National Cancer Institute, 2013). In some cases, however, parents or guardians need to work with medical professionals to help their child process grief.

Pharmacologic Therapy

In most cases involving a child who is having difficulty working through grief, nonpharmacologic options such as therapy or group counseling are effective. Few pediatric patients will require pharmacologic intervention. Those who do need intervention for complicated grief typically have underlying mental health issues, such as anxiety (Melhem et al., 2007). Few studies have been done on the effectiveness of pharmacologic intervention for complicated grief in children and adolescents. Pharmacologic therapies can keep children from developing their own coping and healing mechanisms and may therefore cause problems later in life. In addition, many medications used as pharmacotherapy for extended grief responses must be tapered slowly. Parents or guardians should be informed of all the side effects of these medications so that they can make an informed decision. If cognitive-behavioral therapy and other nonpharmacologic interventions are given a significant trial and still prove ineffective, and if the child is at an increased risk for hurting himself or others, low doses of antidepressants and/or antianxiety medications may be suggested (Melhem et al., 2007). However, use of antidepressants may increase risk for suicidal ideation and behaviors in some children and adolescents, and this information should be provided to parents before they make a decision to begin antidepressant therapy (Potter & Moller, 2016). If the child is prescribed antidepressants, regular follow-up appointments should be scheduled for at least the first 12 weeks after beginning the medication. Antidepressants should also be used in combination with nonpharmacologic options to help the child work through grief and eventually move on to acceptance.

Nonpharmacologic Therapy

Individual sessions with a therapist or participation in a bereavement group can help children work through a difficult loss. Children's bereavement groups often include activities involving drawing, writing, or other forms of arts and crafts. During these activities, the child may be encouraged to draw expressions depicting how he feels about the loss. He may also be given the option of creating a scrapbook or a memory box about the individual who has died (Walsh, 2012, p. 113). Older children and adolescents may be encouraged to practice forms of writing therapy, which can involve keeping a journal about their feelings. Other activities in writing therapy include writing a letter to the deceased. In these writings, individuals are encouraged to be entirely honest without any fear of judgment from others or from themselves. The main idea behind this form of therapy is that writing about intense feelings of grief, pain, or trauma, will eventually cause the feelings to begin to subside. Many individuals are not comfortable talking about these emotions or thoughts and find it easier to express their emotions openly in writing. Therapeutic writing can also be

suggested for terminally ill children as a way to express their fears and uncertainties.

Nursing Care

The nurse assesses the child's and the parents' history of previous losses, coping skills, psychosocial supports, and cultural and spiritual practices and preferences. In the case of a pediatric or adolescent child experiencing grief from a recent loss, the overall health and reactions of the child should be assessed. Some families have difficulty talking about death, and the nurse needs to assess the ability of family members to support the child's grief responses. Additional parent education and referral may be necessary to help parents support their child as she grieves the loss.

Nursing interventions for childhood grief include providing emotional support for both the patient and family as appropriate.

For a child who is dying, comfort measures are essential. Some comfort measures are:

- Provide pain medication as needed to keep the patient comfortable.
- Involve parents by suggesting measures to help the child, including massages, warm or cool blankets as needed, singing, and reading.
- Allow parents to stay with the child as much as possible.
- Offer resources for any spiritual or cultural traditions requested by the child or family.

Some emotional support measures are:

- Encourage the child and family to ask any questions they may have.
- Educate the parents about the signs of impending death.
- Provide information about the normal coping mechanisms generally displayed during the developmental stage of the child.
- Assist in helping the parents find meaning in the child's death; this has been shown to help facilitate acceptance.

For more information, see the exemplar on End-of-Life Care in the module on Comfort, particularly the section on End-of-Life Care for Children.

For a child who is grieving the loss of a loved one or friend, appropriate nursing interventions include the following:

- Encourage the child to honestly express any feelings about the loss.
- Assure the child that it is normal to feel angry, sad, and even confused when someone dies.
- Educate the child and parents about some healthy outlets for childhood grief, such as drawing, painting, or writing to the deceased.
- Provide the parents with information about explaining death in an honest and age-appropriate manner.

Perinatal Loss

Perinatal loss is the death of an infant or fetus at any time from the point of conception to 28 days after birth. Perinatal

loss is a traumatic event for the infant's parents as well as other family members. In the past, some have proposed that perinatal loss results in less intense grief because the parents and family have not had time to form a close bond with the infant. This theory has since been proven incorrect. In fact, the grief associated with the loss of a child can be more intense than most other losses (Kersting & Wagner, 2012).

Causes of Perinatal Loss

Perinatal loss can be difficult for the mother both physically and emotionally. If the fetus is lost during the first 20 weeks of gestation, it is referred to as a **miscarriage** or a **spontaneous abortion**. This is a significant loss for the mother and should not be discounted for any reason. Loss of the infant after 20 weeks' gestation is known as **intrauterine fetal death (IUFD)** but is more commonly referred to as **fetal demise** or **stillbirth**. It is typical to assume that a stillbirth will produce a more difficult grief reaction for mothers. However, a study that looked at mothers experiencing miscarriages, stillbirths, and neonatal death found that the grief responses in the mothers were essentially the same (Kersting & Wagner, 2012). The grief response of fathers in perinatal loss has not been as well researched as that of mothers. What research has shown is that fathers do grieve like mothers, but with less intensity and for a shorter duration (Kersting & Wagner, 2012). In all cases, parents and other family members benefit from nursing care that provides a therapeutic presence and values parent and family statements and emotions (Potter & Moller, 2016).

The loss of a fetus while it is in the womb results from a variety of circumstances that can occur between conception and birth. These include biological conditions such as infection, an abnormality in the fetus, problems with the placenta, or accidents involving the umbilical cord. Environmental conditions also can contribute to, or cause, perinatal loss—for example, domestic abuse, motor vehicle crashes, or other accidents, such as a fall.

Miscarriage

One of the most common causes of miscarriage is **blighted ovum**, which occurs when the egg has been fertilized and both the membrane and placenta have formed, but the embryo has not formed. This condition sometimes results from chromosomal abnormalities in the fetus. Health conditions in the mother can also contribute to miscarriage—in particular, infections, hormonal problems, unmanaged diabetes, and thyroid disease. Other causes include drug and alcohol use, exposure to toxins, and smoking. Most miscarriages occur before the mother knows she is pregnant. Of pregnancies of which the mother is aware, approximately 15 to 20% will end in miscarriage, often around the 7th week of pregnancy (White, 2014).

Stillbirth

It may be impossible to know the reason for a stillbirth, even in the later stages of pregnancy. Some known factors that may contribute to and/or cause fetal demise include birth defects or chromosomal disorders, placental issues, infections, slow fetal growth, and umbilical cord problems.

Placental abruption occurs when the placenta detaches from the uterine wall before delivery. This condition does not always result in fetal demise, but the fetus's survival depends on the stage of development and prompt medical treatment. Umbilical cord abnormalities are relatively unusual, but if a knot in the cord occurs it could cause oxygen deprivation in the fetus. Another rare cause of fetal demise is **Rh disease**, where the mother is Rh negative and the child is Rh positive. If this condition arises, the mother's body sees the Rh-positive cells in the fetus as foreign and produces antibodies to fight off the Rh-positive cells. Rh disease results in the death of the fetus only in extreme cases.

Risk Factors and Prevention

Risk factors for perinatal loss include age, health conditions, and previous instances of perinatal loss. Increased age at the time of conception, particularly for women 40 or older, can increase the risk for complications during pregnancy. A woman's medical history also factors into the risk for complications. Generally having one past experience with a miscarriage or spontaneous abortion does not impact future pregnancies—depending on the cause—but past instances of multiple complications put a woman at higher risk. Similarly, contributing factors involving a weak cervix or other health conditions such as diabetes, obesity, or thyroid disease can lead to miscarriage or fetal demise (National Institutes of Health, 2013). The use of drugs, alcohol, tobacco, and/or caffeine increases the risk for pregnancy complications, as does exposure to harmful chemicals.

When fetal demise occurs and the mother does not go into labor naturally, labor is induced, or a cesarean section is performed. In cases of prolonged retention of the fetus, a condition known as **disseminated intravascular coagulation (DIC)** may occur. DIC is a disorder where the proteins controlling clotting of the blood become abnormally active, causing excessive clotting and then bleeding as available clotting factors are consumed. In addition to DIC, both infection and sepsis can set in if the dead fetus remains in the woman's womb for an extended period.

In the majority of cases it is not possible to prevent perinatal loss. As mentioned in the previous sections, many cases are circumstantial and/or biological and often cannot be detected until the miscarriage or fetal demise has occurred. The best prevention for parents is knowledge of factors that can compromise the mother's health. Women who are pregnant should avoid drugs, chemicals, tobacco, alcohol, and infectious diseases, as they may cause perinatal loss or other health complications for the fetus. Proper maternal care is also important, as some pregnancy complications can be caught early and treated before any harm is done to the fetus or mother.

Clinical Manifestations

The manifestations of perinatal loss involve both physical and emotional changes. The physical changes are either changes to the mother's body, including spotting, severe back pain, and cramping, or changes in fetal movement or heart rate. These manifestations indicate that something has occurred that could lead to fatal complications. After a peri-

natal loss, the parents and family of the infant experience various, and often intense, forms of grief.

Changes in Fetal Activity

Some warning signs of pregnancy complications can be detected through fetal movement or fetal heartbeat. Mothers can generally first detect fetal movement between 18 and 20 weeks' gestation. From this point onward, fetal movement becomes more regular and predictable, with the mother detecting the greatest movement while sitting or lying down. A significant decrease in or stopping of fetal movement before labor may be a sign of complications, such as the fetus's receiving too little oxygen. Mothers should be observant of fetal movements, but not overly anxious. A fetus that does not move for an hour may be sleeping. Similarly, during the last trimester of pregnancy, the fetus may not move as much as in earlier weeks. When a significant decrease in fetal movement is detected, the clinician checks the fetal heart rate. If the heart rate is abnormal or cannot be detected, an ultrasound is done to check for complications. If complications are found and the fetus is still alive, early delivery or a cesarean section may be performed.

Grief

The loss of an infant during any stage of pregnancy can be an extremely traumatic event for both parents, and intense feelings of grief are to be expected. The intensity and duration of this grief depend on the individual, but it should not be assumed that this form of grief resolves quickly simply because the parents have not yet established a direct relationship with their baby. Studies have shown very little difference between the intensity of grief felt when a close family member dies and the grief felt after a perinatal death (Kersting & Wagner, 2012).

Grief in cases of perinatal loss may be intensified by the circumstances involving the loss. Many factors impact the parents' ability to resolve their emotions, including how the loss occurred, how the parents learned about the loss, and if the loss could have been prevented. Perinatal loss may also have a stigma attached to it, as some believe that it is unnecessary to mourn the loss of a child whom the parents have never come to know or raise. Beliefs such as these may hinder the parents' grieving process. These emotions can be further complicated for the mother if she feels guilt associated with the loss, and/or if postpartum depression becomes a factor.

Disenfranchised Grief

The loss of an infant before, or immediately following, birth may result in disenfranchised grief. Perinatal loss is often not a socially recognized loss, particularly if that loss occurred in the early stages of pregnancy. Early miscarriages are generally not discussed except between the parents and healthcare professionals; in such a case, the grief is unacknowledged socially. Losses that occur in the early stages of pregnancy can be more difficult to grieve, as no funeral services or other formal mourning traditions are practiced (Kersting & Wagner, 2012). The result may be that the parents feel they have no right to mourn or feel grief over the loss of their child. Disenfranchised or complicated grief can

also occur if the pregnancy had to be terminated for health reasons. Many parents in this situation choose to tell friends and family that the loss of the child was due to miscarriage or fetal demise.

Postpartum Depression

Postpartum depression is a form of depression that occurs in the first few weeks after a child has been born. Many do not realize that postpartum depression can also occur in women who have sustained perinatal loss; in fact, two of the major risk factors for developing postpartum depression are experiencing complications during the pregnancy and sustaining a perinatal loss. The exact cause of postpartum depression is unknown, but the symptoms are similar to those of other forms of depression and may include anxiety, anger, difficulty concentrating, lack of enjoyment, feelings of inadequacy, sleeplessness or oversleeping, decreased or increase appetite, and suicidal thoughts (National Institute of Mental Health, n.d.). Experiencing these symptoms while trying to mourn the loss of a child can make both the grief and the depression worse. Women who are experiencing these emotions should be encouraged to discuss their thoughts and should be monitored closely for a worsening of symptoms.

SAFETY ALERT Mothers who have lost a child and develop postpartum depression should be closely monitored for signs of serious depression and/or suicidal thoughts. Signs of depression include loss of interest in once-enjoyable activities, alterations in appetite, fatigue, and unexplainable crying spells. Suicidal thoughts may be evidenced by intense periods of depression accompanied by statements such as “everyone would be better off without me,” or “I wish I was dead/had died instead.” Some mothers will make very frank statements like, “That child needs her mother.” Individuals contemplating suicide may also begin to give away items once valued, explaining that the items are not needed anymore.

Spiritual and Cultural Considerations

Parents who have lost a child may desire to speak with a religious or spiritual leader. Nurses can call for the hospital chaplain to meet with the parents or facilitate the presence of a spiritual leader of their choosing. If the infant is born alive but not expected to live long, the parents may want the child

Figure 27-7 » Religious rituals such as baptism and the blessing of an ill infant may provide great comfort to the family. When the infant is stable, a traditional baptism may be performed in the home or church with family and friends present. When the infant has a life-threatening illness, baptism may be performed in the hospital by a chaplain or health professional.

to be baptized or to receive a form of blessing as soon as possible, depending on their beliefs (**Figure 27-7** »). Nurses facilitate the family’s participation in these rituals.

Religious or spiritual beliefs may affect how the parents mourn the loss of a child. Patients of the Catholic faith may worry if their child was stillborn and therefore unable to be baptized, and this may cause considerable anxiety. Some members of the Jewish faith observe the practice that parents and family members are not to mourn for a child who has been alive less than 30 days, and so parents of these babies are unable to hold any traditional services or burials (Dickstein, 1996; Tessler, 2014). Some traditions, such as Islam, believe the child is instantly admitted into heaven. Others, such as Buddhism and Hinduism, believe the child’s soul will be reincarnated. Nurses should be respectful of patients’ beliefs and offer to meet any needs that arise.

Focus on Diversity and Culture

Perinatal Loss

Perinatal death is considered to be death of the fetus at 20 weeks or greater. The neonatal period is considered as the first 28 days of life. Perinatal and neonatal deaths continue to remain steady in the United States, with an average of 5.96 fetal deaths per 1000 live births (MacDorman & Gregory, 2015). The United States ranks 26 out of 26 industrial nations in infant mortality (MacDorman et al., 2014). Fetal mortality is highest in mothers who are either in their teens or older than 35, in mothers who are unmarried, and in mothers carrying multiple fetuses (MacDorman & Gregory, 2015). In terms of race, non-Hispanic Blacks have the

highest incidence of fetal death, with 10.53 per 1000 births, followed by American Indian or Alaska Natives with 6.22 per 1000 births. Mothers of Asian or Pacific Island race, and those of Cuban heritage, have the lowest, with 4.68 and 4.65 per 1000 births, respectively. Although the causative factors for the increase in perinatal deaths in non-Hispanic Blacks compared to other races have not been pinpointed, several possible causes include access to healthcare and prenatal care, maternal pre-conception, health, stress, income, infection, and cultural impact on pregnancy (MacDorman & Gregory, 2015).

Clinical Manifestations and Therapies

Perinatal Loss

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Miscarriage	<ul style="list-style-type: none"> Spotting Cramping Lower back pain 	<ul style="list-style-type: none"> Antibiotics if an infection results
Placental abruption	<ul style="list-style-type: none"> Back pain Uterine contractions Vaginal bleeding Abdominal pain 	<ul style="list-style-type: none"> IV fluids Blood transfusion Delivery of the fetus Antibiotics if infection occurs
Disseminated intravascular coagulation as a result of a retained fetus	<ul style="list-style-type: none"> Bleeding Blood clots Drop in blood pressure 	<ul style="list-style-type: none"> Delivery of the fetus Treatment of clotting Plasma transfusions, if needed Antibiotics if sepsis occurs

Collaboration

After a perinatal loss, tests can be performed on both the mother and the fetus to determine the cause of the fetal demise. Some parents refuse this testing for personal or religious reasons, and that decision must be honored. Parents who have lost a child may also need additional support in the coming months: A large-scale epidemiologically based study found that women experiencing a stillbirth or early infant death (within the first 28 days of life) are 4 times as likely as live-birth mothers to exhibit symptoms of depression and 7 times as likely to exhibit symptoms of post-traumatic stress 9 months after the loss (Gold et al., 2016). Although many support groups and bereavement counselors can be recommended, this study suggests the need for follow-up after discharge, particularly for African American mothers, who were less likely to seek treatment for depressive or post-traumatic stress symptoms (Gold et al., 2016). Members of the interprofessional team caring for mothers experiencing perinatal loss should assess for resiliency factors, including support systems and access to follow-up care. Nurses should provide or ensure referrals for counseling and other resources are made before discharge.

Diagnostic Tests

A series of tests are available to determine the potential cause of fetal demise, but often it is impossible to determine the exact cause. After delivery, with the parents' consent, the fetus will undergo blood tests and placental tests, x-rays and MRIs, as well as chromosomal studies. These tests are done to determine a possible cause of the pregnancy complications and generally include an autopsy. Mothers also undergo a series of blood tests. These tests check to see if the mother has diabetes or thyroid disease, or if she has contracted any infectious disease that could have affected the fetus. A Betke-Kleihauer test may also be performed to check the mother's Rh antibodies to deter-

mine if Rh disease was a contributing factor. These tests can help the parents to know of possible similar problems with future pregnancies.

Pharmacologic Therapy

Depending on the circumstances surrounding the fetal demise, medications may be administered to treat the mother for any infections or complications. If a placental abruption has occurred, the mother may need IV fluids as well as a blood transfusion if the blood loss is substantial. In cases where the fetal demise goes untreated and the dead fetus is retained, disseminated intravascular coagulation may result, which requires treatment for the clotting, possible plasma transfusions, and treatment for sepsis, depending on how long the fetus has been retained. The mother may also need antibiotics if diagnostic tests indicate the presence of infection.

The mother is at risk for developing postpartum depression within the first 4 weeks after a perinatal loss. If this depression becomes overwhelming, especially in combination with the grief, two pharmacologic therapies may be recommended: antidepressants and hormone therapy. Antidepressants have been shown to be effective in the treatment of postpartum depression and can be used in combination with other forms of therapy and counseling. Hormone therapy, in the form of estrogen replacement, may help to dispel some of the symptoms of postpartum depression, but research on this treatment is sparse. Women should be made aware of the risks and benefits of all treatments so they may make an informed decision.

Nonpharmacologic Therapy

The grief resulting from perinatal loss can be intense and even overwhelming. Mothers may feel unnecessary guilt, believing that they, or their bodies, failed in some way and led to the infant's death. Intense grief and even feelings of guilt are entirely normal after the death of an infant and may last for a few weeks or possibly a few months. These emo-

tions generally lessen on their own, but if they do not, or if the parents require further support, various forms of therapy can be helpful. Group therapy in cases of perinatal loss may be useful, or it may be more painful, depending on the patients. Some patients may find it therapeutic and reassuring to talk to other parents who have lost an infant, while others may see it as disorienting and painful to share others' experiences of such a traumatic event. In these cases, individual grief counseling is preferable.

Lifestyle changes may also assist mothers experiencing postpartum depression and grief. In place of isolation, mothers should seek out a strong support system after the loss; sharing their feelings about the loss as well as any trauma experienced has been proven to help prevent or alleviate any PTSD (Sutan et al., 2010). Physical activity and proper nutrition can also help to lessen the effects of depression.

Nursing Care

Perinatal loss can occur at any point in a pregnancy for a multitude of reasons. Mothers who are suspected of having sustained a perinatal loss should be evaluated immediately. A fetal heart monitor can be used to check the heart rate of the fetus. If a heartbeat cannot be found, an ultrasound should be done to determine if fetal demise has occurred. The safety of mother and fetus takes priority; if the assessment determines that the fetus is in distress, immediate action is necessary.

Following confirmation of fetal demise, the parents are informed. Institutional policies vary with regard to when parents are notified of fetal demise. In some cases, the parents are not informed until after the delivery. It is important to adhere to institutional policies and procedures.

The nurse begins assessing the parents' needs and resources as well as planning for needs that will arise during delivery. The nurse assesses the parents' spiritual needs by asking if they would like to speak to the hospital chaplain or if they would like the presence of another spiritual leader. Nurses also collaborate with social workers or grief counselors to provide further assistance to the parents after the birth.

Caring for Parents

When parents are admitted with a possible perinatal loss, they should be put in a private room as far away from the other mothers as possible. If it is determined that perinatal loss has occurred, the privacy provided is likely to benefit both parents. Once tests are performed and perinatal loss is confirmed, parents are informed of the test results and encouraged to ask any questions they may have. Nurses should allow parents time to process their grief before asking about the mother's birthing preferences. When the parents have indicated that they are ready to discuss the birthing process, the nurse should explain what will happen in the delivery of a stillborn infant; the parents should also be informed about the methods of inducing labor, if induction is to occur. The mother's birthing preferences determine how the birth takes place. Nurses consult her regarding how the room should be lit, who she would like in the birthing room with her, if she would like relaxing music playing, and what position she would prefer to give birth in. The moth-

er's comfort and understanding are an important priority for a nurse during the birthing process.

Before the child is born, the nurse should establish when and if the parents would like to see the infant. Parents should be gently encouraged to see the infant for their own sense of acceptance. If the parents wish to see the infant, the nurse should prepare them for how the child may look. For example, if the child is not fully developed, if the child is slightly blue or yellow from complications, or if the child is deformed in any way, the parents should be told before viewing the infant. It is important for nurses to respect parents' wishes if they would like time alone with the infant. The nurse also consults the parents to determine if they would like to take home keepsakes of the child, such as a picture, a lock of hair, or foot- or handprints.

After the birth has taken place and the parents have seen the infant, the nurse should again ask if they have any questions. The nurse assures both parents that any questions they may have are normal, even if the parents feel their questions are odd or morbid in some way. The nurse provides time and space for the parents to express their feelings, being careful to address feelings of guilt by explaining that most cases of perinatal loss cannot be prevented. Nurses provide information on discharge regarding the need to report any signs of infection, such as fever, chills, or dizziness. Nurses also make referrals for grief counseling and other sources of support the parents may require.

Caring for Siblings

If possible, the nurse should encourage parents to include siblings in the process of grieving for a stillborn baby. Siblings should be able to experience their newborn brother or sister, even if the infant is dead. Studies have shown that siblings who are able to experience the deceased brother or sister are able to mourn the death with less traumatic results (Avelin et al., 2012). In addition, having the older sibling create memories, such as taking pictures with or holding the deceased, also helped the older child cope with the loss. Children, however, should not be forced to hold, touch, or otherwise experience a deceased sibling. Rather, the parents and nurse should let the living sibling lead the encounter (Avelin et al., 2012).

Older Adults' Responses to Loss

Older adults' responses to grief and loss can be intricate because of inherent factors unique to this age demographic. Older adults are defined as anyone 65 years of age or older. At this point in life, the older adult has more than likely accumulated a number of losses, both symbolic and actual. This accumulation may compound any new grief felt by the individual: A new loss may bring up grief from one or more previous losses.

Sources of Loss

Grief and loss as experienced by older adults can be more complicated than at other ages. A single death may trigger multiple losses. For example, a woman in the early stages of Alzheimer disease may be able to live in her home while her husband is in good health. When he dies and she moves in

with one of her children, her loss of independence may accelerate or she may experience relocation syndrome and a worsening of her dementia (see the exemplar on Alzheimer Disease in the module on Cognition for more information on relocation syndrome). Older adults also begin to lose friends and acquaintances in their age group, and as that happens they begin to anticipate their own death as well as the death of their partners (Walsh, 2012).

Losses associated with aging are varied and may include loss of independence, loss of mobility, loss of health, and loss of memory. Unfortunately, these create a misperception among some younger adults that aging brings frailty and deterioration of mental function. These misperceptions are considered a form of **ageism**, which involves forming stereotypes about older adults. Nurses must guard against such misperceptions. Many older adults live active, healthy, fulfilling lives.

Older adults are at greater risk of depression following significant real or symbolic losses. Depression in older adults is rarely the result of only one factor. Among the most common causes of depression in this population are the death of a loved one, loss of independence, illness, and isolation and loneliness. Untreated depression can worsen and is very serious. It can lead to the prolonging of other illnesses, and even to suicide. Unfortunately, death by suicide continues to be a factor in the aging population. Statistics show an increase of suicide in the geriatric population, 65 to 74 years of age, both men and women (Curtin, Warner, & Hedegaard, 2016). It should be noted there has been a slight decrease in suicides in those older than 75 years of age in the years 1999–2014 (Curtin et al., 2016). Grief is a powerful emotion, particularly when coupled with other losses. Older adults should be assessed for signs of serious depression and suicidal ideation, especially after the loss of a spouse or other loved one.

SAFETY ALERT Suicide in older adults is commonly the result of untreated depression. In the past, the chronic underdiagnosis of minor depression in older adults led to high suicide rates—particularly in men. Nurses in all settings should assess for signs of depression, even if it appears minor, and then assess for increased risk of suicide.

Clinical Manifestations

Manifestations of grief in older adults may be more profound than those observed in younger patients. Accumulating losses in combination with existing health conditions and medication side effects may contribute to a complicated grief reaction. As a result, grief in older adults that may present as a response to the loss of a single person, object, or freedom may actually be a reaction to numerous losses that have accumulated over time. How older adults handle loss depends on the circumstances of the loss, as well as the overall health of the individual—both physically and mentally.

Grief initially presents in older adults much as it presents in younger adults; anger, sadness, longing, disbelief, and depression may be present. The duration and intensity of these emotions vary from patient to patient. Older adults may seem to experience the emotional aspects of

grief more acutely than younger adults; for example, older adults may show pronounced and overwhelming feelings of anger or sadness in response to a death. It also is common for older adults—particularly those living alone—to respond to intense grief by neglecting their own needs. Eating habits, personal hygiene, and health maintenance may fluctuate during periods of bereavement. Nurses need to be particularly observant of these changes in regular nutrition, hygiene, and health, as they indicate that patients are not taking care of themselves and may need additional support.

Patient's History

In working with older adults who are experiencing grief, it is important to inquire about other recent losses, as well as any present health concerns such as dementia, Alzheimer disease, or a history of depression or suicide attempts. If a patient has recently experienced a number of losses, a common experience for older adults, the accumulation of these losses can be overwhelming. When assessing the span of loss in older adults, it is important to consider all losses. For example, the loss of mobility, the loss of independence, and even the loss of a beloved pet can all contribute to feelings of overwhelming grief.

For patients with dementia or Alzheimer disease, the death of a loved one is very complicated. The affected patient may have been told about the individual's death and been emotional, but may then have forgotten that this individual has died. Even in the early stages of Alzheimer disease, newly learned information is often forgotten quickly. A patient's loss of memory of a loved one's death can be hard on the nurse and/or the patient's caretaker, as the individual may ask to see the loved one who has died. Similarly, the patient may become very upset because the deceased has not come to visit. If the patient were to be reminded daily of the loss, then he would experience fresh grief for the individual who had died. With the progression of Alzheimer disease, the grieving process becomes virtually impossible as it constantly requires time to accept and process the loss.

Complicated Grief

Complicated grief in older adults manifests in feelings of unrelenting preoccupation and yearning resulting from the loss, experienced over an increased duration of time (at least 6 months or more). Memories, even those that are happy, elicit strong emotions, which may be coupled with an avoidance of familiar places or individuals who trigger thoughts of the deceased or regret for the loss. Patients may also manifest trust issues, suspecting once close friends and family members of judging their pain or not understanding their emotions. Because of these feelings of judgment or betrayal, the patients may appear distant and even uncaring. This may be especially true of older adults who have experienced a loss of independence or mobility. Nurses need to be observant of the progression of grief in older adults. If symptoms intensify or affect the patient's overall health, appropriate assessments and interventions need to be made. Signs of intense depression should also be monitored, as complicated grief and depression are often comorbid disorders (Robinaugh et al., 2012).

Spiritual and Cultural Considerations

Many older adults find deep meaning in their religious or spiritual beliefs and practices, possibly because they grew up during a time when religious practices were more widespread than they are today. Religious and spiritual practices can provide comfort for patients and their families. If the patient is in a nursing home, hospital, hospice, or an extended care facility and is working through grief, nurses should inquire if the patient would like to participate in any specific form of religious practice. Nurses should assist patients in meeting these needs when possible.

Sometimes, patients experience a disruption of their spiritual beliefs and/or values. This is known as spiritual distress. Rather than turning to religion in times of grief or loss, the patient may question or express anger toward the higher power or faith-base as to why the loss occurred. Nurses can encourage patients to regain a sense of spirituality. The nurse can guide the patient to address her spiritual distress, refer the patient to a spiritual leader or chaplain, and meet the patient's spiritual need requests when feasible. Those patients with a strong sense of spirituality have better coping mechanisms with serious illness, including less depression and better quality of life (Puchalski, 2012).

Collaboration

Older adults experiencing significant losses may require support in a variety of areas. Nurses must assess their need for support carefully. Patients might find it helpful to talk to others who have had similar losses, or they might want to

speak individually with a professional therapist. Some patients may need referral to a social worker to learn more about means of financial support, including financial assistance with groceries or housing. Some patients may require pharmacologic therapy.

Pharmacologic Therapy

Two conditions involving grief may require pharmacologic therapies: depression and complicated grief. While many studies have been done regarding antidepressants in the elderly, studies regarding the use of antidepressants for treatment of complicated grief in the elderly are sparse (Shear, 2015). Treatment of depression begins with assessment to determine the underlying cause of the depression. Most of the time depression can be treated quite effectively through nonpharmacologic therapies, but if these prove ineffective, antidepressants may be used. Antidepressants should be used with caution in older adults, however, as various other medications have adverse reactions with some forms of antidepressants. Similarly, some conditions that are particularly prevalent in older adults—such as diabetes, dementia, and heart problems—can be made worse by antidepressants (Wiese, 2011; Wilson, Shannon, & Shields, 2017).

Treatment of complicated grief sometimes involves antidepressants, generally in the form of SSRIs. Some of the common SSRIs used are escitalopram, paroxetine, and nortriptyline. These are used in combination with Complicated Grief Treatment, as they have not proved effective when used alone to treat complicated grief (Robinaugh et al., 2012). Both escitalopram and nortriptyline are mildly contraindicated for use in older adults and are to be used with caution; similarly, paroxetine may cause negative side effects in patients with heart disease (Wilson et al., 2017). Older adults who are prescribed antidepressants for grief should be monitored closely for any side effects or complications.

Nonpharmacologic Therapy

Treatment of grief in older adults can be successful without medications. Group therapies can be quite effective, as they can be a means of support that the individual may be lacking, as well as a place where the patient can discuss any concerns in a judgment-free setting. This type of therapy can also be particularly helpful, as it introduces the patient to other individuals who have experienced the same loss and who may be having similar grief responses. For some patients, group therapy may not be a good option, but individual therapy may be helpful. Complicated grief is generally treated with a form of psychotherapy called Complicated Grief Treatment, a type of therapy in which the individual focuses on relationships and personal goals (Wetherell, 2012). Those who participate in Complicated Grief Treatment respond more quickly and have better outcomes than those using other therapies (Shear et al., 2005; Wetherell, 2012). Support groups have also proved effective in the treatment of complicated grief in older adults.

Focus on Diversity and Culture

Loss Among Older Adults

Nurses practice culturally sensitive care by assessing patients' cultural and spiritual beliefs and practices and incorporating them into the care plan appropriately. This aspect of nursing is particularly important in work with older adults experiencing loss. Culturally sensitive care requires assessing each individual patient's and family's beliefs and practices. Traditionally, however, certain cultures have had particular beliefs regarding the care of elders in the community (Purnell, 2014; Spector, 2017):

- Those who uphold traditional Asian cultural beliefs have a great respect for older adults and are expected to take care of their parents if they need assistance in later life.
- Muslims are instructed by the Qur'an to honor, respect, and care for their parents as they age. It might be considered dishonorable for an older Muslim adult to be placed in a retirement or nursing home if a child or grandchild is still available to see to the patient's care.
- In many Native American traditions, elders are considered the keepers of wisdom and knowledge. In some tribes, the care of the elderly is not just by immediate family, but also by extended family and community members.

American families of European descent are often scattered throughout the United States. Family members are sometimes faced with having to place an elderly relative in an assisted living or nursing home situation in order to provide care. Some American families bring the elderly family member into the home, but many times the elder is placed in a long-term care facility.

Nursing Care

Nursing care for older adults who are working through loss and grief requires a certain amount of sensitivity and understanding. Older adults may be reluctant to admit difficulty coping with grief, in part due to ageism and the stigma attached to conditions such as depression and dementia and mental health treatment. It is important for nurses to remember that, because of a patient's history with previous losses, a current loss that does not seem significant to the nurse may be very significant to the patient. Careful, holistic assessment is necessary for nurses to gain an accurate picture of the patient's care needs.

Nurses working with older adults who have experienced a loss and are subsequently grieving should complete a full assessment of the patient's history—both physical and mental health—as well as an assessment of the patient's coping mechanisms. Older adults, especially older adult men, are at a

particularly high risk for both depression and suicide, so the nurse should assess for signs of depression. The patient's support system should also be evaluated. Studies have found that the stronger the support of the patient, the quicker the return to normalcy. If the patient has been grieving for 6 months or more and the grief has not lessened, or has significantly increased, then the nurse should assess for signs of a complicated grief reaction. Collaboration with social workers can be quite helpful when working with patients who are grieving.

The nurse should provide the patient with assistance involving spiritual or cultural needs. If the patient would like to attend religious services or talk to a pastor, rabbi, or other spiritual leader, then the nurse should help to facilitate these needs. Similarly, the nurse should try to help the patient who mentions finding comfort in religious or spiritual texts, but not having access to them. Nursing interventions to assist older adults in coping with loss and grief are outlined in the Independent Interventions section earlier in the module.

Nursing Care Plan

Loss of a Parent by a Pediatric Patient

Justin Ferris, an 8 year-old boy, is brought in to his primary care provider's office by his father. Since Justin's mother died 8 months ago after a motor vehicle crash, Justin has been very withdrawn and

quiet. In the last 2 weeks, he has stopped eating regularly, and his sleeping habits have been irregular.

ASSESSMENT

Mr. Ferris tells Justin's primary care nurse, an RN named Fatima Forez, that Johnny has been acting very strangely since his mother died. He has stopped playing with his regular friends or with anyone else. Justin has also been very quiet, only speaking to others if he is required to. The school has reported that Justin's grades have been declining. At first, Mr. Ferris thought Justin was experiencing normal grief reactions, but 2 weeks ago he stopped eating almost entirely, and he has been sleeping only a few hours a night.

Ms. Forez checks Justin's vitals and discovers that his blood pressure and temperature are both normal. When she checks Justin's weight, Ms. Forez notices that he has lost 7 pounds since his last visit 2 months ago. When Ms. Forez asks Justin why he has been having trouble eating and sleeping, he refuses to answer the question and looks down at the floor instead.

After discussing Justin's case with his primary care provider, Ms. Forez recommends that Justin start seeing a grief counselor once a week for help working through a probable complicated grief reaction.

DIAGNOSES

- *Complicated Grieving* related to psychosocial conflicts associated with coping with the loss of a parent
 - *Imbalanced Nutrition: Less Than Body Requirements* related to loss of appetite secondary to grief and feelings of guilt
 - *Disturbed Sleep Pattern* related to unexpressed emotions
 - *Ineffective Coping* related to complicated grief reaction
- (NANDA-I © 2014)

PLANNING

Goals for Justin's care include:

- The patient will keep weekly appointments with grief counselor.
- The patient will eat at least one full meal per day and eat whenever he feels hungry.
- The patient will regain a relatively normal sleep schedule.

IMPLEMENTATION

- Teach about complicated grief reactions.
- Explain the benefits of grief counseling.
- Emphasize the importance of eating to maintain and increase weight.

EVALUATION

Justin begins going to grief counseling every week. His therapist works with Justin to develop healthy coping mechanisms to work through his emotions and grief. Justin starts to get his appetite

back, and his sleeping habits begin to improve. After 2 months of grief counseling, Justin goes to his follow-up appointment; his weight and disposition have returned to normal.

CRITICAL THINKING

1. If Justin had not improved after 2 months with a grief counselor, how would you change the nursing care plan?
2. What resources could the nurse provide to Justin's father other than individual grief counseling to help with Justin's needs?
3. What role could a school nurse play in Justin's recovery in collaboration with the primary care nurse?

REVIEW The Concept of Grief and Loss

RELATE Link the Concepts

Linking the concept of grief and loss with the concept of violence:

1. You are caring for a 25-year-old woman who has sustained a perinatal loss as the result of domestic abuse. Describe at least four factors that put this patient at a high risk for a complicated grief reaction.
2. An 8-year-old boy has been physically abused by his father until 2 months ago, when the father died suddenly. What nursing interventions would be appropriate for this boy's grief? How could his history of abuse make the grief more difficult?

Linking children's response to loss with the concept of development:

3. While assessing a 4-year-old whose mother died 2 years ago, you find the child has some small delays in developmental milestones. Why might this have happened?
4. What interventions can you initiate to help this child meet future developmental milestones?

Linking older adult's response to loss with the concept of mobility:

5. What are your goals for the older adult patient who has lost the use of his or her legs?
6. Create a plan of care for an older adult patient who lives alone and is wheelchair bound.

REFLECT Apply Your Knowledge

Carol Iverson, a 56-year-old woman, lives in a rural town with her husband, James. Their only child, James Iverson Jr., a Marine, was deployed in the Middle East where he was killed by an explosive device. While his remains were able to be returned to the family for burial, his casket was sealed. The community provided a hero's funeral with a great amount of support for Mr. and Mrs. Iverson and their extended family. However, within a few weeks, the town went back to its normal routine. Mrs. Iverson comes to the town's one health clinic 8 months later, complaining of lack of energy, little motivation, and poor appetite. She relates to the nurse that she hasn't had much closure with James Jr.'s death, even with the town's outpouring of grief. She reports that while her husband has been supportive, he too has gone back to his routine. She tells the nurse, "It seemed like everyone was there for me, and then the next minute, everyone was gone, just like James. I can't get over the last time I saw him, when he told me not to worry, and that he would be home soon. I believed him."

1. What would be a priority nursing diagnosis for Mrs. Iverson? What goals of care would be appropriate for her?
2. What factors play a role in Mrs. Iverson's grief response and possible development of complicated grief?
3. What would be the impact of resources for Mrs. Iverson living in a rural area versus an urban setting?

Module 28

Mood and Affect

Module Outline and Learning Outcomes

The Concept of Mood and Affect

Normal Mood and Affect

28.1 Summarize the characteristics of normal mood and affect.

Alterations to Mood and Affect

28.2 Differentiate alterations in mood and affect.

Concepts Related to Mood and Affect

28.3 Outline the relationship between mood and affect and other concepts.

Health Promotion

28.4 Explain the promotion of healthy mood and affect.

Nursing Assessment

28.5 Differentiate common assessment procedures and rating scales used to assess mood and affect.

Independent Interventions

28.6 Analyze independent interventions nurses can implement for patients with alterations in mood and affect.

Collaborative Therapies

28.7 Summarize collaborative therapies used by interprofessional teams for patients with alterations in mood and affect.

Lifespan Considerations

28.8 Differentiate considerations related to the assessment and care of patients with alterations in mood and affect throughout the lifespan.

Mood and Affect Exemplars

Exemplar 28.A Depression

28.A Analyze depressive disorders and relevant nursing care.

Exemplar 28.B Bipolar Disorders

28.B Analyze bipolar disorders and relevant nursing care.

Exemplar 28.C Postpartum Depression

28.C Analyze postpartum depression and relevant nursing care.

Exemplar 28.D Suicide

28.D Analyze the nurse's role in preventing and responding to patient suicide attempts.

>> The Concept of Mood and Affect

Concept Key Terms

Adjustment disorder with depressed mood, 1914	Bipolar disorder, 1914	Euthymia, 1910	Moods, 1910	Postpartum psychosis, 1914
Affect, 1910	Circadian rhythms, 1915	Hypomania, 1912	Mood stabilizers, 1926	Seasonal affective disorder (SAD), 1916
Aggressive behavior, 1924	Depressive disorder with peripartum onset, 1914	Learned helplessness, 1916	Passive behavior, 1924	Serious mental illness, 1910
Anhedonia, 1912	Dysthymia, 1913	Major depressive disorder (MDD), 1913	Persistent depressive disorder, 1913	Serotonin syndrome, 1926
Anxious distress, 1912	Electroconvulsive therapy (ECT), 1928	Mania, 1910	Postpartum blues, 1914	Somatization, 1913
Assertive behavior, 1924	Emotions, 1909	Mental health, 1910	Postpartum depression, 1914	Unipolar depression, 1913
		Mental illness, 1910		

Emotions, mood, and affect are critical elements of the human experience in that they shape and reflect our perceptions of and interactions with the world around us. Although often used interchangeably, each of these terms refers to unique psychosocial attributes (Ekkekakis, 2013).

Emotions are an individual's feeling responses to a wide variety of stimuli. An emotion is reactionary and linked to a specific event or object that can be identified by the person who is experiencing the emotion (Baumeister & Bushman, 2017). Emotions tend to be intense, focused, and relatively

short lived. Examples include joy, surprise, fear, anger, and disgust (Liu, 2015). Frequently, an individual's emotions precipitate certain physiologic responses, such as smiling, frowning, clenching fists, pacing, sweating, and increased heart rate. Although an individual may choose not to verbally communicate emotions to others, it is difficult to prevent nonverbal expression of emotions.

Moods are similar to emotions but are typically longer lasting, less focused on a particular object or event, and less intense. A mood might have one trigger, multiple triggers, or no specific cause at all. Because **mood** is an enduring state of mind rather than a discrete reaction, it can shape a person's general expectations about the future (Liu, 2015). Unlike emotions, moods do not produce observable physiologic reactions. Therefore, only the individual is capable of describing mood; nurses and other clinicians must be careful not to assume they know a patient's mood based solely on their observations.

Affect refers to an individual's automatic reaction to an event or situation—the immediate, observable expression of mood. Like emotion, affect is evidenced by verbal and nonverbal responses; however, emotion involves a person's **conscious** reaction to an object or event, whereas affect involves a person's **unconscious** response to something as either good or bad. Affective reactions occur faster than emotional reactions, sometimes within a few microseconds. Individuals do not need to understand or even be familiar with something in order to have an affective response to it (Baumeister & Bushman, 2017).

Together, mood and affect play a large part in determining an individual's **mental health**, defined as a state of well-being in which an individual is able to work productively, cope with change and adversity, engage in meaningful relationships, and realize his or her own potential. Alterations in mood and affect can disrupt an individual's ability to accomplish one or more of these tasks. When these alterations are severe enough to have lasting detrimental effects on a person's life, they may rise to the level of mental illness. **Mental illness** can be defined as a condition that affects emotions, thinking, behavior, or any combination of the three. Mental illness is not typically confirmed until the individual experiences serious and lengthy impairment in the ability to function (American Psychiatric Association [APA], 2013).

This module explores the concept of mood and affect and provides exemplars that facilitate an understanding of impaired mood and affect. Both depression and bipolar disorder are classified as **serious mental illnesses** that increase the possibility the individual will experience serious dysfunction related to daily functioning and ability to achieve life goals (Potter & Moller, 2016). Information related to assessment of individuals with alterations in mood and affect, collaborative therapies, and nursing care is also provided.

Normal Mood and Affect

Defining or describing normal mood and affect can be challenging for a number of reasons. For one, standards of desired or acceptable attitudes and behavior vary widely among cultures as well as among individuals. Also, nearly

Figure 28-1 » Range of mood states.

all individuals experience ongoing fluctuations in mood and affect in response to various biological, psychologic, sociologic, and cultural events and experiences (Potter & Moller, 2016).

In light of these complicating factors, mental health professionals typically describe mood and affect in terms of certain qualities rather than in terms of concrete categories of “normal” and “abnormal.” Mood, as depicted in **Figure 28-1**, is said to exist on a continuum ranging from **depression** (an abnormally lowered mood characterized by sadness, emptiness, and irritability) to **mania** (an abnormally elevated mood that impairs functioning). Between these two extremes lies **euthymia**, or a stable range of mood that is neither elevated nor depressed. Although euthymic individuals experience occasional fluctuations in mood (for example, happiness at achieving a life goal or frustration associated with a temporary injury), these fluctuations are appropriate to the situation, are typical of the individual's usual pattern of response, and do not impair functional ability. Accordingly, an individual's mood is said to be “normal” if it falls somewhere in the central or euthymic portion of the continuum (Potter & Moller, 2016).

When evaluating a person's affect, healthcare professionals focus on several characteristics. **Appropriateness**, or **congruence**, refers to affect that matches the individual's emotional state and the immediate situation (Stuart, 2014). **Range** refers to the variety of feelings an individual conveys through affect. Most people exhibit a broad or full range of affect, meaning they are able to convey many different feelings using verbal and nonverbal responses. **Broad affect** is therefore considered normal. In contrast, individuals with **restricted affect** express only a limited range of feelings. For example, a patient who weeps when describing his wife's illness but shows no sign of happiness or excitement when discussing the birth of his child may have a restricted affect.

Intensity describes the degree of emotion displayed in a person's affect. Normal intensity means that the level of emotion expressed in an individual's affect is proportionate to the situation. In contrast, individuals with flat affect display no visible cues to their feelings whatsoever. Intensity may be described as:

- **Moderate.** The individual displays a level of emotion that is appropriate to the situation.
- **Overreactive.** The individual's level of emotion is disproportionate or extreme given the situation.
- **Blunted.** The individual displays a level of emotion that is dulled or muted given the situation.
- **Flat.** The individual's affect provides no visible cues to his emotions.

Stability refers to how often and how rapidly an individual's affect fluctuates. A stable affect, or one that remains consistent when there is no provocation in the environment,

is considered normal. Conversely, a labile or rapidly changing affect is often suggestive of disease or disorder (Stuart, 2014). As illustrated by the preceding discussion, both mood and affect become dysfunctional when they are inappropriate to the situation, when they are out of proportion to the stimulus, and/or when they shift dramatically or rapidly out of proportion to external events.

Factors Contributing to Mood and Affect

Mood and affect are shaped by a number of internal and external factors, including neurologic function, personality, stress level, social interactions, day, time, gender, age, and illness status. Each of these factors is briefly discussed below, and several are visited in greater depth later in the module in the section describing various theories of depression. Other factors that may influence mood and affect are identified in the Concepts Related to Mood and Affect section and within the specific exemplars.

Neurologic Function

Emotions, mood, and affect all originate deep within the brain, in an interconnected set of structures called the limbic system. Three structures of the limbic system—the hippocampus, the hypothalamus, and the amygdala—appear to be particularly important in the production and regulation of mood and affect. Under normal circumstances, limbic system activity is regulated by a nearby area of the brain called the medial prefrontal cortex (MPFC). If the MPFC fails to function properly, the limbic system may become overactive, and alterations in mood and affect may result. This is evidenced by brain imaging studies that show increased activity in the limbic systems of individuals with alterations in mood. Studies also reveal that these individuals tend to have decreased gray matter volume and lower metabolic activity in the MPFC, which helps explain why this structure is unable to properly control the limbic system (Field & Cartwright-Hatton, 2015; Grieve et al., 2013).

The exact cellular mechanisms of normal function within the MPFC and limbic system remain unclear. The prevailing theory is that alterations in neurotransmitter activity and/or neuronal receptivity to neurotransmitters contribute to the development of mood disorders such as depression and bipolar disorder (as described later in this module). Thus, normal neurotransmitter and neuronal function appears to be a key contributor to normal mood. Emerging research also suggests that proper glial cell function is necessary for normal mood and affect (Ongur et al., 2014).

Personality

Temperament and personality play a large role in shaping an individual's mood and affect. In general, high levels of neuroticism (emotional instability) and introversion and low levels of conscientiousness and agreeableness predispose individuals to negative affect, greater affect variability, and depressed mood. Conversely, low levels of neuroticism and high levels of extraversion, conscientiousness, and agreeableness are associated with greater likelihood of positive affect, lower affect variability, and elevated mood (Bowen et al., 2012; Hoerger, Chapman, & Duberstein, 2015; Komulainen et al., 2014).

Stress

Excessive stress and/or maladaptive coping responses are well-known contributors to alterations in mood and affect. When stress is chronic, it can lead to hormonal imbalances that disrupt normal brain function, especially in the hippocampus (Lucassen et al., 2016). Stress also appears to have a negative effect on the reward circuitry within the MPFC (Kumar et al., 2015). In addition, chronic stress increases a person's likelihood of inadequate sleep, poor dietary intake, and physical disease, which are themselves risk factors for altered mood and affect (as described later in this section).

Social Interactions

Social support and positive social interactions are clearly connected to stable, positive mood and affect: Multiple studies indicate that high-quality, positive social interactions themselves contribute to enhanced mood (Pemberton & Fuller Tyszkiewicz, 2016). Similarly, an individual's overall level of social support is often an important predictor of mood. Generally speaking, individuals who have greater levels of perceived support and larger, more diverse social networks tend to be at lower risk for depression and other alterations in mood and affect, which suggests that these factors offer a protective effect (Santini et al., 2015).

Day and Time

Both day of the week and time of day influence mood and affect. Most likely because of hormonal fluctuations associated with the body's circadian (24-hour) rhythms, people tend to experience lower mood in the morning. Most people's mood and affect then gradually become more positive throughout the day, reaching their peak in the afternoon hours before declining in the evening. This is true regardless of whether an individual is a so-called morning person or evening person. Interestingly, however, people with a preference for mornings tend to show better mood during all parts of the day than do people with a preference for evenings (Diaz-Morales, Escribano, & Jankowski, 2015; Jankowski, 2014).

Gender and Age

Research indicates that, as compared to men, women are more likely to physically express their emotions, are more comfortable discussing their feelings, and are more skilled at reading others' emotions (Fischer & LaFrance, 2015). Women are also more likely to experience negative emotions like guilt and shame (Else-Quest et al., 2012), and they tend to have stronger negative reactions to unpleasant stimuli (Gomez, von Gunten, & Danuser, 2013). In addition, research suggests that women tend to internalize and dwell on their emotions more than men (Chaplin & Aldao, 2013; Trives et al., 2016). In light of these factors, it is not surprising that women are more than 2 times as likely as men to experience mood disorders. However, the causes of these differences in emotional processing, mood, and affect remain an issue of debate, as described in the section on the gender bias theory of depression.

Age also tends to influence a person's mood and affect. As people grow into adulthood, the mood swings typical of early adolescence become less common (Maciejewski et al., 2015). Also, contrary to popular belief, older adults generally have more positive mood and affect than younger

adults, perhaps because of their better use of various strategies of emotional regulation (English & Carstensten, 2014; Masumoto, Taishi, & Shiozaki, 2016; Stanley & Isaacowitz, 2011).

Illness Status

Given that overall health promotes normal mood and affect, it is not surprising that physical disease and injury are significant risk factors for alterations in mood and affect. In some cases, the nature of the disease or injury itself may account for the disruption. For example, conditions that affect the brain tissue or that cause alterations in hormone levels may be directly responsible for alterations in affect or unusually high or low mood. Research has also found a link between autoimmune diseases and mood disorders, which suggests that some alterations in mood may have an immunologic basis (Benros et al., 2013).

Individuals who have chronic conditions such as heart disease, diabetes, and cancer often face ongoing stress, physical limitations, alterations in self-concept, decreased quality of life, and/or concerns about mortality that contribute to negative mood. In fact, depression is one of the most common complications of chronic disease, and it can actually worsen the course of the disease if not promptly identified and addressed (DeJean et al., 2013; Gunn et al., 2012).

Alterations to Mood and Affect

An elevation or decrease in mood and affect may impair an individual's ability to cope with typical daily life stressors. Prolonged alterations may progress into a depressive or bipolar disorder and require professional intervention.

Individuals with depressive disorder exhibit depressed mood characterized by feelings of sadness or emptiness. Other core symptoms include **anhedonia** (a loss of interest or inability to experience pleasure with activities), fatigue and sleep disturbances, and somatic complaints. In children and adolescents, irritability is a common symptom of depression. In contrast, individuals with bipolar disorder typically experience a major depressive episode alternating with a period of mania or hypomania. **Mania** is an abnormal, persistent, expansive, elevated mood that lasts at least 1 week and that significantly impairs functioning, potentially requiring hospitalization. **Hypomania** is a similar impairment of mood that lasts at least four consecutive days; its symptoms, although significant, do not necessitate hospitalization (APA, 2013). Because of the degree to which mood disorders may impact daily functioning, they can affect individuals across a wide variety of systems and situations (see Concepts Related to Mood and Affect).

Anxious distress is associated with depressive and bipolar disorders with sufficient frequency that the *Diagnostic and Statistical Manual of Mental Disorders*, 5th ed. (DSM-5) (APA, 2013), includes it as a specifier clinicians may add to a diagnosis of depression or bipolar disorder. **Anxious distress** is a combination of symptoms associated with high anxiety, including restlessness, impaired concentration due to worry, fear of impending doom, and fear of losing control.

SAFETY ALERT Patients who experience anxious distress in combination with a depressive or bipolar disorder typically are harder to treat and at greater risk for suicide (APA, 2013).

The National Institute of Mental Health (NIMH) (n.d.a) reports that mood disorders affect nearly 10% of adults, with 45% of cases classified as severe. Mood disorders impact individuals of every race and age. Treatment is critical: Without it, patients are at increased risk for suicide. Mood disorders also carry economic costs. For example, depression is associated with lower rates of productivity, increased absenteeism, and increased rates of short-term disability (Greenberg et al., 2015). Patients with depressive and bipolar disorders are found in the community and in all clinical settings, and they frequently experience difficulties with their communication skills, family relationships, and ability or motivation to adhere to a treatment plan.

Pathophysiology of Altered Mood

As mentioned earlier, both the limbic system and the MPFC play a central role in normal mood and affect, so disruptions in either portion of the brain may result in altered mood. The cellular mechanisms that underlie these disruptions are an area of intense interest to researchers, although they are widely believed to involve alterations in neurotransmitter activity and/or neuronal receptivity to neurotransmitters.

Thus far, the so-called neurotransmitter hypothesis has largely focused on two monoamine neurotransmitters: serotonin and norepinephrine. Serotonin (5-HT) is involved in the regulation of aggression, mood, anxiety, impulsivity, appetite, sleep, and sex drive, whereas norepinephrine (NE) is involved in the regulation of attention, arousal, and behavior. Given that alterations in all of these areas are characteristic of mood disorders, dysregulation of both 5-HT and NE is thought to be a contributing factor to depression and bipolar disorder. This conclusion is supported by research showing decreased levels of both neurotransmitters in the brains of individuals with mood disorders (Patrick & Ames, 2015; Varcarolis, 2013).

More recently, scientists have also begun to investigate the potential contribution of other neurotransmitters, including dopamine (DA), acetylcholine (ACh), gamma-aminobutyric acid (GABA), and glutamate. DA is an essential component of the brain's reward circuitry, and ACh helps regulate the sleep-wake cycle. GABA reduces the ability of nerve cells to transmit information, whereas glutamate causes the opposite effect. Although all of these neurotransmitters—along with 5-HT and NE—appear to be involved in the pathophysiology of mood disorders, the exact nature of their roles remains unclear. Some studies suggest that abnormal levels of these substances contribute to depressive and bipolar disorders, while other studies suggest that altered neuronal receptivity to neurotransmitters may be to blame. Most likely, there are different combinations of problems with each of these neurotransmitter systems. It is also likely that the systems interact with one another in a variety of ways that scientists have yet to discover (Halter, 2014; Varcarolis, 2013; Werner & Covenas, 2015). As research continues to tease out the connections between these neurotransmitters and the cells on which they act, the underlying pathophysiology of mood disorders will no doubt become clearer.

Alterations and Manifestations

Alterations in mood and affect may be seen at any point across the lifespan. Brief periods of sadness, irritability, and excitement are common as individuals encounter hardship,

challenge, and joy. At times, however, these periods extend beyond just a few days or weeks, depending on the nature of the stressor or situation and the individual's own ability to cope. In such instances, patients may demonstrate any number of manifestations of altered mood. Often, these manifestations exist independently of any diagnosable mental illness. Other times, they are part of a larger set of symptoms indicative of a mood disorder.

Common Manifestations of Altered Mood and Affect

As mentioned earlier, an individual's mood is considered altered if it is excessively elevated (manic) or excessively depressed. Similarly, affect is said to be altered if it is inappropriate (incongruent), narrowed, overreactive, blunted, and/or excessively labile. Beyond these basic indicators of abnormality, a number of other manifestations are common in individuals who are experiencing altered mood and affect.

Maladaptive Coping Responses

As previously described, high stress levels and maladaptive coping responses are well-known contributors to altered mood and affect, but they can also be manifestations of such alterations. Some of the most commonly observed maladaptive coping responses include avoidance (i.e., refusal to confront stressors), escape, rumination (i.e., persistent mental focus on stressful situations or symptoms and their implications), denial, helplessness, isolation, self-pity, self-blame, excessive dependency, and aggression. Note, however, that a wide range of other responses may also be considered maladaptive if they impair an individual's ability to function effectively when faced with life's demands (Michl et al., 2013; Skinner & Zimmer-Gembeck, 2016).

Altered Thought Processes

Altered thought processes can also be a manifestation of disrupted mood and affect. Decreased concentration, poor memory, impaired problem-solving ability, indecisiveness, and poor decision making are among the most common alterations. Less common but more drastic alterations in thought include paranoid thinking, hallucinations, and other forms of psychosis, all of which are associated with unstable mood (Marwaha et al., 2013).

Sleep Disturbances

Changes in sleep patterns are often observed in patients with altered mood and affect. In fact, sleep disturbances are a defining characteristic of nearly all mood disorders. People with manic or elevated mood tend to have difficulty sleeping, whereas individuals with low or depressed mood may experience either insomnia or excessive sleepiness. Even when patients with mood alterations are able to fall and remain asleep, they may not feel adequately rested or refreshed upon awakening (Potter & Moller, 2016).

Somatization

Somatization is the phenomenon in which individuals experience or express psychologic distress through physiologic responses. Although somatization may occur in the absence of mood disruptions, it is commonly associated

with alterations in mood and affect. Examples of somatic symptoms frequently seen in individuals with mood alterations include fatigue, headache, heart distress, and dizziness.

Between 65 and 80% of individuals with depression report pain as a symptom. For some patients, pain may be an expression of their illness; for others, altered mood and affect may result from pain. Regardless of the exact circumstance, the complicated and likely bidirectional connection between mood and pain highlights the need to assess all patients with chronic pain for signs and symptoms of depression (de Heer et al., 2014; Potter & Moller, 2016).

Difficulties with Adaptive Functioning

Adaptive functioning refers to the ability to safely and independently participate in the demands of daily life—such as activities of daily living, maintaining home or living space, obtaining proper nutrition and medical care, managing finances, completing occupational tasks, planning for the future, and engaging in social interactions. Individuals with altered mood and affect commonly experience difficulties in one or more of these areas.

Disorders of Mood and Affect

When of sufficient duration and intensity, alterations in mood and affect may constitute a diagnosable disorder. Common mood disorders include depressive disorders, adjustment disorder with depressed mood, bipolar disorders, and postpartum mood disorders.

Depressive Disorders

Mental health practitioners recognize several types of depressive disorders, the most common of which is **major depressive disorder (MDD)**, also called **unipolar depression**. MDD is what most Americans think of when they hear the term “depression.” MDD is diagnosed when the patient experiences either depressed mood or anhedonia most of the day, almost every day, during the same 2-week period. The depression or loss of interest must be accompanied by at least four of the following core symptoms:

- Sleep disturbances
- Significant weight change (5% or greater in either direction) or change in appetite
- Fatigue or loss of energy
- Feelings of worthlessness or guilt
- Change in activity level (either psychomotor agitation or retardation)
- Poor concentration
- Suicidal ideation or attempt.

MDD may involve just a single depressive episode, although most affected individuals experience multiple recurring episodes over the course of their lives (APA, 2013).

Persistent depressive disorder (dysthymia) is sometimes also referred to as depression, but the diagnostic criteria differ from those for MDD. Dysthymia may be diagnosed when a depressed mood is present for most of the day, more days than not, for at least 2 years. Symptoms of dysthymia are similar to but less severe than those of MDD (APA, 2013).

Adjustment Disorder with Depressed Mood

Individuals often experience dramatic life changes related to events such as death of a loved one, relocation, loss of autonomy, illness, and financial stress. One or more life changes or stressors may contribute to the development of **adjustment disorder with depressed mood**, also known as *situational depression*. Adjustment disorder with depressed mood is a maladaptive reaction to an identifiable psychosocial stressor (or stressors) that occurs within 3 months after the stressor occurs and persists for no longer than 6 months after termination of the stressor (APA, 2013). Symptoms of adjustment disorder with depressed mood are similar to those of the other depressive disorders but are less severe, although a higher level of anxiety may be present.

Bipolar Disorders

Bipolar-related disorders include bipolar I, bipolar II, cyclothymic disorder, and other related disorders. The medical diagnosis of **bipolar disorder** is given when an individual's mood alternates between the extremes of depression and mania or hypomania, interspersed with periods of normal mood. **Bipolar I disorder** is characterized by the occurrence of one or more manic episodes and one or more depressive episodes. **Bipolar II disorder** is characterized by one or more hypomanic episodes (less severe) and one or more depressive episodes.

Bipolar disorders may be further classified as follows (APA, 2013):

- **With mixed features.** The individual experiences symptoms of depression (e.g., depressed mood, anhedonia, and suicidal ideation or attempt) during episodes of mania or hypomania; or the individual experiences manic/hypomanic symptoms during the depressive episode.
- **With rapid cycling.** The individual experiences four or more mood episodes of illness (mania, hypomania, or depression) within a 12-month period, with at least 2 months between each episode OR with alternating episodes (e.g., a period of mania followed by a depressive episode). There is a higher risk of rapid cycling, cycle acceleration, and severity of mood episodes in women (Erol et al., 2015).

Postpartum Mood Disorders

Often, women can experience **postpartum blues** after childbirth, which includes symptoms such as mood swings, tearfulness, sleep disruptions, and increased anxiety. These symptoms usually occur within the first 2–3 days postpartum and may last up to a couple of weeks (Mayo Clinic, 2015a). When these symptoms are more severe and of longer duration, the woman may be diagnosed with **depressive disorder with peripartum onset**, often referred to as *peripartum* or **postpartum depression**.

Postpartum depression is defined as moderate to severe depression experienced during pregnancy and/or up to a year after giving birth. In up to 50% of cases, the depression begins during pregnancy. When postpartum depression arises after delivery, it usually starts within a few weeks after giving birth; however, sometimes the symptoms may present up to 12 months after birth (APA, 2013). Women who give birth to multiple children and/or to preterm children also are at higher risk for postpartum depression.

It is important to identify depression occurring during or following pregnancy as early as possible in order to try to prevent increasing duration and severity of symptoms. Symptoms of postpartum depression are outlined in the Alterations and Manifestations feature and the exemplar that appears later in this module. Symptoms may escalate to severe anxiety, panic attacks, and thoughts of suicide (suicidal ideation) or causing harm to the baby (Mayo Clinic, 2015a). Contributing factors include hormonal changes, family history of depression, feelings of being overwhelmed by parenting tasks, changes in family dynamics, and inadequate support.

Postpartum mood episodes accompanied by psychotic features occur in between 1 in 500 and 1 in 1000 deliveries. **Postpartum psychosis** is characterized by psychotic features associated with peripartum or (more commonly) postpartum depression. These episodes frequently involve command hallucinations or delusions. The command hallucinations may direct the mother to harm the infant, while the delusions may cause the mother to feel that the baby is possessed (APA, 2013).

Suicide

Suicide is itself a mood disorder and may be triggered by one or a series of event in individuals not previously diagnosed with a mood disorder. However, all major depressive episodes include the possibility of suicidal behavior. Suicide is the extreme of negative coping, leading to self-injurious behaviors causing death. The most reliable predictor of risk is a past history of suicidal threats or attempts. Other risk factors include gender (males are at higher risk), living alone, and persistent feelings of hopelessness (APA, 2013). It is critical that the nurse obtain a thorough history so that risk factors are identified and an appropriate plan of care may be developed. An individual who is actively suicidal requires inpatient hospitalization for safety and stabilization.

Theories of Depression

Depressive and bipolar disorders are currently thought to be caused by an interaction of individual genetic, biological, environmental, and psychosocial factors. Depressive disorders are considered spectrum disorders, occurring along a continuum of mild to severe. Most cases fall somewhere between these two extremes.

Both a patient's history (e.g., history of medical illness, trauma, and coping mechanisms) and current factors inform the clinical presentation of the patient's disorder, as well as how the individual copes with or responds to the disorder. For example, an individual may have a genetic predisposition to abnormalities in neurotransmission, but these abnormalities may occur only when certain psychologic mechanisms are present, or they may operate only when particular social interactions occur (Mullins et al., 2016). Furthermore, different forms of depression may have different risk factors. In some forms of depression, genetic predisposition may have a stronger role, whereas in other forms, stressors may have a greater role. Most likely, depression and other mood disorders represent a common final pathway of multiple underlying factors, with most affected individuals possessing more than one risk factor.

Alterations and Therapies

Mood and Affect

ALTERATION	DESCRIPTION	THERAPIES
Depression (including major depressive disorder and persistent depressive disorder)	Depressed mood that varies from mild to severe with severe phases lasting longer than 6 weeks. Symptoms include: <ul style="list-style-type: none"> Feelings of sadness, hopelessness, powerlessness, apathy, or guilt Changes in sleep and/or appetite Anhedonia Inability to concentrate Psychomotor retardation or agitation 	<ul style="list-style-type: none"> Antidepressant medications: SSRIs, SNRIs, bupropion, TCAs, MAOIs Antidepressants may be combined with low-dose antipsychotic medication in resistant cases Nonpharmacologic therapy: cognitive-behavioral therapy (CBT); electroconvulsive therapy (ECT); transcranial magnetic stimulation (TMS); vagus nerve stimulation (VNS)
Bipolar disorders	Extreme alterations in mood (mood swings) with intermittent periods of normal mood	<ul style="list-style-type: none"> Mood-stabilizing medication Psychotherapy Hospitalization or partial hospitalization during severe episodes
Depressive disorder with peripartum onset (postpartum depression)	Severe depression that appears during pregnancy or within the first year following the birth of a child. Symptoms include: <ul style="list-style-type: none"> Sleep disturbances Fatigue Crying Feelings of despair Anxiety Mood swings 	Combination of antidepressants and psychosocial interventions is most effective.
Adjustment disorder with depressed mood (situational depression)	Hyperreaction to an identifiable, life-altering (but not life-threatening) stressor that occurs within 3 months after the onset of the stressor and persists for no more than 6 months after termination of the stressor; symptoms are similar to but less severe than those of major depressive disorder	Psychotherapy alone may be sufficient to relieve symptoms and return patient to premorbid level of functioning
Suicide	Self-injurious behaviors resulting in death	Inpatient hospitalization for safety and stabilization. Stabilization will include therapies for the diagnosed depressive disorders and any comorbid disorders, such as substance abuse

But precisely what factors (besides genetics) increase a person's likelihood of depression? Thus far, researchers have proposed several theories, each of which focuses on a different potential contributor and is described in the sections below. By remembering and applying elements from each of these theories, nurses can approach patients with depression from a more holistic perspective.

Biological Theories

Numerous studies demonstrate that depression has a biological basis. As explained earlier in the concept, specific alterations in structure, function, and neurotransmitter activity have been noted in the brains of individuals with depression. As described throughout the concept, depression also appears to be at least partially rooted in a person's genetics. Still, structural, functional, and genetic variations may not be the only biological contributors to depressive

disorders. Other proposed contributors include disrupted biological rhythms, hormonal factors, and inflammation.

Biological Rhythms

Biological rhythms are regular fluctuations in the body's physiologic processes over a given period of time. When these fluctuations occur on a 24-hour cycle, they are known as **circadian rhythms**. Research suggests that for some individuals, internal desynchronization of the body's circadian rhythms may result in depression. The tendency toward internal desynchronization is probably inherited, but stresses, lifestyle, and normal aging also influence it. It is unclear, however, whether changes in circadian rhythms cause mood disturbances or whether changes in mood alter circadian rhythms (Baron & Reid, 2014; Bechtel, 2015). (See the module on Health, Wellness, Illness, and Injury for a more detailed discussion of circadian rhythms.)

Disruptions in the body's seasonal rhythms may also be problematic. For example, many people are at greater risk of depression during a specific time of year (typically, the winter months). This increased correlation between depressive symptoms and time of year is commonly referred to as **seasonal affective disorder (SAD)**, although the actual DSM-5 diagnosis is *major depressive disorder with seasonal pattern*. Common manifestations of SAD include decreased energy, increased periods of sleep, increased appetite, overeating, and weight gain (APA, 2013).

Hormonal Factors

Several lines of evidence support the theory that hormonal factors play a role in depression. One compelling finding is that individuals with depression tend to have increased levels of cortisol and corticotropin-releasing hormone. Both of these hormones are produced in the brain's hypothalamic-pituitary-adrenal (HPA) axis, which plays a major role in regulating mood and the body's response to stress. High levels of cortisol and corticotropin-releasing hormone are indicative of HPA hyperactivity, which (as described earlier) is commonly observed in individuals with mood disorders (Potter & Moller, 2016). Researchers aren't sure whether depression precipitates HPA hyperactivity and excess hormone production or whether HPA hyperactivity and excess hormone production precipitate depression. However, recent studies suggest that variations in the genes that code for corticotropin-releasing hormone may lead to increased susceptibility to major depression following negative life events (Liu et al., 2013; Waters et al., 2015).

The fact that women experience higher rates of depression than men indicates a connection between estrogen and depression. Decreased estrogen levels in particular seem to play a role, as evidenced by women's greater likelihood of depressive symptoms at certain points in the menstrual cycle, as well as at the onset of menopause. The exact nature of the estrogen-depression relationship remains unclear, however (Halter, 2014; Wharton et al., 2012).

Inflammation

Within the past decade, multiple research studies have noted that depressed individuals tend to have increased levels of inflammatory biomarkers called cytokines (Raison & Miller, 2012; Vogelzangs et al., 2014). Similar elevations have also been observed in individuals with bipolar disorder (Stertz, Magalhaes, & Kapczinski, 2012). These findings suggest that mood disorders have an inflammatory component, although scientists aren't yet sure of the precise connection between inflammation and depression. One factor complicating research in this area is the fact that elevated cytokine levels are not universal across all depressed individuals. Furthermore, many individuals who have elevated cytokine levels show no symptoms of depression. Together, these findings have led to the hypothesis that some (but not all) people with depression may have a genetic predisposition toward elevated cytokine production when faced with external stressors, as well as the hypothesis that other individuals may have genetic factors that protect them against the potentially mood-lowering effects of cytokines (Raison & Miller, 2012; Slavich & Irwin, 2014).

Interpersonal Theory

Interpersonal theory is rooted in the idea that all people have a basic inborn need for interpersonal relationships, because these attachments provide a sense of security and allow individuals to develop a healthy sense of self. When these relationships are threatened, individuals experience feelings of grief and anger. These emotions are a normal response to real or anticipated loss, but when they remain unrecognized or unresolved, depression may result (Verdeli & Weissman, 2014). Some interpersonal theorists believe that individuals who have been taught that it is inappropriate to experience and express anger learn to repress it. The result is that their anger is turned inward and against the self, triggering a depressive episode. Other theorists believe depression arises because of sadness and disappointment about failure to achieve desired goals, the loss of those goals, and/or a feeling of lack of control in life. Most interpersonal theorists also emphasize that there is a reciprocal relationship between depression and interpersonal problems. In other words, not only do threatened interpersonal attachments trigger depression, but depression itself can cause a person to interact with others in a way that promotes rejection, thus perpetuating the cycle and worsening the individual's depression (Hames, Hagan, & Joiner, 2013; Lipsitz & Markowitz, 2013).

Learning Theory

Learning theory states that individuals learn to be depressed in response to an external locus of control, in which they perceive themselves as having no ability to control the outcome of their life experiences. According to this theory, many individuals with depression have limited success in achieving gratification and little positive reinforcement for their attempts to cope with negative incidents. Over time, these repeated failures teach them that what they do has no effect on the final outcome of a situation. The more stressful their life events, the more these individuals' sense of helplessness is reinforced—a phenomenon referred to as **learned helplessness**. When these individuals reach the point of believing they have no control whatsoever, they no longer have the will or energy to cope with life, and a depressive state results (Halter, 2014; Potter & Moller, 2016).

Cognitive Theory

The cognitive theory of depression is based on the idea that internal thought processes influence the way individuals with mood disorders experience themselves and others. According to this theory, which comes largely from the work of Aaron Beck (1967), individuals with depression have skewed core views of themselves, of their environment, and of the future. Moreover, their characteristically negative way of thinking makes it impossible for these individuals to alter their behavior or even see the possibility for change at some point in the future. Consequently, people with depression have deeply held negative life views that tend to be based on cognitive distortions rather than reality (e.g., "I am a bad parent because I yelled at my child yesterday") (Potter & Moller, 2016).

Sociocultural Theory

Sociocultural theory emphasizes the role that social stressors play in the development of depression. These stressors take

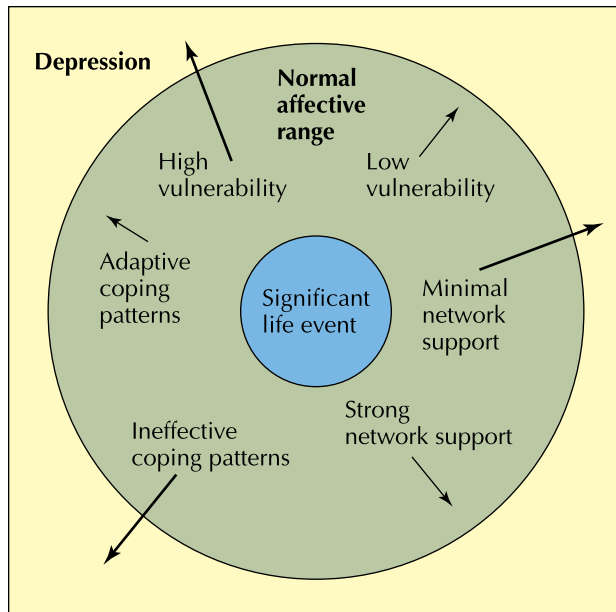

Figure 28-2 » The relationship between life events and depression.

a variety of forms. Some are economic; common examples include poverty and job insecurity (Brown, 2012). Others involve a disruption in the family system, including divorce, children leaving home, or the death of a loved one. Some stressful life events involve a threat (e.g., illness, encounters with law enforcement), while others are emotionally exhausting (e.g., celebrating holidays, changing residences, or arguing with family and friends). Many individuals who experience stressful events do not become depressed. However, for those who are vulnerable to depression, stressors may play a significant role in the exacerbation and course of the disorder (Potter & Moller, 2016).

A number of factors influence the degree of stress that accompanies significant life events. **Figure 28-2** » illustrates the relationship between life events and depression. The presence of a social support network can decrease the impact that an event may have on an individual. Individuals who have developed adaptive coping patterns such as problem solving, direct communication, and use of resources are more likely to maintain their normal mood. Those who feel out of control, are unable to problem solve, and ignore available resources are more apt to feel depressed. Thus, an individual's perception and interpretation of significant events may contribute to depression (Evans et al., 2015; Holden et al., 2012; Morris et al., 2015). Perception and interpretation of events may be informed by cultural or gender norms (see Focus on Diversity and Culture).

SAFETY ALERT Childhood sexual abuse (CSA) is a significant risk factor for depression during both childhood and adulthood, as well as for self-harming behaviors (e.g., cutting), posttraumatic stress disorder (PTSD), and suicide (Devries et al., 2014; National Center for PTSD, 2015). Therefore, depressed patients with a history of CSA should be assessed and closely monitored for self-harming and suicidal behaviors.

Focus on Diversity and Culture

Influence of Culture and Gender on Depressive Disorders

Throughout the world, women experience more depression than men. Certainly, there are cross-cultural similarities in the way women are socialized and in the inferior status they experience in many societies. Psychosocial stressors, including multiple work and family responsibilities, poverty, sexual and physical abuse, gender discrimination, unequal pay, lack of social supports, and traumatic life experience, may contribute to women's increased vulnerability to depression (Platt et al., 2015; World Health Organization, 2016a).

Gender socialization differences may also be a factor in the higher rate of depression in women. In many cultures, children are socialized to believe that girls are more influenced by emotions while boys are more influenced by reason. Similarly, girls are taught that it is acceptable to share their thoughts and feelings with others, while boys are encouraged to keep their emotions to themselves. Many societies also promote the idea that girls should be submissive and "nice" while boys should be tough and aggressive. Various disciplines—including psychology, sociology, nursing, and psychiatry—continue to study the effects that these differing messages have on children and adolescents, and how expectations related to gender roles impact men and women into adulthood. Many researchers have theorized that these messages create an environment in which women feel devalued, thus increasing their risk of depression. It is also likely that internalization of these societal messages has created a healthcare system in which both patients and practitioners are more likely to view depression as a "women's disorder," whether consciously or not. As a result, women are more likely to be diagnosed with depression even in the absence of severe symptoms, whereas men are less likely to be diagnosed and indeed less inclined to seek help for their symptoms in the first place (Swami, 2012; World Health Organization, 2016a).

Prevalence

According to the Centers for Disease Control and Prevention (CDC), 18.8 million American adults (9.5% of the adult population) will experience a depressive disorder. The CDC's National Center for Health Statistics (NCHS) reports that from 2009 to 2012, 7.6% of Americans age 12 and over reported moderate to severe depressive symptoms in the 2 weeks prior to the survey (CDC, 2014).

Major Depressive Disorder

Of the 7.6% of Americans age 12 and over who experience major depression adults age 40 to 59 experience the highest rates (9.8%), and adults age 60 and older experience the lowest rates (5.4%). Approximately 5.7% of adolescents experience major depressive disorder, and some 7.4% of young adults (those age 18 to 39) experience the disorder (CDC, 2014).

In every age group, females experience depression at higher rates than males. The highest rate of depression, 12.3%, is in women age 40–59. The lowest rates of depression are for males age 12–17 (4.0%) and age 60 and over (3.4%). According to the CDC (2014) and National Institute of Mental Health (NIMH) (2015), groups with the highest prevalence of depression include adults age 45 to 64; women; Native Americans,

Alaskan natives, and non-Hispanic Whites; and individuals living below the federal poverty level.

According to the CDC (2014), individuals living below the poverty line are more than twice as likely to experience depression than those who live above the poverty line. This difference may be in part due to poor access to healthcare, making those who live in poverty less likely to receive healthcare and obtain routine screenings. Without identification and treatment of medical issues, acute medical conditions may become chronic, and this can impact mental health. Other conditions associated with poverty can impact mental health, including difficulty maintaining a healthy lifestyle and accessing healthy food and exercise options.

Bipolar Disorders

Approximately 0.6% of people residing in the continental United States have been diagnosed with bipolar I disorder as defined by the DSM-5. The lifetime male-to-female ratio is approximately 1.1:1 (APA, 2013).

Postpartum Depression

According to the APA (2013), between 3 and 6% of women will experience the onset of a major depressive episode during pregnancy or within the months following pregnancy.

Suicide

According to the CDC (2015), suicide was the 10th leading cause of death in all age groups in 2015. In 2013, there were 41,149 suicides, or 113 suicides each day, or 1 suicide every 13 minutes. Furthermore, the CDC reports that males complete suicide 4 times more than females and represent 77.9% of all suicides. Suicide is the third leading cause of death in children age 10–14; second leading cause in persons age 15–34; fourth among persons age 35–44; fifth among 45–54; eighth among persons age 55–64; and seventh among those age 65 and older.

Genetic Considerations and Nonmodifiable Risk Factors

Increasingly, genetics and neurobiology have been found to play a role in the development of depressive and bipolar disorders. However, all individuals operate within the context of their environments. Genetics and neurobiology inform nursing care and treatment for individuals with mood disorders, but nurses and clinicians must not overlook other determinants when providing care.

According to the APA (2013), first-degree family members of an individual with major depressive disorder have a two- to fourfold increase in risk of being diagnosed with a similar disorder. Heritability is approximately 40%. For bipolar disorder, a family history of bipolar disorder is one of the most reliable indicators of increased risk. Individuals have a tenfold increase in risk of developing bipolar disorder if a relative has been diagnosed with bipolar disorder.

Case Study » Part 1

Jason is a 22-year-old college student. He has missed several classes and did not turn in a major paper. When contacted by his professor, Jason admits to feeling so depressed that he has not been able to concentrate on his course work and has not left his apartment for several days. His professor expresses concern and

suggests Jason go to the campus health center, which takes walk-ins. Jason agrees to go to the campus health center as a condition of getting an extension on the paper. Once there, he tells the nurse he has no appetite and complains of difficulty falling asleep. Jason says he feels guilty for not getting his assignments done and is not doing well in any of his classes. He states he doesn't know what is wrong with him, he just can't seem to get motivated and he doesn't know why. He looked forward to going to college and was excited to be accepted and move away from home for the first time. Jason did very well last semester and in the beginning of this semester. He was active in several clubs and was thinking of running for the student senate and joining the track team, but recently things just seemed to fall apart. Although Jason has many acquaintances through his classes and activities, he has no close friends in the area. During the intake interview, the nurse observes that Jason sits hunched forward in his chair with his eyes downcast. He becomes tearful at times and never smiles.

Clinical Reasoning Questions Level I

1. What is the most important issue the nurse should assess? Explain the rationale for your prioritization.
2. How would you describe Jason's affect?
3. What are the physical health priorities for Jason at this time? If those physical needs are met by changes in lifestyle, for example, would Jason experience a sense of well-being?

Clinical Reasoning Questions Level II

4. What additional information would the healthcare providers need to determine the most likely cause of Jason's depressed mood? What is a good approach to obtaining relevant additional information?
5. What are the considerations in contacting Jason's family regarding his situation?
6. What sociocultural factors or stressors might be contributing to Jason's distress?

Concepts Related to Mood and Affect

Mood and affect are related to so many concepts and systems that a full discussion of these relationships is beyond the scope of this text. Selected examples of related concepts include addiction; cognition; health, wellness, illness, and injury; healthcare systems; stress and coping; and trauma.

The rate of comorbidity between mood disorders and substance use disorders is high. Results of the National Epidemiologic Survey on Alcohol and Related Conditions showed that 20.5% of those surveyed who were alcohol dependent also had an independent major depressive disorder. Respondents who reported alcohol dependence were 3.7 times more likely to have major depression than respondents who were not dependent on alcohol (Pettinati & Dundan, 2011). Similarly, bipolar disorders are associated with some of the highest rates of alcohol and substance abuse (Petrakis, Rosenheck, & Desai, 2011). Furthermore, suicide is the leading cause of death among individuals with substance abuse disorders (Substance Abuse and Mental Health Services Administration [SAMHSA], 2014).

As mentioned earlier in the module, disturbances in mood and affect frequently lead to alterations in an individual's normal thought processes. Individuals who are experiencing mania often have racing thoughts, whereas individuals who are experiencing depression are more likely

to report that their thinking feels slow or cloudy. Other alterations in thought processes that may occur include decreased concentration and memory and impaired problem-solving and decision-making ability. Although far less common, hallucinations, delusions, and other forms of psychosis may also be manifestations of mood disorders (Marwaha et al., 2013; Potter & Moller, 2016).

Depressive and bipolar disorders impact functioning and overall wellness on a number of levels. Both categories of illness can manifest sleep disturbances. Numerous studies show a direct link between decreased amount and/or quality of sleep and negative mood and affect (Gobin et al., 2015; Minkel et al., 2012; Pemberton & Fuller Tyszkiewicz, 2016). On the other hand, regular physical activity appears to have a protective effect against depression and negative affect (Pemberton & Fuller Tyszkiewicz, 2016; Saneei et al., 2016). Individuals with moderate to severe alterations in mood and affect may neglect their physical health and personal hygiene and experience changes in eating patterns and weight gain or loss. Poor health outcomes can affect overall functioning.

Patients with mental illness may not have insurance to pay for health services; therefore, providing a list of free community resources (such as support groups) as well as scheduling appointments with community mental health centers may be necessary to assist the patient in securing increased access to care.

Individuals with depressive or bipolar disorder often have a history of trauma. By providing trauma-informed care to these patients, nurses can help protect them from retraumatization, assist them in understanding the manifestations of their illness in the context of their life experiences, and reframe their symptoms as a method of coping (Potter & Moller, 2016).

Similar to trauma, prolonged and overwhelming stress can result in depression or trigger a manic episode. Anxiety disorders often occur along with depression, and poorly managed anxiety can use up the coping reserves needed to prevent the onset of a depressive or manic episode.

The Concepts Related to Mood and Affect feature links some, but not all, of the concepts integral to mood and affect. They are presented in alphabetical order.

Health Promotion

There is no definitive way to prevent depression due to causative and contributing genetic and biological factors that cannot be modified. Some strategies can be useful, however, for modifying stressors and environmental factors that can contribute to depressive illnesses. For instance, research demonstrates that certain lifestyle choices can help protect individuals against the onset of mood disorders. Patients should be encouraged to reduce their intake of sugar, saturated fat, and refined foods and increase their consumption of fruits, vegetables, legumes, fish, and whole grains. Research also suggests that increased intake of certain nutrients—including omega-3 fatty acids, folic acid, vitamin D, selenium, and calcium—may play a protective role (Roca et al., 2016; Sanchez-Villegas & Martinez-Gonzales, 2013; Saneei et al., 2016; Whitaker et al., 2014; White, Horwath, & Conner, 2013). Similarly,

multiple studies emphasize the importance of adequate sleep and regular exercise in preventing mood alterations (Gobin et al., 2015; Minkel et al., 2012; Pemberton & Fuller Tyszkiewicz, 2016; Saneei et al., 2016). Additional research indicates that smoking cessation may decrease the risk of various mental disorders, including depression (Jacka, Mykleton, & Berk, 2012).

Additional primary prevention strategies focus on psychosocial factors rather than biological factors: Education about stress management, coping strategies, or positive parenting is a primary strategy that may be helpful to many individuals. Other strategies may need to be more community- or situation-specific: For example, veterans and people who live in communities where large-scale tragedy has occurred may benefit from measures that help them better cope with past traumatic events; and parents and children who are going through divorce or another stressful situation may benefit from facilitated discussion and use of coping strategies (Potter & Moller, 2016). Research also indicates that children of depressed parents are less likely to develop depression themselves after participating in family-based cognitive-behavioral interventions (Compas et al., 2015; de Angel et al., 2016).

Secondary and tertiary prevention strategies are similar to primary strategies that focus on psychosocial factors. Notable secondary approaches include regular screening (described in greater detail below); referring individuals with suspected mood disorders for accurate diagnosis and treatment; and counseling patients about their relative risks for developing mood disorders. Useful tertiary prevention measures include establishing collaborative care programs for patients with mood disorders; employing clinic- and home-based approaches to reducing depression among older adults and individuals with chronic health problems; and developing community-based programs that provide mental health services to homeless and impoverished individuals (Potter & Moller, 2016).

Screenings

The U.S. Preventive Services Task Force (USPSTF) recommends that all adults, including pregnant and postpartum women, be screened for depression by their primary care providers. Although the organization does not specify precisely when or how often screening should occur, it encourages nurses and clinicians to use a pragmatic approach that “might include screening all adults who have not been screened previously and using clinical judgment in consideration of risk factors, comorbid conditions, and life events to determine whether additional screening of high-risk patients is warranted” (Siu & USPSTF, 2016a). A similar screening approach is recommended for adolescents between the ages of 12 and 18, but not for children age 11 and under (Siu & USPSTF, 2016b). According to the USPSTF (2016a, 2016b), research indicates that screening patients age 12 and up presents little to no risk of harm. Moreover, there is adequate evidence that early detection of depression followed by use of appropriate pharmacologic and/or psychotherapy decreases clinical morbidity and improves clinical outcomes.

Concepts Related to Mood and Affect

CONCEPT	RELATIONSHIP TO MOOD AND AFFECT	NURSING IMPLICATIONS
Addiction	Addiction → depression Mood disorders → addiction Mood disorders + addiction = ↑ severity of both Mood disorders + addiction = ↑ suicidal behavior	<ul style="list-style-type: none"> Assess for suicidal ideation. Assess for substance use. Provide concurrent treatment for mood disorders and substance abuse. Refer to community resources. Assess and educate family regarding codependency issues. Anticipate patient denial of substance use.
Cognition	Mood disorders → ↓ concentration, memory, problem solving, and decision making; ↑ risk of psychosis Depression → ↓ clarity and speed of thought processes Mania → ↑ flight of ideas and racing thoughts	<ul style="list-style-type: none"> Conduct mental status examination. Provide patients who demonstrate slowed thinking adequate time to respond. Because patients may have trouble concentrating, simplify the communication process by offering limited choices. Do not challenge the patient's belief systems or values. Provide a safe environment and seek immediate medical intervention for patients with signs of psychosis.
Health, Wellness, Illness, and Injury	Depression = ↓ sleep/nutrition/wellness → physical illness and functional status → ↑ depression	<ul style="list-style-type: none"> Promote self-care, adequate rest and sleep, and exercise as appropriate. Assess for signs of physical illness and for somatic symptoms of depression (e.g., pain in the absence of injury). Promote routine health maintenance, screening, healthy lifestyle, and preventive care.
Healthcare Systems	↓ Access to healthcare → ↑ risk for depression and ↑ risk of suicide Depressive and/or manic symptoms ↑ individual use of healthcare systems Healthcare systems often ill-equipped to respond to comorbid psychiatric illness	<ul style="list-style-type: none"> Conduct routine screenings for depression and suicidal ideation as recommended. Collaborate with interprofessional team to address psychologic needs of patients. Refer patient to a mental health professional for follow-up. Provide list of community services, including contact information. Make first appointment for the patient.
Stress and Coping	↑ Stress → depression or triggers mania Ineffective coping → depression and/or anxiety	<ul style="list-style-type: none"> Assist patient in developing effective coping mechanisms. Assess for symptoms of anxiety. Assist patient in identifying triggers for anxiety symptoms. Teach stress reduction techniques.
Trauma	Experiencing violence → depression Exposure to trauma → depression and/or posttraumatic stress disorder	<ul style="list-style-type: none"> Assess for suicide risk. Assess for history of violence. Assess for exposure to traumatic event. Provide safe environment. Educate regarding community resources.

A number of different instruments may be used when screening for depression and other mood disorders (**Table 28-1** >>). For example, the Patient Health Questionnaire (PHQ-9) is one of the most common instruments and can be used in a variety of settings to screen individuals to determine whether referral is necessary. The questionnaire is freely available in more than 30 languages (American Psychological Association, 2016a). Other screening tools that may be used in

adult populations include the Hospital Anxiety and Depression Scales (for all adults), the Geriatric Depression Scale (for older adults), and the Edinburgh Postnatal Depression scale (for pregnant and postpartum patients) (Siu & USPSTF, 2016a). Providers may also choose from a number of screening instruments for children and adolescents, including the Patient Health Questionnaire for Adolescents (PHQ-A), the Mood and Feelings Questionnaire (MFQ), and the Children's

TABLE 28–1 Common Instruments Used to Screen for Depression and/or Bipolar Disorder

Screening Tools	Description
Children	
Children's Depression Inventory (CDI-2)	Short and long forms are available. The child or adolescent completes the self-report scale; parents and teachers complete separate forms.
Patient Health Questionnaire for Adolescents (PHQ-A)	41-question self-report scale assesses indicators of anxiety and depression.
Mood and Feelings Questionnaire (MFQ)	Short and long forms available; requires both child and parent(s) to complete a series of questions.
Center for Epidemiological Studies–Depression Scale for Children (CES-DC)	20-item self-report scale that screens for depression.
Mood Disorder Questionnaire (MDQ)	Brief self-report form used to screen adolescents for bipolar disorder.
Adults	
Patient Health Questionnaire (PHQ-9)	Commonly used, 10-question self-report scale used to screen adults for depression; may be used to monitor depression levels throughout treatment.
Beck Depression Inventory (BDI)	21-question self-report scale to screen adults for depression.
Center for Epidemiological Studies Depression Scale–Revised (CESD-R)	20-item self-report scale to screen adults for depression.
Older Adults	
Geriatric Depression Scale (GDS)	Individuals may complete the scale themselves or have a healthcare provider read it to them and score their answers. Long and short forms available.
Cornell Scale for Depression in Dementia (CSDD)	Clinicians use the CSDD to screen individuals with dementia for depression; clinicians use the scale with the caregiver and briefly interview the patient.
Postpartum Depression	
Edinburgh Postnatal Depression Scale (EPDS)	Self-report form that may be used in any setting to screen postpartum mother for depression.
Beck's Postpartum Depression Screening Scale (PDSS)	35-item response scale for use during routine care with all postpartum women to identify those who might be experiencing postpartum depression.

Depression Inventory (CDI-2) (Corona, McCarty, & Richardson, 2013). Regardless of which instrument is used, patients who score in the range indicative of depression or another mood disorder should be referred to a mental health professional for a thorough diagnostic evaluation.

Care in the Community

Most people with mental illness are treated in the community. Deinstitutionalization has required more services to be available to the public at a lower level of care. Community services may include outpatient, intensive outpatient (part-day programs approximately 4 hours in duration), and partial-hospitalization (typically services are provided at the hospital daily or near daily for a full day and the patient goes home in the evenings). There are also a multitude of support groups and hotlines available for the public. Group homes (residences for individuals who are functional but chronically mentally ill) and half-way houses (usually a step-down from rehabilitation) are also part of community services.

Nursing Assessment

The first and most important aspect in conducting an assessment is to establish a therapeutic relationship based on mutual trust. The nurse should ask open-ended questions and allow adequate time for patient response. It is important

that the nurse remain nonjudgmental and validate the patient's feelings. It may be necessary to reduce the patient's anxiety. The nurse should communicate with brief, clear statements, verify the patient's understanding, and clarify areas that may not be understood. Refer to the exemplar on Therapeutic Communication in the module on Communication for additional information.

The nurse conducting an assessment of the patient who reports feelings of sadness and irritability or exhibits symptoms of mania must remember that these disorders affect individuals in a variety of ways. More detail is provided below and in the exemplars that follow.

Observation and Patient Interview

Patients experiencing alterations in mood and affect may exhibit a variety of behavioral changes that will suggest the need for further assessment. For example, patients experiencing severe depressive or manic symptoms may exhibit poor hygiene. Other behavioral cues include incongruent verbal and nonverbal communication, irritability, exhaustion, lack of motivation, excitability, grandiosity, altered thought processes, pressured speech, and psychosis. Assess energy level, psychomotor symptoms such as agitation or retardation, and dietary and fluid intake.

During the patient interview, assess for previous diagnosis of mental illness, family history of mental illness, sleep quality, eating patterns, cognition, presence of chronic illness, and substance use.

Assess mood and affect, cognition and thought content, communication patterns, and pain and pain history. Obtain information about any mood fluctuations that may have occurred in the past. Assess the patient's perception of wellness and functioning. Is the patient's perception of health and mental health status congruent with the report of family members or caregivers? What is the patient's priority for care?

Assess coping patterns, home environment, and financial status as well as cultural beliefs and practices. These factors have important implications for treatment planning and patient adherence to treatment regimens.

Self-reporting scales are among the most common instruments used to screen for depression (see Table 28–1). These scales may be used as part of the assessment process but should not be used alone or out of context. Manifestations of altered mood may have their origins in other areas (such as physical illness or adverse effects of medications), and nurses must screen for the presence of these as well.

Cultural Considerations

Appropriate expressions of mood are largely culturally determined. For example, situations in which people are expected to experience sadness, anger, loneliness, frustration, joy, or happiness are defined by the culture. Culture also determines how people are to behave when experiencing a variety of feelings.

To effectively assess and care for patients with diverse backgrounds, it is important to learn and understand their societal norms related to thoughts, emotions, and behaviors. Furthermore, nurses must understand the impact of culture on both the expression of depression as well as the risks for depression. (See the Focus on Diversity and Culture feature.) Nurses should also remember that help-seeking behaviors can be culturally determined. For example, African Americans and Latinos often look to their family and faith communities for help before considering seeing a professional. There is a strong fear of hospitalization and involuntary commitment, both of which are more likely for African Americans and Latinos than for Caucasians. Both African Americans and Native Americans have reported greater distrust of the medical community and greater communication challenges (Spector, 2017). Members of communities of color continue to face greater financial hardship related to medical care. A report by the U.S. Census Bureau (2015) indicates that, in 2014, 11.8% of African Americans had no medical insurance at all, in contrast to 7.6% of the Caucasian population.

Although nurses need to take cultural factors into account during assessment (e.g., ensuring careful assessment that includes access to financial resources and attitudes toward the healthcare community), nurses must be careful not to stereotype patients during the assessment process. When nurses engage in stereotyping, they risk failing to assess for important indicators and are likely to increase barriers to trust and understanding when they should be building the therapeutic alliance and gaining patient trust.

Physical Examination

When conducting a physical examination of patients with diagnosed or suspected mood disorders, obtain a complete set of vital signs, including pain. Obtain a baseline weight and body mass index (BMI) to allow for the possibility of weight

Focus on Diversity and Culture Depression in Recent Immigrants

Recent immigrants are at higher risk for depression as they cope with multiple stressors such as long-distance family relationships, unemployment or underemployment, discrimination, language problems, and a new environment. Immigrant children are at risk for depression as they are often expected to interpret the concerns of adult family members to outside authority figures such as physicians, nurses, teachers, and government officials (Guo et al., 2015; Smith, 2011).

monitoring if the treatment plan includes an antidepressant or mood stabilizer. Also be sure to assess sleep, nutrition, activity, and elimination patterns.

A thorough physical examination is necessary to rule out any medical or drug-related causes of presenting signs and symptoms and to identify any comorbid medical illnesses that require treatment. Some chronic medical conditions, especially those that cause pain and/or fatigue, increase the risk of depressive symptoms. Further, patients with depressive and bipolar disorders may be at greater risk of experiencing comorbid medical illness because their mental illness may impair functioning in the areas of self-care and nutrition.

Diagnostic Tests

Although no diagnostic laboratory or medical tests exist for mood disorders, a thorough workup is necessary to rule out any underlying medical conditions that could mimic or cause symptoms of mood disorders, as well as to detect comorbid medical illness that could contribute to symptoms and functional abnormalities. Diagnostic and laboratory tests may include hormone levels and thyroid function tests to rule out endocrine disorders, which can mimic depression or hypomania; electrolyte panels, urinalysis, and toxicology to rule out substance abuse; and liver function tests, because antidepressants are metabolized in the liver. Other tests may be ordered on the basis of the patient's individual symptoms and history (e.g., tests for specific nutritional deficiencies, presence of infection, or medication toxicity). A pregnancy test may be done in women of reproductive age because antidepressants may affect fetal development (Halverson et al., 2016; Tesar, 2010).

Case Study » Part 2

Following a clinical interview and administration of the Beck Depression Inventory, the healthcare provider at the campus health center diagnosed Jason with major depressive disorder and prescribed extended-release venlafaxine (Effexor XR). One month later, Jason comes to the health center for his follow-up appointment. The nurse notes that his behavior is nearly the opposite of what she observed at the initial visit. He describes his current mood as "fabulous." He states he is only sleeping about 2 hours a night but that "it's OK"—he feels great and is getting so much done in the extra hours of wakefulness. Jason also reports a heightened sexual desire and urges and attributes this to his decreased need for sleep. Jason tells the nurse that he completed his required paper and that it is so good, he is turning it into a book about the secret to the meaning of life, although he has not yet received a grade. He is running for student senate, tried out for the track team, and volunteered at the campus tutoring center. The

increased participation in activities has resulted in making new friends with whom he goes drinking 2–3 nights a week. Jason is considering taking five accelerated courses during the summer.

During the interview, Jason's speech is loud, rapid, and pressured. He is restless, unable to sit still for more than 5 minutes. He offers to give the nurse his autograph because he is convinced his intended book will win a Pulitzer Prize. Jason denies side effects of the medication, and considers it a miracle drug because he feels better than he ever has in his entire life. When questioned about thoughts of suicide, he denies them stating, "A person as special as I am needs to be cloned, not killed!"

Clinical Reasoning Questions Level I

1. What else should the nurse assess?
2. How would you describe Jason's affect during this visit?
3. What are the priority health and safety considerations for Jason?

Clinical Reasoning Questions Level II

4. What could be responsible for Jason's remarkable change in mood, affect, and behavior?
5. What are the priority topics to address in Jason's healthcare teaching plan during this visit?
6. How would you rate Jason's risk for suicide? Given your assessment, what would be an effective care plan suggestion?

Independent Interventions

Nurses are in the singular position to provide a number of caring interventions for patients with depressive or bipolar disorders and their families. The most important of these are preventing patient suicide and promoting patient and family safety.

Although treatment of patients with depressive and bipolar disorders is best accomplished by an interprofessional team that includes nurses, mental health professionals, and primary providers, of those individuals who seek and receive treatment, many see only one provider. Nurses working in any setting should consider the following points of treatment management outlined in the APA (2015a) Practice Guidelines for the Treatment of Patients with Major

Depressive Disorder. These points are valid for any patient with any alteration of mood and affect:

- Establish safety
- Promote treatment adherence
- Coordinate care
- Monitor responses to treatment
- Provide education to patients and families.

Prevent Suicide and Promote Safety

Patients experiencing alterations in mood are at increased risk for suicide. When the risk for self-directed violence is high, immediate intervention is necessary. The risk of suicide increases as patients in the severest stage of depression begin to improve; it is then that patients have sufficient energy and cognitive ability to plan and successfully implement a suicide plan. When a patient expresses suicidal ideation, confidentiality does *not* apply. It is the nurse's duty to report suicidal thoughts or actions to the treatment team, or take necessary steps to have the patient transported via ambulance or police to a community crisis screening center, hospital emergency department, or other appropriate facility according to state guidelines. See **Box 28–1** for guidelines to help prevent inpatient suicide and promote safety.

Nurses should assist in the transition from hospital to home by helping patients identify situations or events that trigger feelings of altered moods and to learn to use coping methods they find helpful. Nurses also assist in the transition by helping patients develop a safety plan that includes these strategies as well as information on how to contact family members or their mental health professional if they are unable to return to stable mood without help from someone else.

Monitor Patient Response to Treatment

Nurses must closely monitor how patients with depressive or bipolar disorders respond to treatment. Close monitoring can help reveal whether patients are actually adhering to

Box 28–1

Preventing Inpatient Suicide and Promoting Safety

Check the policy and procedures of the individual inpatient treatment facility and implement those guidelines. For patients who express intent to kill themselves (with or without a plan) or who have made a suicide attempt within the past week, institute safety precautions and request a psychiatric consult as well (Columbia University Medical Center, n.d.).

- Evaluate the patient's level of suicide intent regularly and institute the appropriate level of staff supervision following unit protocol. Patients may deny suicidal ideation or underestimate their own risk (Knoll, 2012).
- Let suicidal patients know that the environment is safe for them. Remove sharp objects, razors, breakable glass items, mirrors, matches, and straps or belts and explain why these objects are being removed. Monitor the use of scissors, razors, and other potential weapons.
- Do not leave patients at risk for suicide alone. In acute care hospitals or residential settings, one-to-one observation must be instituted until a psychiatrist or qualified physician determines the patient is no longer at risk. Family members cannot substitute for

staff in performing one-to-one observation. Some facilities use 15-minute checks, but these are not recommended for use with patients who are seriously suicidal or whose risk level is uncertain (Knoll, 2012).

- Be particularly alert during change of shifts and on holidays or other times when staffing is limited and during times of distraction, such as mealtimes and visiting hours.
- Examine items brought by visitors and monitor for safety. Many units have policies regarding what can and cannot be brought into the unit. Most prohibit food of any kind from outside of the facility.
- Facilitate the development of the therapeutic alliance and maintain a nonjudgmental attitude. Staff members' attitudes toward patients with mental illness can lead to breakdown of the therapeutic alliance and may indirectly increase patients' risk for attempting suicide (Knoll, 2012).
- Use a calm, reassuring approach and encourage patients to discuss all of their feelings. Patients need to know that all feelings are valid and that it benefits them to express their emotions appropriately.

their treatment regimen. If they are not, the nurse should investigate the reasons for nonadherence. When barriers to treatment are identified (e.g., financial constraints, trouble obtaining and/or taking medication, uncomfortable side effects), the nurse can work with the patient to develop strategies to overcome these barriers or possibly to seek another means of treatment. If the patient is adhering to the treatment plan but her condition is not improving, the nurse, patient, and other members of the healthcare team can collaborate to identify potential adjustments to the therapeutic regimen.

Monitoring the treatment response is also important for patients whose symptoms appear to be improving. In these cases, the nurse should consider whether the patient's recovery is occurring at an appropriate pace, whether any supplementary treatment approaches may be helpful, and/or whether any therapeutic measures are no longer necessary.

Support Family Functioning

The family members of an individual diagnosed with mental illness play an important role in treatment. The family member(s) also take responsibility for the patient's care, which can cause frustration and exhaustion, especially with repeated episodes. This care can lead to role strain as the family member(s) often have to care for children, work, and compensate for the mentally ill person's inability to perform usual tasks. It is important to involve the family member(s) as early in treatment as possible. They will be able to assist with maintaining the treatment plan while the nurse lends support when needed. Family, along with the affected individual, will need to have coping skills reinforced and will require education regarding the nature of the patient's illness and the treatment plan.

Teach Assertive Behavior

Nurses working with patients can model, encourage, and teach assertive behavior. Assertiveness is a learned behavior. Everyone has the potential to be assertive, but not everyone instinctively knows how. Children learn patterns of communicating from the adults around them. Individuals can unlearn poor communication patterns that do not work and learn new ones, which is the idea behind assertiveness training. The goal is to help individuals express themselves without fear of disapproval from others. Being assertive does not guarantee that others will agree, but it does provide an individual the satisfaction of offering a personal opinion without ignoring the opinions of others.

Aggressive behavior is directed toward getting what one wants without considering the feelings of others. Aggressive communicators want to get their own way at any cost and may use intimidation to do so. An example of aggressive behavior is insisting on going to a certain movie even though you know your companion does not enjoy that type of movie. The outcome of aggressive behavior is that although you may get what you want in the short run, others feel discredited and tend to avoid you.

Passive behavior consists of avoiding conflict at any cost, even at the expense of one's own happiness. An example of passive behavior is agreeing to go to a movie you do not want to see because your friend pressures you to go. Passive communicators hold their feelings in and allow anger to build up. Anger can explode suddenly or can be expressed

in passive-aggressive behavior. An example of passive-aggressive behavior is taking a long time to get ready to go out while your friend is waiting because you are angry at him for insisting on seeing a movie you do not want to see. The outcome is that the passive person gives up control and is left with resentment, which usually emerges in other ways that damage relationships.

Assertive behavior consists of expressing one's wishes and opinions, or taking care of oneself, but not at the expense of others. An example of assertive communication is saying, "I really don't care for violent movies. Let's look at the movie listings and see if there is something playing that we can both enjoy." The outcome of assertive behavior is self-confidence and self-esteem.

Maintain Professional Boundaries

Patients who are hopeless have a tendency to form dependent relationships. Nurses must work from the first contact with these patients to minimize the likelihood that maladaptive dependence occurs in the nurse-patient relationship. Strategies to minimize maladaptive dependence include the following:

- Emphasize the short-term nature of the relationship.
- Recognize that a patient who singles out one staff member exclusively and refuses to relate to others is developing dependence.
- Avoid giving patients the hope that the nurse-patient relationship can continue after therapy has ended.
- Refuse (kindly but firmly) requests for your address or telephone number.
- Remind patients that social contact will not be allowed.

If you find yourself wanting to continue relationships with certain patients, discuss these feelings with your instructor (if you are a student), your supervisor, or a respected professional peer (if you are a practicing nurse). It is essential that you separate your professional life from your social life.

Collaborative Therapies

Collaborative therapies for patients with mood disorders include pharmacotherapy, CBT and other psychotherapies, and complementary health approaches. Often, combining therapies leads to greater success. Nurses help patients determine what combination of therapies may be most helpful for them, encourage adherence to the treatment plan, and suggest alternatives if a sufficient trial of a treatment or therapy (typically at least 6 weeks) proves ineffective.

Pharmacologic Therapy for Depressive Disorders

Drugs used to treat depression by enhancing mood are categorized as antidepressants. Antidepressants are also sometimes prescribed to treat anxiety disorders. It is thought that antidepressants exert their effect through their action on certain neurotransmitters in the brain, including norepinephrine, dopamine, and serotonin. The two basic mechanisms of action are blocking the enzymatic breakdown of norepinephrine and slowing the reuptake of serotonin (see **Figure 28-3** »). Nurses working with patients taking antidepressants must be

Figure 28-3 ➤ The mechanism of action of TCA, SSRI, and MAOI antidepressant drugs.

alert to the symptoms of **serotonin syndrome**, which can occur in individuals taking two or more medications that increase serotonin levels. Serotonin syndrome exhibits in altered mental status (e.g., anxiety, disorientation, agitation); neuromuscular abnormalities (e.g., tremor, muscle rigidity); and autonomic hyperactivity (e.g., gastrointestinal distress, hypertension, tachypnea, tachycardia, diaphoresis) (Volpi-Abadie, Kaye, & Kaye, 2013; Mayo Clinic, 2017b). Supportive measures and discontinuing the medications involved usually will resolve the patient's symptoms.

Nursing considerations for all antidepressants include:

- Assess health history, including history of sexual dysfunction.
- Monitor for suicidal ideation and behaviors throughout treatment. As patients begin to recover, their energy levels rise, which may increase suicide risk.
- Obtain a baseline body weight to monitor weight gain.

Patient education for all antidepressant medications include:

- It may take several weeks or more to achieve the full therapeutic effect of the drug.
- Risk of suicide increases as therapeutic effect begins.
- Monitor for and report increased suicidal thoughts and behaviors.
- Keep all scheduled follow-up appointments with your healthcare provider.
- Report side effects, including nausea, vomiting, diarrhea, sexual dysfunction, and fatigue.
- Do not take other prescription drugs, over-the-counter (OTC) medications, or herbal remedies without notifying your healthcare provider.
- Avoid using alcohol and other central nervous system (CNS) depressants.
- Immediately discuss with your healthcare provider an intention or desire to become pregnant.
- Exercise and monitor caloric intake to avoid weight gain.
- Do not discontinue medication abruptly.

SAFETY ALERT The Food and Drug Administration (FDA) requires a “black box warning” for all antidepressants related to the increased risk for suicidal thoughts and behaviors associated with taking antidepressant medications. The nurse must be aware of this and educate patients and families to monitor for this and provide 24-hour emergency center contact numbers for use if this occurs. Patients age 24 and younger are especially at risk.

Pharmacologic Therapy for Bipolar Disorders

Drugs used to treat bipolar disorders are called **mood stabilizers** because they have the ability to moderate extreme shifts in emotions between mania and depression. Some anticonvulsive drugs are used for mood stabilization in patients with bipolar disorders. Medications commonly prescribed for the treatment of bipolar disorders include lithium carbonate (Eskalith); atypical antipsychotics, such as aripiprazole (Abilify) and olanzapine (Zyprexa) (see

Exemplar 23.C: Schizophrenia for additional information on antipsychotic medications); and antiseizure medications such as carbamazepine (Tegretol) and valproic acid (Depakote). Side effects and adverse effects of these drugs are many and varied. Generally speaking, however, nursing considerations for patients receiving pharmacologic therapy for bipolar disorders include the following (Wilson, Shannon, & Shields, 2016):

- Monitor drug levels (especially lithium), blood glucose levels, and electrolyte panels periodically. (Note that older adults require more frequent monitoring for drug toxicity.)
- Monitor for and report increased signs of suicidality and suicidal ideation. (Children and adolescents may need more frequent monitoring.)
- Monitor for and report changes in cardiovascular status, particularly orthostatic hypotension. (Older adults require more frequent monitoring.)
- Monitor for and report signs of extrapyramidal symptoms or neuroleptic malignant syndrome.
- Monitor neurologic and neuromuscular status in older adults.

SAFETY ALERT Patients with bipolar disorders who are in the depressive phase and prescribed only an antidepressant are at high risk for switching to a manic episode. For that reason, mood stabilizers are always prescribed at the same time.

Lithium Therapy

The role of the nurse in lithium therapy involves carefully monitoring a patient's condition and providing education as it relates to prescribed drug treatment. Because lithium is a salt, patients with a history of cardiovascular and kidney disease should not take it. Patients frequently experience dehydration and sodium depletion; therefore, patients on a low-salt diet should not be prescribed lithium. Assess for and identify signs and symptoms of lithium toxicity, which include diarrhea, lethargy, slurred speech, muscle weakness, ataxia, seizures, edema, hypotension, and circulatory collapse. Serum lithium levels should be ordered every 1–3 days when therapy is initiated and periodically thereafter because of the narrow therapeutic window between toxicity and effectiveness. They should be drawn at least 8 hours after the last dose. This is essential because lithium is nephrotoxic, and hemodialysis may be necessary if overdose occurs (Adams, Holland, & Urban, 2017). Some 30% of individuals taking lithium will experience lithium toxicity at least once during their course of treatment. Lithium toxicity can lead to altered mental status accompanied by poor oral intake, increasing the patient's risk for acute renal failure resulting from severe dehydration and volume depletion (Lederer, 2015). See the Patient Teaching feature for more information related to lithium. Further information about pharmacologic therapies for bipolar disorders is provided in Exemplar 28.B.

Nonpharmacologic Therapy

A nonpharmacologic approach to treatment for depression is commonly used in conjunction with pharmacologic therapy. Examples of nonpharmacologic therapies include

Medications

Antidepressants

CLASSIFICATION AND DRUG EXAMPLES	MECHANISM OF ACTION	NURSING CONSIDERATIONS
Selective Serotonin Reuptake Inhibitors (SSRIs) Drug examples: Citalopram, escitalopram, fluoxetine, paroxetine, sertraline, vilazodone	Slows the reuptake of serotonin into presynaptic nerve terminals. Increases the availability of serotonin in the synaptic cleft for post-synaptic receptors. May also be used for: <ul style="list-style-type: none"> ■ Anxiety disorders ■ Eating disorders 	Take most SSRIs in the morning with food to avoid gastrointestinal upset and insomnia. If the patient complains of feeling sedated or tired, the SSRI may be taken in the evening. St. John's wort and <i>Ginkgo biloba</i> may cause serotonin syndrome when taken with SSRIs. Provide patient teaching related to suicidal ideation and serotonin syndrome.
Atypical Antidepressants (including SNRIs) Drug examples: Bupropion Duloxetine, venlafaxine, and mirtazapine are serotonin–norepinephrine reuptake inhibitors (SNRIs).	Bupropion works by inhibiting the uptake of dopamine, serotonin, and norepinephrine and elevating mood by increasing the levels of these neurotransmitters in the CNS. SNRIs inhibit the reabsorption of serotonin and norepinephrine and elevate mood by increasing the levels of serotonin, norepinephrine, and dopamine in the CNS. May also be used for: <ul style="list-style-type: none"> ■ Smoking cessation (bupropion “Zyban”) ■ Anxiety disorders (duloxetine, venlafaxine) ■ Fibromyalgia, chronic musculoskeletal pain (duloxetine) ■ Neuropathic pain (duloxetine and off-label for bupropion and venlafaxine) ■ Attention-deficit disorder (venlafaxine, and off-label bupropion) 	Take mirtazapine at bedtime because it usually causes excessive drowsiness, especially at lower doses. Should be used with caution in patients with seizure disorders because it lowers the seizure threshold. Monitor patients closely if a seizure disorder is present. Monitor for serotonin syndrome and neuroleptic malignant syndrome-like reactions. Increased risk of hepatotoxicity. Instruct patient on changing positions slowly secondary to potential for orthostatic hypotension. Should not be used as a single therapy for patients diagnosed with bipolar disorder, as it may worsen psychotic features or precipitate manic or hypomanic symptoms.
Tricyclic Antidepressants (TCAs) Drug examples: Amitriptyline, clomipramine, doxepin, imipramine, nortriptyline	Inhibits reuptake of both norepinephrine and serotonin into presynaptic nerve terminals May also be used for: <ul style="list-style-type: none"> ■ Anxiety ■ Neuropathy 	TCAs may cause decreased sweating, along with anticholinergic side effects such as dry mouth, constipation, blurred vision, and increased heart rate. For patients over the age of 40, an electrocardiogram may be ordered prior to initiation of treatment to detect preexisting arrhythmias. TCAs are contraindicated in patients in the acute recovery phase of a myocardial infarction (MI), with heart block, or with a history of dysrhythmias because of the effects of TCAs on cardiac tissue. TCAs lower the seizure threshold, so patients with epilepsy should be closely monitored. Patients with urinary retention, narrow-angle glaucoma, or prostatic hypertrophy may not be good candidates for TCAs because of anticholinergic side effects.
Monoamine Oxidase Inhibitors (MAOIs) Drug examples: Selegiline, isocarboxazid, phenelzine, tranylcypromine	Inhibit monoamine oxidase, the enzyme that terminates the actions of neurotransmitters such as dopamine, norepinephrine, epinephrine, and serotonin.	Interacts with a large number of foods and other medications—sometimes with serious effects. Hypertensive crisis can occur when an MAOI is used concurrently with other antidepressants or sympathomimetic drugs. MAOIs also potentiate the hypoglycemic effects of insulin and oral antidiabetic drugs. A hypertensive crisis also can result from an interaction between MAOIs and foods containing tyramine, a form of the amino acid tyrosine. There must be at least a 14-day interval between the use of MAOIs and other drugs and food restrictions. Advise patient to wear a medic alert bracelet.

Patient Teaching

Lithium

The nurse should provide patients who take lithium with information related to their medication, including:

- Take medication as ordered because adherence is the key to successful treatment.
- Keep all scheduled laboratory visits to monitor lithium levels.
- Do not change diet or decrease fluid intake, because any changes in diet and fluid status can affect therapeutic drug levels.
- Avoid alcohol use.
- Do not take other prescription medications, OTC drugs, or herbal products without notifying your healthcare provider.
- Do not discontinue use except under the guidance of the healthcare provider.

psychotherapy, light therapy, support groups, and meditation. ECT may be used for treatment-resistant depression. Both medication and psychotherapy alone are effective in treating depression; however, the combination of both medication and psychotherapy is most effective. Therefore, psychotherapy is almost always recommended.

One of the most successful forms of psychotherapy is CBT. However, a number of different forms of psychotherapy can be considered. The best approach to psychotherapy is chosen based on the cause and symptoms of the depressive condition as well as the patient's needs and personality.

Cognitive–Behavioral Therapy

CBT focuses on skill training and problem solving to help patients reorient patterns of negative thinking and negative behaviors. The clinician or therapist works with patients to identify the most troubling problems in their lives and erroneous thought patterns or behaviors that may reinforce or exacerbate them. Therapists help patients problem solve by asking questions that help patients reflect and reconsider troubling situations. Examples of questions include: *What happens? What do you think when this happens? What do you do? Why do you think this happens to you? What would need to happen for you to feel differently? What might you do to change the situation?*

Cognitive–behavioral therapists use various techniques. One is **cognitive modification** of negative thought patterns. Every individual has automatic thought patterns, some of which are helpful and some of which are negative. An example is that of a teenage daughter who is 1 hour late for her curfew and has not called. The mother's automatic thought might be one of the following:

- "She must have been in an accident and can't call."
- "She cares so little for me that she can't call even though she knows how much I worry."
- "She is usually very responsible, so I am sure she will be home soon and will be able to tell me what happened."

Cognitive–behavioral therapists help patients identify these patterns of irrational thinking and find ways to replace

them with more logical and fact-based patterns of thinking. For example, a mother experiencing depression may constantly choose to believe the worst in a number of given scenarios involving her children. In CBT, the therapist may help the mother view her children as they really are and begin to reorient her expectations. For example, the mother of a teen may change her thinking from "Something must have happened to Sarah!" to recognizing more likely scenarios: "Sarah is late for curfew, but she was at the football game with some friends. They probably went to get something to eat afterward and she's forgotten to call."

A technique promoted in CBT that may specifically help patients with depression is mindfulness training. Most people usually go through daily routines with little awareness or attention. *Mindfulness* is the art of conscious living by focusing one's full attention on the activity at hand. While it may be simple to practice mindfulness, it is not necessarily easy. Habitual unawareness is persistent, and mindfulness requires effort and discipline. Cognitive–behavioral therapists believe that the way for people to start changing their minds is not to force the change, but to watch it. Through the process of mindfulness, individuals can learn to identify destructive thought patterns, simply label them, and watch them pass by whenever they come to mind. As individuals learn how their brains "tell stories," they can begin to change their negative thought patterns.

Electroconvulsive Therapy

Electroconvulsive therapy (ECT) is a treatment procedure that passes an electric current through the brain to induce a seizure. It has been used clinically since the 1930s. It is usually given 2–3 times weekly for 3–4 weeks until a course of 6–12 treatments is completed. Research suggests that twice-weekly ECT is preferable, as it is roughly as effective as thrice-weekly administration but frequently requires fewer treatments and may be associated with longer-lasting therapeutic effects (Charlson et al., 2012). ECT is typically considered a second-line therapy for both treatment-resistant MDD and bipolar disorder, and it produces similar overall remission rates in patients with either condition (Dierckx et al., 2012). A systematic review of ECT (Allan & Ebmeier, 2011) cited the following findings from studies completed within the previous 10 years:

- ECT is effective in treating depression, with responses of over 80%.
- Response is even higher in patients who have depression with psychotic features.
- Response is relatively rapid (greater than 60% within 3 weeks).
- ECT is associated with improved mood, functional status, anxiety, and quality of life.
- Individuals of all ages, even older adults with cognitive impairment, tolerate and respond well to ECT.
- It does not cause a switch to mania when used to treat bipolar depression, and it may also be used in patients with bipolar disorder with mixed features.
- It is especially useful for patients with severe depression who are resistant to other treatments, those who are severely suicidal, and those with severe psychomotor retardation.

A review of ECT in pregnancy demonstrated its effectiveness in treating depression; however, it is linked with potential fetal and maternal complications such as premature labor, decreased fetal heart rate, and uterine contractions (Leiknes et al., 2015). Risks and benefits of ECT must be weighed carefully on an individual case basis before deciding to treat a pregnant woman with ECT.

ECT is administered while the patient is under anesthesia. A thorough medical examination is required prior to the procedure to clear the patient for anesthesia. Muscle relaxants are usually administered. The patient is ventilated during the procedure. Electroencephalogram (EEG) and electrocardiogram (ECG), oxygen saturation via pulse oximetry, and vital signs are monitored during the procedure, which only takes 5–10 minutes. Mild confusion following the procedure (a postictal state) is typical. Vital signs must be monitored frequently for several hours after the procedure. During a course of ECT, a transient short-term memory loss (anterograde amnesia) is expected. This is distressing to some patients, and they need to be reassured that memory is usually restored. In rare cases, however, retrograde amnesia occurs and may be permanent. There are the usual risks associated with anesthesia. It is essential that all the potential risks and benefits of ECT be explained to and understood by

the patient. A written, informed consent form must be signed by the patient before the procedure. Patients have the right to refuse treatment at any time during the course of therapy.

Transcranial Magnetic Stimulation

Repetitive transcranial magnetic stimulation (rTMS) is an FDA-approved treatment for depression that involves the use of a magnetic field that passes through the skull, causing cells in the cerebral cortex to fire. The target area is the left prefrontal cortex, which is one part of the brain thought to be disrupted in depression. Targeting the opposite lobe, the right prefrontal cortex, has therapeutic effects in manic episodes. This therapy has a rapid onset of action of 1–2 weeks, which is faster than most psychotropic medications. Although rTMS produces fewer short-term adverse cognitive effects than ECT, numerous studies have found that its benefits are fewer and of shorter duration than those associated with ECT (Health Quality Ontario, 2016; Janicak & Dokucu, 2015; Minichino et al., 2012).

Complementary Health Approaches

In community surveys, depression, fatigue, insomnia, and anxiety are among the most commonly reported reasons for the use of alternative therapies. The following are some

Patient Teaching

Electroconvulsive Therapy (ECT)

Prior to ECT, the nurse will complete a medical history, a physical exam, and a mental health assessment. Tests that will be needed include blood work and an electrocardiogram (ECG). Upon arrival for the first ECT, the patient will need to be educated on what to expect, which will include the following:

- If part of your responsibility, educate patient about the procedure, potential side effects, and expected effects of ECT. Because ECT requires the administration of anesthesia, provide necessary information regarding anesthesia administration and recovery. Ensure that all necessary consent forms have been signed by the patient before continuing. Although informing patients and obtaining consent forms is legally a medical responsibility, in practice it is often shared by nurses.
- Inform the patient of the need to review his or her medical history and perform a short physical assessment.
- Ensure that the patient has had nothing by mouth for at least 4 hours before treatment.
- Just prior to treatment, request that the patient empty the bladder and remove contact lenses, jewelry, hairpins, and dentures.
- The nurse will initiate an IV, and electrodes will be placed on the patient's head.

During the ECT treatment, the patient should understand what will occur, including:

- Vital signs will be monitored and oxygenation will occur.
- General sedation will be given, oxygen will be administered via mask, and a mouth guard may be used to prevent breakage of teeth and biting of tongue.
- The anesthetic preparation usually consists of the following:
 - a. Generally, an atropine-like medication such as glycopyrrolate (Robinul) is given to decrease secretions and block cardiac vagal reflexes during the seizure.

- b. A short-acting anesthetic such as methohexital sodium (Brevital) is administered intravenously.
 - c. Following induction, a skeletal muscle relaxant such as succinylcholine chloride (Anectine) is administered to prevent injuries during the seizure.
 - d. The patient will be artificially ventilated until the muscle relaxant is fully metabolized, usually in 2–3 minutes. Oxygen is administered with a rubber bite block in place. If necessary, oxygen may be administered by positive pressure.
- An electric current is passed through the brain by means of unilateral or bilateral electrodes placed on the temples. This causes a generalized (or tonic-clonic) seizure that lasts for usually less than 60 seconds, the effects of which are masked by the muscle relaxant. Often the only observable signs of seizure are a fluttering of the eyelids and carpopedal spasms.
 - The patient will have vital signs and brain activity monitored during the entire process.

Once the ECT is completed, the patient should understand that the following will occur:

- General anesthesia will begin to wear off.
- The nurse will monitor vital signs frequently.
- Upon awakening, the patient may experience some confusion and memory loss, which may be short term or permanent.
- Patients are recovered in the lateral recumbent position to facilitate drainage and to prevent aspiration. After they are fully recovered and have been reoriented by the nurse, they will be able to eat.
- After vital signs are stabilized, the patient is able to leave (if ECT is being performed on an outpatient basis).
- The patient should not drive for the remainder of the day and should also have someone with them for the day (Kellner et al., 2012; Mayo Clinic, 2017a).

complementary therapies used for mood disorders. Note that these types of therapies should be used as complementary, rather than alternative, therapies in patients experiencing significant disruption in functioning related to mood disorders. Patients taking pharmacologic therapy should be encouraged to consult their prescribing provider before trying herbs or dietary supplements.

Exercise

Research indicates that exercise can reduce anxiety and promote healthy behaviors and overall health (Bertisch et al., 2012; Herring, O'Connor, & Dishman, 2010). These benefits alone make exercise a key part of health promotion and patient teaching in patients with alterations in mood and affect. However, a Cochrane review of 39 studies with 2326 participants found no conclusive evidence that exercise improves symptoms of depression (Cooney et al., 2013), indicating that nurses should emphasize the overall health benefits of exercise rather than its use as a complementary or alternative therapy to patients with alterations in mood and affect. Still, exercise is recommended for people with mild to moderate depression, provided they are physically able to participate (Cooney et al., 2013; Josefsson, Lindwall, & Archer, 2014). Although some reviews indicate that no one form of exercise is best, others suggest that individuals with depressive symptoms should engage in moderate-intensity aerobic exercise three times a week for a minimum of 9 weeks. Exercise also appears to be most beneficial when used in combination with antidepressant medications (Danielsson et al., 2013; Stanton & Reaburn, 2013).

SAFETY ALERT St. John's wort is not a proven therapy for depression (National Center for Complementary and Integrative Health [NCCIH], 2016) and should not be used to postpone or replace conventional treatment. It should **not** be combined with prescription antidepressants. It also may interfere with the action of antiepileptic medications. St. John's wort has been found to reduce the effectiveness of birth control pills and HIV medications, among others (NCCIH, 2016). If taken with SSRIs, TCAs, or some atypical antidepressants, serotonin syndrome may result.

Vitamin B

Low levels of the B vitamins have been linked to depression, as vitamin B plays a role in the development of serotonin and norepinephrine (Bottiglieri, 2013; Lewis et al., 2013). A systematic review found that short-term increase of folate or vitamin B₁₂ is not helpful in the treatment of depression but may be helpful if taken for the long term (Almeida, Ford, & Flicker, 2015). There is inconsistent evidence that folic acid may improve the action of some antidepressants (Bedson et al., 2014; Coppen & Bailey, 2000).

Omega-3 Fatty Acids

A systemic review and meta-analysis of 13 randomized controlled trials that studied the role of omega-3 fatty acids as an adjuvant treatment for depression found no significant benefit when compared to placebo use, despite earlier reports of patients' experiences of mild to moderate improvements in mood (Bloch & Hannestad, 2012).

Acupuncture

Acupuncture is best known for pain relief but may be coupled with SSRI antidepressants for increased benefit. Clinical trials indicate that acupuncture, when used with SSRI antidepressants, enhances the therapeutic response, has an early onset of action, and is well tolerated compared to the use of SSRIs alone (Chan et al., 2015). Furthermore, patients who are treated with acupuncture coupled with SSRIs demonstrate a faster response time and decreased side effects (Liu et al., 2015). There is also some evidence that acupuncture may be beneficial in the treatment of depression in pregnant women when the acupuncture is targeted toward treatment of depression and not generalized (Sneizek & Siddiqui, 2013).

Case Study » Part 3

Jason was admitted to the short-term acute care psychiatric unit of the local hospital. He was diagnosed with bipolar I disorder and started on aripiprazole (Abilify). Jason reports feeling as if he has to keep moving all the time, and he has mild dystonic symptoms involving muscle twitches in his hands. He is currently taking 20 mg of aripiprazole daily. He is attending individual and group therapy sessions. He is sleeping and eating more normally; his speech is no longer rapid and pressured. Jason no longer believes he has special talents. He says he now feels stupid about his previous behavior and ashamed that he ended up being hospitalized. He states, "I can't face anyone I know now that they know I am crazy. I don't want to live the rest of my life like this. What's the point?"

Clinical Reasoning Questions Level I

1. What symptoms should be reported to the physician and therapist?
2. Based on the information provided, what does the nurse need to assess immediately?
3. What is the probable cause of Jason's feelings of restlessness and muscle twitches? What additional treatments might be indicated to address them?

Clinical Reasoning Questions Level II

4. What do Jason's statements indicate and how should the nurse respond?
5. What is the priority nursing diagnosis for Jason at this time?
6. Why do you think Jason was not prescribed an antidepressant?

Lifespan Considerations

Mood and Affect in Children and Adolescents

Determinants of normal mood and affect in children and adolescents are generally the same as those for adults; however, a greater level of lability is common in younger patients and should not necessarily be considered suggestive of a mood disorder. Causes of "mood swings" among children and adolescents include anxiety about the physical changes they are experiencing; hormonal fluctuations associated with the onset of puberty; immaturity of the prefrontal cortex; and the pressures of adjusting to new roles and expectations (Balzer et al., 2015; Guyer, Silk, & Nelson, 2016; Larson, Csikszentmihalyi, & Graef, 2014). As adolescents progress toward adulthood, the mood swings

typical of the teenage years become progressively less common (Maciejewski et al., 2015).

When a child's mood and affect fall outside the normal range for members of his age group, the possibility of a mood disorder should be considered. According to the NIMH (2013a), the 12-month prevalence of mood disorders among children age 8–15 is 3.7%. Girls are affected nearly twice as often as boys. Children experience depression, although onset typically occurs sometime between puberty and young adulthood; hence, depression rates rise during the later teenage years. In fact, according to the CDC (2014), 5.7% of adolescents age 12–17 experience depression. Bipolar disorder is rarely observed in this population, because onset nearly always occurs in late adolescence or when individuals are in their 20s (APA, 2013).

Initially, many parents choose to try psychotherapy alone to treat depressive disorders in their children and adolescents. However, if this proves unsuccessful, medication is indicated. Currently, fluoxetine (Prozac) is the only antidepressant that is FDA-approved for use in children. However, many healthcare providers prescribe other SSRIs for children with depression. For example, sertraline (Zoloft) is approved for use in treating obsessive-compulsive disorder in children but not depression. However, some providers may prescribe sertraline for children and adolescents with depression—an example of “off-label” use. Most prescribers will start children on a lower dose of antidepressant than is normally prescribed for adults and titrate up to a dose that is effective in symptom relief.

After a comprehensive review of published and unpublished controlled clinical trials of antidepressants in children and adolescents, the FDA issued a public warning in October 2004 regarding increased risk of suicidal thoughts or behavior in children and adolescents treated with SSRI antidepressant medications. However, several newer studies indicate that the benefits associated with taking antidepressants may be greater than the risk of suicide (Cooper et al., 2014; Gibbons et al., 2012; Isacson & Rich, 2014).

SAFETY ALERT Note that the FDA does not recommend paroxetine (Paxil) to treat depression in children and adolescents (NIMH, 2013a). There are reports of increased suicidal thinking and behavior during initial treatment using paroxetine in children and adolescents. There is a “black box” warning secondary to these findings (FDA, 2014).

Mood and Affect in Pregnant Women

Manifestations and potential causes of depressive disorder with peripartum onset are detailed in the exemplar on Postpartum Depression. Generally speaking, new onset of depression during pregnancy appears to be related to anxiety about the fetus's health and the birth process, concern about relationship changes and adapting to the maternal role, and the many physical and hormonal changes of pregnancy. It is also important to note that many women who previously experienced depression either continue to experience symptoms or have a recurrence of symptoms during pregnancy (Fall, Goulet, & Vézina, 2013). When both women with existing mood disorders and women with new-onset

depression are considered, experts estimate that between 12 and 20% of women experience depression during the antepartum period. Many of these women remain undiagnosed or untreated, often because they feel ashamed to be depressed during a time in life when society expects them to be filled with joy and anticipation. Unfortunately, failure to seek treatment during pregnancy can have detrimental effects on both mother and child, including elevated likelihood of pregnancy complications, premature birth, high-risk maternal behavior, postpartum depression, intrauterine growth restriction, and developmental difficulties during childhood (Chan et al., 2014; Fall, Goulet, & Vézina, 2013; Syka, 2015).

Several treatment options are available for women who experience mood disorders during pregnancy. Many women opt for group therapy or psychotherapy, often because they are hesitant to pursue or continue pharmacologic treatment. A major reason for this hesitation is that, to date, no psychotropic drug has been assigned a Category A rating by the FDA. (A Category A rating indicates that there are no known fetal risks associated with a medication.) Research indicates, however, that many women and prescribers alike overestimate the risk associated with pharmacologic therapy during pregnancy. For example, SSRIs are among the most studied drugs in pregnant women, and substantial evidence exists that these drugs (with the exception of paroxetine [Paxil]) present low risk of major birth defects. Nonetheless, babies of mothers who took SSRIs during pregnancy do have a slightly elevated risk of persistent pulmonary hypertension in the newborn (PPHN) and neonatal withdrawal. TCAs are also considered low risk, although use of MAOI antidepressants is not recommended (Chan et al., 2014; Freeland & Shealy, 2014; Kalfoglou, 2016). For more information on the care and treatment of pregnant women with mood disorders, see the exemplars in this module.

Mood and Affect in Older Adults

Depression is not a normal part of aging; research suggests that older adults generally have more positive mood and affect than younger adults (English & Carstensten, 2014; Masumoto et al., 2016; Stanley & Isaacowitz, 2011). Thus, when older adults present with symptoms of depression, these symptoms need to be addressed. In many cases, these symptoms may be related to life changes, such as retirement; loss of aging friends, family, or spouse to death; downsizing or placement in assisted care; and loss of physical function. Major life-changing events can be precipitating factors to inability to cope leading to increased risk of depression (Potter & Moller, 2016). The presence of a chronic illness elevates the older adult's risk for depression.

When working with older patients, a thorough evaluation is necessary to rule out any underlying medical cause of mood alterations before medication is prescribed. As with most medications in older adults, the cardinal rule is to start with the lowest dose and increase slowly as tolerated and as needed to achieve therapeutic effect. Older adults may respond to a lower drug dose, but it is important to treat to remission. Also, because the majority of psychotropic medications are metabolized in the liver, caution must be taken in

older adults with liver disease. For patients with depression, SSRIs are usually the drug of choice. Because psychotropic drugs lead to increased risk of orthostatic hypotension in older adults, patients should be educated to sit before standing and stand before walking to reduce their likelihood of falls. The patient and family should also be educated on fall-risk reduction strategies. In addition, a thorough medication history and periodic medication reconciliation should be conducted because of the risk of medication interactions and polypharmacy (Frank, 2014; Lindsey, 2009; Mulsant et al.,

2014). Most older adults with mood disorders respond well with antidepressants, psychotherapy, or a combination of the two (Potter & Moller, 2016).

SAFETY ALERT Atypical antipsychotics, often used to treat bipolar disorder, all have an FDA “black box” warning that they may increase mortality in older adults with dementia-related psychosis. Older adults taking these medications for bipolar disorder should be monitored carefully.

REVIEW The Concept of Mood and Affect

RELATE Link the Concepts

Linking the concept of mood and affect with the concept of development:

1. Explain how failure to master the developmental tasks of older adulthood could contribute to the development of depression (refer to developmental theories).
2. How can resiliency theory be applied to the development or prevention of depression?

Linking the concept of mood and affect with the concept of family:

3. How can the burden of having a family member with a severe mental illness such as bipolar disorder affect the family system?
4. How does the stage that the family is in affect family recovery from a mood disorder?

Linking the concept of mood and affect with the concept of self:

5. How would you assess self-esteem in a patient suspected of having a mood disorder?
6. What are some strategies that can be used to enhance the low self-esteem often experienced by patients with mood disorders?

REFLECT Apply Your Knowledge

Gerald Hanes is a 72-year-old widowed man who is brought in to his primary care provider's office by his daughter, who is worried about his unexplained weight loss. Gerald lives independently and is in good general health. Since Gerald's regular checkup 2 months ago, he has lost 20 pounds. He denies any concerns at this time. Gerald's daughter reports that he has not been attending church, which he used to do weekly. She further reports that ever since his wife died 3 months ago, he has not been maintaining his relationships with the family. She states that he still has most of the groceries left in the kitchen that she purchased for him 2 weeks ago. When asked if he is eating, Gerald states, “I'm just not hungry anymore.” Gerald presents with a flat to sad affect and depressed mood. All laboratory test results are reported as negative or within normal limits.

Clinical Reasoning Questions Level I

1. What additional questions should the nurse ask Gerald during the assessment?
2. In further discussion with the daughter, she states that she knows that this is typical for the aging population. How should the nurse respond to this statement?
3. What are three appropriate nursing diagnoses for Gerald at this time?

Exemplar 28.A Depression

Exemplar Learning Outcomes

28.A Analyze depressive disorders and relevant nursing care.

- Describe the pathophysiology of depressive disorders.
- Describe the etiology of depressive disorders.
- Compare the risk factors and prevention of depressive disorders.
- Identify the clinical manifestations of depressive disorders.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with a depressive disorder.
- Differentiate care of patients with depressive disorders across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with a depressive disorder.

 Seasonal affective disorder (SAD), 1935
 Situational depression, 1935

Overview

Depression is a disorder characterized by a sad or despondent mood or loss of interest in usual activities. Many symptoms are associated with depression, including lack of energy; sleep disturbances; anxious distress; abnormal eating patterns; psychomotor retardation or agitation; and/or feelings of despair, guilt, and hopelessness. Depression is one of the most common mental health disorders and encompasses a variety of physical, emotional, cognitive, and social considerations. The Substance Abuse and Mental Health Services Administration (SAMHSA) (2015a) reports that just under 16 million American adults (approximately 6.6% of the population) will experience a major depressive episode in a given year. Treatment rate estimates for adults with depressive disorders are as low as 29% and as high as 41% (Olson, Blanco, & Marcus, 2016; SAMHSA, 2013).

The majority of patients who experience depression are found in mainstream everyday settings. Proper diagnosis and treatment require collaboration among healthcare providers. Because patients with depression are present in multiple settings and in all areas of practice, every nurse should be proficient in the assessment and nursing care of patients with this disorder.

Pathophysiology and Etiology

Pathophysiology

As described in the Concept section of this module, the exact pathophysiology of depression has yet to be determined. However, individuals with depression often have increased limbic system activity, along with decreased gray matter volume and lower metabolic activity in the MPFC (Field & Cartwright-Hatton, 2015; Grieve et al., 2013). Specific reasons for these findings remain unclear, although the working theory is that they involve alterations in neurotransmitter activity and/or neuronal receptivity to neurotransmitters. Several different neurotransmitters have been implicated in the pathophysiology of depression, including 5-HT, NE, DA, ACh, GABA, and glutamate (Halter, 2014; Patrick & Ames, 2015; Potter & Moller, 2016).

More recent studies have focused on a potential connection between depression and inflammation, based on the fact that many depressed individuals have increased levels of inflammatory biomarkers called cytokines (Raison & Miller, 2011; Vogelzangs et al., 2012). However, not all individuals with depression have elevated cytokine levels, and not all people with elevated cytokines have depression. Together, these findings have led to the hypothesis that some people with depression may have a genetic predisposition toward elevated cytokine production when faced with external stressors, as well as the hypothesis that other individuals may have genetic factors that protect them against the

potentially mood-lowering effects of cytokines (Raison & Miller, 2011; Slavich & Irwin, 2014).

Hormonal factors also continue to be investigated as a possible cause of depression. Researchers have noted that individuals with depression tend to have increased levels of cortisol and corticotropin-releasing hormone, both of which are produced in the brain's HPA axis. High levels of cortisol and corticotropin-releasing hormone are indicative of HPA and limbic system hyperactivity, which (as described earlier) is commonly observed in individuals with depression (Potter & Moller, 2016). However, researchers aren't sure whether depression precipitates HPA hyperactivity and excess hormone production or whether HPA hyperactivity and excess hormone production precipitate depression.

Etiology

Depression has been linked to multiple possible causes. Genetics clearly plays some role, although the exact nature of this role remains unclear. Other potential causative mechanisms (many of which may have a genetic component) include hormonal imbalances, disruptions in biological rhythms, high stress levels, poor coping mechanisms, traumatic life events, unhealthy or insufficient interpersonal relationships, and internalization of unhealthy or unrealistic gender-based expectations. Refer to the "Theories of Depression" section in this module for more information on each of these possible contributors.

Risk Factors

Risk factors for depression include family history of depression or other mental illness, female gender, history of child abuse or trauma, unemployment, poverty, lower education, and lack of social supports (Andrews, 2016; Halverson, 2016). It should be noted that first-degree relatives of individuals with depression are three times as likely to develop depression than the general population (Halverson, 2016).

Prevention

As discussed at the beginning of this module, there is no definitive way to prevent depression, because of causative and contributing genetic and biological factors that cannot be modified. However, a number of approaches can be useful in controlling these factors. Individuals should be encouraged to eat a healthy diet, engage in regular exercise, avoid smoking, and obtain adequate sleep. Other primary prevention strategies include providing education about stress management and healthy emotional functioning; encouraging patients to participate in meaningful social relationships; providing targeted teaching and support to individuals who have experienced traumatic or otherwise life-altering events; and using family-based cognitive-behavioral interventions to reduce the likelihood of depression among children with depressed parents. Secondary

prevention strategies include regular screening, counseling patients about their relative risks for depression, and referring individuals with suspected depression for accurate diagnosis and treatment. Finally, tertiary prevention focuses on provision of collaborative care and establishment of community-focused programs that target depressed and high-risk individuals. For a detailed discussion of all of these prevention approaches, refer to the Health Promotion section within this module.

Clinical Manifestations

Some of the clinical manifestations of depression seem fairly obvious: feelings of sadness and despair and sleep disturbances, for example. Others may not be as obvious, such as anger and physical complaints. Manifestations of depression also can differ according to culture, especially if mental illness is stigmatized within the culture. Mental illness is often displayed with somatic symptoms such as headaches, gastrointestinal discomfort, or sleep disturbances that may require assessment by a healthcare provider. Studies indicate that Chinese patients are more likely to report somatic symptoms when depressed than are Euro-Canadian patients (Dere et al., 2013). Depression is seen worldwide and is especially increased in post-conflict settings. For example, a study of post-conflict South Sudan reported rates of depression as high as 50% (Ameresekere & Henderson, 2012). It is important for nurses involved with patients with depression to know and recognize the symptoms.

Major Depressive Disorder

A **major depressive episode** is characterized by a change in several aspects of an individual's emotional state and functioning consistently over a period of 14 days or longer. The most important factor is the patient's mood, which the patient may not describe in terms of "depression." Instead, the patient may describe feelings of sadness, discouragement, or hopelessness. Some patients may report vague somatic (physical) complaints such as aches and pains; other patients may report increased anger, frustration, and irritability, with uncharacteristic outbursts over minor matters. It is not difficult to imagine that someone who looks and feels sad or empty is depressed. A diagnosis of depression is more likely to be missed when an individual simply seems anxious or irritable.

Major depressive disorder (MDD) may consist of a single episode or may exhibit as recurrent major depression at various points in life. Signs and symptoms of single-episode and recurrent major depression are found in **Box 28-2**. Onset of MDD generally occurs gradually, with symptoms progressing from anxiety and mild depression to a major depressive episode over a period of days, weeks, or months. The course of MDD is extremely variable, with some individuals experiencing remission for a period of months and others experiencing many years between episodes (APA, 2013). Individuals who experience MDD in the context of another disorder, such as substance abuse or borderline personality disorder, often experience symptoms that are more difficult to treat (APA, 2013). A diagnosis of MDD requires that the individual not have any previous episodes of mania or hypomania (which suggest a bipolar rather

Box 28-2

Symptoms of Major Depressive Disorder

- Significant distress or impairment of functioning
- Feelings of despair, hopelessness
- Sadness, crying
- Feelings of worthlessness, guilt
- Loss of self-esteem
- Loss of interest or pleasure in activities
- Substantial changes in weight or appetite over a short period of time
- Impairments in executive functioning (e.g., ability to plan, organize, solve problems, concentrate)
- Visible psychomotor agitation or retardation
- Aches and pains
- Excessive sleep loss or excessive sleeping
- Recurrent thoughts of death or suicide

Major depressive disorder is associated with broad impairments on neuropsychological measures of executive functioning: A meta-analysis and review. *Psychological Bulletin*, 139(1), 81–132.

than a depressive disorder) and be free of any medical disorder that might otherwise explain the symptoms the individual is experiencing (e.g., dementia) (APA, 2013).

SAFETY ALERT Healthcare providers often use language that is unfamiliar to patients and their families. To help patients and families understand the symptoms of a major depressive episode, nurses should discuss symptoms and characteristics using terms patients and families are more likely to understand. For example, rather than using the phrase "psychomotor retardation," nurses can inquire whether the patient is experiencing difficulty or slowness in speaking or in performing tasks.

Individuals with a history of a manic or hypomanic episode are considered to have a bipolar disorder and are not classified under the categories of depressive disorders.

Individuals experiencing MDD often no longer enjoy activities that previously brought pleasure, such as hobbies, sports, and sex. This is a condition known as **anhedonia**. Changes in appetite, usually experienced as a reduction or loss of interest in food, are often seen, although increased appetite and cravings are also reported.

Sleep disturbances, particularly **insomnia** (inability to fall or stay asleep or, in some individuals, early morning awakening), are common in individuals with depression. Two types of insomnia are most often experienced by people having a major depressive episode. *Middle insomnia* refers to waking up during the night and having difficulty falling asleep again. *Terminal insomnia* refers to waking at the end of the night and being unable to return to sleep. Depressed patients also may report **hypersomnia**, in which the individual sleeps for prolonged periods at night as well as during the day but still wakes up tired or fatigued. These sleep disturbances are discussed at length in the module on Comfort.

Fatigue and decreased energy are characteristic symptoms of depression. Individuals with depression may

report being tired upon awakening regardless of how long they have slept. Even the smallest task seems insurmountable, and routine activities require substantial effort and take longer to accomplish. Decreased energy may be manifested in **psychomotor retardation**, in which thinking and body movements are noticeably slowed and speech is slowed or absent. Psychomotor agitation also may occur, in which the individual cannot sit still; paces; wrings the hands; and picks at the fingernails, skin, clothing, bedclothes, or other objects.

Other common symptoms in individuals with moderate to severe depression include guilt or a sense of worthlessness, self-blame, impaired concentration and decision-making ability (even about trivial things), and suicidal ideation. Martin Seligman, PhD, was researching animal behaviors in 1967 and accidentally discovered what is now known as “learned helplessness.” He found that learned helplessness occurs when an individual experiences unpredictable or uncontrollable events, which are usually traumatic, resulting in an internal perception of decreased ability to cope or change future situations (Overmier, 2013). Even if the individual may have the ability to avoid or control the adverse stimulus, the individual feels powerless and accepts the negative stimulus or situation. Learned helplessness is often a trigger for depression. The characteristics of a major depressive episode are illustrated in **Figure 28-4** ».

Persistent Depressive Disorder

The term **persistent depressive disorder**, also known as **dysthymia** or **dysthymic disorder**, describes chronic depression for the majority of most days for at least 2 years (1 year for children and adolescents). Throughout those 2 years, no more than 2 months can be described as symptom-free. The symptoms of dysthymic disorder, while distressing, tend to be less severe than those of MDD, with fewer physiologic symptoms, but the degree of impact on individual functioning can be as great or greater than that of MDD. Individuals with persistent depressive disorder are at higher risk for developing other mental health disorders than those with MDD (APA, 2013).

Persistent depressive disorder often occurs in childhood, adolescence, or early adulthood and tends to be chronic. Whereas both girls and boys are equally affected as children, there are two to three times as many adult women as men

with dysthymic disorder. Factors that contribute to poorer long-term outcomes include the presence of a comorbid anxiety or conduct disorder, greater symptom severity, and greater impairment in functioning (APA, 2013).

Seasonal Affective Disorder

Seasonal affective disorder (SAD) is not an official DSM diagnosis, but rather a specifier of MDD “with seasonal pattern.” Individuals with SAD typically experience symptoms, including sadness and low energy, during the winter months, when the days are shorter. Factors that increase a person’s risk for SAD include female gender, age (with younger people being affected more often), and personal or family history of depression or bipolar disorder. Not surprisingly, the condition is also more common among people who live farther from the equator, where winters are longer (Melrose, 2015).

SAD arises due to biological fluctuations triggered by decreased exposure to natural light. People with SAD have elevated levels of SERT, a protein involved in serotonin transport in the brain. SERT binds with serotonin, so higher SERT levels lead to lower serotonin activity. SERT levels are naturally suppressed by exposure to sunlight, so when days grow shorter during the winter months, affected individuals’ SERT levels rise, causing their serotonin activity to decline and their depressive symptoms to increase. Evidence also indicates that individuals with SAD overproduce melatonin. Melatonin is a hormone secreted by the pineal gland that causes sleepiness. Melatonin production increases in all people in response to darkness, but levels are particularly elevated in patients with SAD. Together, decreased serotonin and increased melatonin cause disruptions in affected individuals’ circadian rhythms (Melrose, 2015).

Pharmacologic approaches to the treatment of SAD generally involve either bupropion (Wellbutrin) or SSRI antidepressants, with fluoxetine (Prozac) being the most common choice. Another common treatment approach is light therapy, also called phototherapy. With this approach, patients are exposed to a bright light that replicates natural outdoor lighting for 20–60 minutes each day. Light therapy is frequently the first-line treatment for SAD, as it generally has fewer adverse effects than drug therapy. However, recent research suggests that fluoxetine therapy is more cost-effective than light therapy and just as effective. Beyond pharmacologic and light therapy, counseling can also be useful in the treatment of SAD (Cheung et al., 2012; Melrose, 2015; Potter & Moller, 2016).

Adjustment Disorder with Depressed Mood

Adjustment disorder with depressed mood represents a change in mood and affect following a stressor, such as the end of a relationship, or multiple stressors; it may also be called **situational depression**. Symptoms generally begin 3 months after the event and typically last no more than 6 months. Adjustment disorder with depressed mood is differentiated from an appropriate change in mood following a sad or stressful event in that the distress experienced by the patient is out of proportion to the event and results in significant impairment in functioning (APA, 2013).

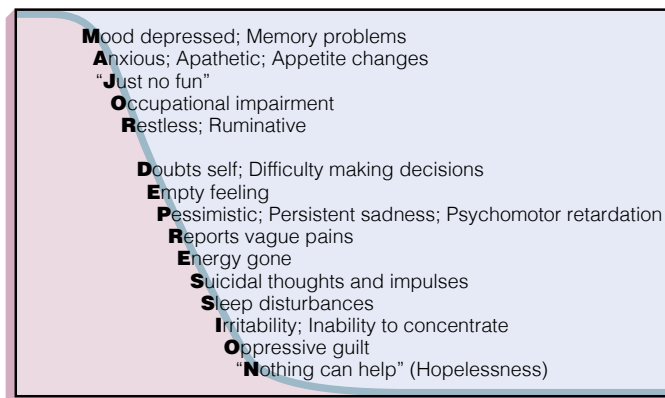

Figure 28-4 » Characteristics of major depression.

Any life-altering event can create risk for the occurrence of adjustment disorder with depressed mood. This risk is further increased by a preexisting mental health issue, ineffective or unhealthy coping mechanisms, or lack of a support network. Patients with these preexisting conditions may find that adjustment disorder with depressed mood has exacerbated their condition. For example, in an attempt to diminish feelings of depression, a patient who has remained sober after a history of alcohol abuse may resume drinking as a coping mechanism following a stressful event.

Differentiating Depression from Grief

In some patients, depression and grief may present similarly on initial assessment. Nurses must distinguish whether a patient who exhibits sadness and anhedonia is depressed or grieving (**Table 28-2** »). Although this may appear to be easy, it can be difficult when working with new patients with whom the nurse has not yet developed a therapeutic relationship. Careful assessment includes determining if the feelings described by the patient were triggered by a loss or losses (such as the death of a family member).

Collaboration

As many as two thirds of those with depression may not receive appropriate treatment for their illness (Andrews, 2016). For those who do, many are treated in the community by a primary care provider or may go directly to a mental health provider for counseling but elect not to use prescription medications. In inpatient settings, nurses play an important role as a member of the interprofessional team that includes psychiatrists, social workers, occupational therapists, and other healthcare professionals. In outpatient settings, nurses may be the first healthcare provider to screen or assess an individual for depression. In any setting, nurses play an important role in providing patient education about therapies, in answering questions, and in encouraging patients to follow their treatment regimens.

Diagnostic Tests

Although there is no diagnostic test to determine depression, primary care clinicians typically perform a complete medical history and thorough physical exam to rule out the

Clinical Manifestations and Therapies Depressive Disorders

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Major depressive disorder	Symptoms must last 14 days or longer and may include: <ul style="list-style-type: none"> Feelings of sadness and hopelessness Somatic complaints such as pain, stomachaches Anxiety, anger, irritability Loss of interest in pleasurable activities Sleep disturbances 	<ul style="list-style-type: none"> Pharmacologic therapies include: <ul style="list-style-type: none"> Selective serotonin reuptake inhibitors (SSRIs). Tricyclic antidepressants (TCAs). Atypical antidepressants. Electroconvulsive therapy (most often used for those who are resistant to treatment with medications). CBT.
Adjustment disorder with depressed mood	Symptoms develop within 3 months in response to an identifiable stressor and may include: <ul style="list-style-type: none"> Insomnia, hypersomnia Crying Avoiding pleasurable activities Avoiding family and friends Ignoring financial responsibilities Performing poorly at work and school Fighting, behaving recklessly 	<ul style="list-style-type: none"> Improved sleep hygiene. Short-term sedative. CBT alone may be sufficient to help the individual return to normal. Alternative therapies such as massage therapy may provide relief. Antidepressant therapy. CBT. Family therapy. Antidepressant therapy.
Persistent depressive disorder (dysthymic disorder)	Symptoms are not as severe as those of major depressive disorder, but last beyond 2 years with period of relief lasting less than 2 months.	<ul style="list-style-type: none"> Pharmacologic therapies are the same as for MDD. Electroconvulsive therapy (most often used for those who are resistant to treatment with medications). CBT.
Seasonal affective disorder	Depressive symptoms occur in relation to the seasons; usually during the winter months, when days are shorter.	<ul style="list-style-type: none"> Bupropion extended-release. Light therapy. CBT.

TABLE 28-2 Differences Between Depression and Grief

Trait	Depression	Grief
Trigger	Specific trigger not necessary, but may be present.	Trigger is usually loss or multiple losses.
Active/passive	Passive behavior tends to keep patient “stuck” in sadness.	Actively feel their emotional pain and emptiness.
Emotions	Generalized feeling of helplessness, hopelessness.	Experience a range of emotions that are usually intense.
Ability to laugh	Likely to be humorless and incapable of being happy or even temporarily cheered up; likely to resist support.	Sometimes will be able to laugh and enjoy humor; more likely to accept support.
Activities	Lacks interest in previously enjoyed activities.	Can be persuaded to participate in activities, especially as they begin to heal.
Self-esteem	Low self-esteem, low self-confidence; feels like a failure.	Self-esteem usually remains intact; does not feel like a failure unless it relates directly to the loss.
Feeling of failure	May dwell on past failures, catastrophize feelings.	Any self-blame or guilt relates directly to the loss; feelings resolve as they progress toward healing.

possibility of an underlying medical condition causing the patient’s depressive symptoms. If no physical causes are found, the clinician can start the patient on the depression “treatment cascade”: recognizing the clinical illness, initiating treatment, and evaluating the patient’s response to treatment (Pence, O’Donnell, & Gaynes, 2012). Existing medical conditions, such as diabetes, may inform selection of medication therapy if determined appropriate.

Pharmacologic Therapy

Antidepressant medications are often prescribed for patients with depression. Because individuals experience different dysfunctions in neurotransmission, individuals respond differently to various antidepressants. A period of trial and error may be necessary to determine which medication is most effective for the patient. See the Collaborative Therapies section in the Concept section of this module for a more detailed discussion of these medications.

Psychotherapy

Psychotherapy often is used in combination with medications to treat major depression. Some of the psychosocial problems associated with depression (e.g., ability to relate to others, motivation, problem-solving ability) cannot be resolved with medications. Psychotherapy promotes effective coping skills and positive, helpful patterns of thinking and behavior. Patients with mild depression may benefit from therapy alone. CBT is the most effective type of psychotherapy for depression.

Other Therapies

As discussed earlier in this module, ECT and integrative therapies may be appropriate for the patient diagnosed with depression. Another therapy, magnetic seizure therapy (MST), is being studied for efficacy. This treatment uses a magnetic pulse to stimulate the brain to induce a seizure, similar to ECT, but early results show fewer side effects than ECT and reduced recovery time. MSTs are shorter in duration and are thought to cause less cognitive loss after treatment (Cretaz, Brunoni, & Lafer, 2015).

The nurse’s role includes assessing for safety, assessing for potential contraindications, encouraging patient communication with all healthcare providers (e.g., primary care

provider and mental health provider or therapist), and providing patient teaching related to types of therapies and the importance of adhering to the treatment plan.

Lifespan Considerations

Symptoms of depression can vary among age groups, although sadness and anhedonia are common at all ages. Treatment considerations also may vary.

Depressive Disorders in Children and Adolescents

Careful and thorough assessment of a child suspected of having depression is necessary to rule out physical illness that can be linked to depressive symptoms. Other tests, such as hearing and vision tests, may be indicated as well. It is essential to question parents, caregivers, or guardians regarding their observations of the child’s behavior and recent changes or precipitating factors. Diagnostic evaluation must be performed by a child psychiatrist, psychiatric nurse practitioner, or other mental health professional experienced in the diagnosis and treatment of children and adolescents. A variety of scales and techniques are used; however, very little guidance is available relating to evaluation of children under 6 years of age. See the Concept section of this module for commonly used screening tools. Thorough assessment for both physical and mental health disorders is necessary because comorbidities (appearance with other disorders) are common. Examples of these include a history of bullying or substance abuse.

Depressive symptoms may vary with each age group. The following list indicates symptoms of depression with each age group through adolescence:

- Toddlers can show regressive behaviors in toileting and other activities.
- Preschoolers have fewer symbolic and other play activities and demonstrate self-destructive play themes. They may whine and show irritability, lack of interest, and lack of confidence.
- School-age children may show a decrease in academic performance, increased or decreased physical activity, somatic complaints, and loss of friends. The older school-age child may talk of running away or show signs of boredom and low self-esteem.

- The adolescent can have a wide array of symptoms (e.g., decreased social contact, poor school performance, lack of involvement in typical activities, poor self-care, difficulty with parents and teachers, or a focus on violence).

See the section Lifespan Considerations: Mood and Affect in Children and Adolescents for additional information on treatment for depression in children and adolescents.

Depressive Disorders in Pregnant Women

Depression can occur at any time during or after the course of a woman's pregnancy. See the exemplar on Postpartum Depression for a detailed outline of manifestations and treatment of women with peripartum depression.

Depressive Disorders in Older Adults

Depression is common among older adults, but it is important to note that it is not a normal part of aging. Manifestations of depression in older adults may include memory problems, social withdrawal, sleep disturbances, loss of appetite, and irritability. Some individuals may experience delusions or hallucinations. Depression in older adults can complicate treatment of other conditions because impairment of functioning due to depression may impair the individual's ability or motivation to participate in treatment. Other medical conditions can complicate treatment of depression if nurses and clinicians dismiss symptoms as related to another medical condition (or side effects of treatment) without doing a full assessment for depression.

Older adults are at risk for a depressive episode, especially when they experience two or more stressors in proximity. Development of a disabling illness (whether cognitive, physical, or otherwise), loss of a loved one, retirement, moving out of the home, or another stressful event may result in a depressive episode in the older adult (American Psychological Association, 2016b). Even those older adults who "see the glass as half full" are challenged by these types of stressors. The loss of driving privileges (due to physical or cognitive changes) is a huge loss to older adults, often putting a great deal of strain on family members who must accommodate the older adult who can no longer drive as well provide support as the individual learns to cope with this loss of independence.

Because of the increased risk older adults have for medical illness, careful assessment of the older adult is critical. Polypharmacy issues may make prescribing for older adults a challenge, and older adults taking psychotropic medications often require more frequent monitoring and laboratory tests (e.g., blood glucose levels). The Geriatric Depression Scale can be useful in screening older adults for depression and determining the need for further evaluation (Sheikh et al., 1991).

NURSING PROCESS

Priorities of nursing care focus on safety and meeting functional needs until the patient's condition improves. Risk of suicide must always be a consideration when caring for patients who are depressed. Patients with depression may not meet their daily hygiene, sleep, nutrition, or other needs. They are also at increased risk for accidental injury and

medical illness. The nurse can initiate strategies to help them until they are able to function autonomously.

Assessment

- **Observation and patient interview.** Assessment of patients with suspected depression begins with a thorough history and interview. Inquire about any past depressive, manic, or hypomanic episodes or behavior, as well as family history of mood disorders. Ask about and observe for the signs and symptoms discussed throughout the Concept section. Patients with depressive disorders may articulate any number of changes in mood and behavior: feelings of sadness, lack of interest in relationships and activities that previously brought pleasure, feelings of worthlessness or guilt, anxious distress, withdrawal, and/or social isolation. Patients may also articulate tearfulness and emotional outbursts.

Cognitive alterations are another frequent feature of depression. Accordingly, be alert for signs or descriptions of problems such as impaired concentration, difficulty making decisions, poor memory, and impaired problem-solving ability. In severe cases, patients might also report or demonstrate paranoid thinking, delusions, and other forms of psychosis.

The interview and history portion of the assessment is also a good time to observe for difficulties with adaptive functioning. Patients will often describe how long it takes them to complete activities that they formerly accomplished easily, such as preparing a simple meal. They may also neglect regular grooming and hygiene tasks, either skip meals or eat excessively, and/or respond inappropriately to social cues.

- **Physical examination.** The next step in assessment is to consider the patient's physical manifestations; in fact, somatic concerns are often the presenting complaint. Among the most common problems are fatigue, sleep disturbances or excessive sleep, and changes in appetite and/or weight. Patients with depression may complain of abdominal pains, headaches, and vague body aches. A problem with sexual functioning or lack of desire also may be a presenting complaint. Constipation is a common result of the general slowing of metabolism due to inactivity. Patients from some cultures are more likely to express symptoms of depression through complaints about body function and discomfort. See **Box 28-3** >> for information on how depression evidenced by somatic concerns can be detected in other settings. Possible medical problems that could be the cause of the patient's physical symptoms should always be investigated and ruled out before a diagnosis of depression is made.

Suicide Assessment

Assess all patients for suicide risk by using direct questioning. Ask whether the patient has thoughts of self-harm (*suicidal ideation*), how often these thoughts occur, and whether or not the person would act on these thoughts (intent). Inquire whether or not the patient has a plan regarding carrying out suicide (*plan/method*). If a plan exists, it is crucial to assess the lethality of the plan: degree of effort required, specificity of plan, accessibility of means to carry out the plan. Assess for

Box 28–3

Physical Complaints and Depression

Frequently, individuals will feel aches and pains more acutely when they are depressed. The natural reaction to pain is to seek help from a primary medical healthcare provider. There is a strong correlation between depression and pain, with either chronic pain causing depression or depression causing pain (Hall-Flavin, 2016). It is important for individuals who are experiencing depression to talk to their healthcare providers about other experiences and symptoms during their lifetime.

More than two thirds of patients diagnosed with depression express concerns with somatic symptoms and reports of pain (Bai et al., 2014; Bair et al., 2003). The implications of pain in patients with depression are serious: The presence of pain and other

somatic symptoms may complicate recovery and remission (Karp et al., 2005; Kroenke et al., 2008). Traditionally, pain and somatic symptoms accompanying depression were attributed to a psychologic reaction. However, there is increasing evidence that neurobiology plays a role (Bai et al., 2014).

Many people—perhaps as many as two thirds of affected individuals—are unaware that they have depression (Andrews, 2016). They are more likely to assume that not enjoying their usual activities, experiencing changes in eating or sleeping habits, and feeling bad in one way or another are caused by a physical problem. Determining the real cause of distress will help to ensure effective responses to treatment.

history of prior suicide attempts or family history of suicide, as this signals increased risk. Note that asking about suicide will not “plant the idea” in the patient’s mind. Rather, it is often a relief for the patient to be able to openly discuss these feelings and thoughts. See the Independent Interventions section and the exemplar on suicide for more information.

Assess for Comorbidities

Assess for the presence of medical illnesses. This is important not only to rule out the possibility of an underlying medical condition causing the patient’s symptoms of depression, but also to identify illnesses that may trigger depression. These include autoimmune, oncologic, metabolic, and endocrine disorders. Chronic illnesses, such as asthma and diabetes, are associated with increased risk of depression. A diagnosis of a chronic or life-threatening illness may also trigger a depressive episode.

Alcohol, which is a CNS depressant, and certain legal and illegal drugs can cause or complicate depression. Through matter-of-fact questioning, obtain a complete list of all substances and medications the patient uses. A few prescription medications (such as beta-blockers and steroid medications) have depression as a side effect, and they should not be overlooked in the complete assessment (Halverson, 2016).

Diagnosis

A number of nursing diagnoses may be appropriate for patients with depression, including the following:

- *Self-Directed Violence, Risk for*
- *Situational Low Self-Esteem or Chronic Low Self-Esteem*
- *Hopelessness*
- *Social Isolation*
- *Health Maintenance, Ineffective*
- *Coping, Ineffective.*

(NANDA-I © 2014)

Planning

When planning care, the nurse’s immediate priority should be to ensure that patients with depression remain free from injury and refrain from attempts to hurt themselves or others. Other high-priority goals include alleviating any

vegetative symptoms, ensuring adequate nutritional intake, and promoting restful sleep. Then, together with the patient, the nurse should design a plan of care that may include any of the following objectives:

- The patient will engage in necessary daily self-care activities (e.g., eating three meals a day, wearing clean clothes, and bathing regularly).
- The patient will resume normal activity patterns, such as returning to work or school.
- The patient will seek and engage in meaningful social interactions.
- The patient will articulate taking steps to feeling better, such as adopting healthy lifestyle behaviors (e.g., exercise) or engaging in recreational activities or exercise *before* beginning to feel better.
- The patient will comply with all aspects of the treatment regimen, including pharmacologic and/or psychologic therapy.
- The patient will describe feelings of hope for the future.

Implementation

When implementing interventions designed to help patients with depression, keep two general principles in mind:

1. It is impossible to make patients with depression feel better by being cheerful. In fact, an overly cheerful attitude tends to make them feel even worse because it trivializes or minimizes the impact of their feelings. Try to adopt a more emotionally neutral attitude while maintaining confidence that they will feel better.
2. Recognize that working with patients with depression may eventually lower your own mood and make you feel “down” yourself. This is called *emotional contagion*. The nurse should be aware of personal feelings and, if necessary, ask to be assigned to a different type of patient for a time.

Interventions to address risk for suicide and self-harm are detailed in the exemplar on suicide. For patients with severe depression who manifest vegetative symptoms and altered thought processes, the nurse will facilitate pharmacologic and collaborative therapies as ordered; assess and facilitate orientation to person, place, time, and circumstance; promote adequate nutrition and rest; and take other actions to

promote recovery such as reducing environmental stimuli and other potential triggers of anxiety.

Many patients with depression experience problems with self-esteem and social interaction as a result of their illness. Progression toward recovery requires that patients address these areas. Nursing interventions to promote self-esteem and social interaction follow.

Improve Self-Esteem

Although low self-esteem is a chronic problem, the nurse can take a number of actions to reduce negative thinking, thereby promoting improved self-esteem:

- Encourage patient participation in recreational activities. Simple conversation with a staff member or another patient helps interrupt the pattern of negative thoughts. Use care to identify activities that are not too complex for the patient's current level of functioning. Experiences of success, not more failures, are needed.
- Give positive, matter-of-fact reinforcement, such as "I notice that you combed your hair," rather than overly enthusiastic compliments or excessive praise such as "What a great hairstyle!" Appropriate recognition increases the likelihood that the patient will continue the positive behavior, while insincerity can be perceived as ridicule or infantilizing.
- Be accepting of patients' negative feelings, but set limits on the amount of time spent discussing accounts of past failures. Be alert for opportunities to interrupt negative conversational patterns with more neutral ones.
- Teach assertiveness techniques, such as the ability to say "no" to protect one's rights while respecting the rights of others. Patients with low self-esteem often allow others to take advantage of them. Practice these techniques with the patient, providing feedback on how it feels to be the recipient of assertive communication or an assertive action.

Instill Hope

It is equally important to help patients identify the aspects of their lives that are not within their control. Being able to accept what *cannot* be changed is just as essential as developing the ability to bring about positive change. This skill is particularly helpful in reorienting patients from feelings of hopelessness to

a more hopeful aspect. Other interventions to help patients combat hopelessness include the following:

- Help patients identify their personal strengths. It may be useful to write these down. Recognize that it often takes time for patients to realize that they have any strengths. Recognizing strengths helps a patient design an activity or engagement plan that the patient is more likely to enjoy and find successful.
- Help patients weigh and choose alternatives. Taking responsibility even for small choices, such as when or where to eat, helps the patient regain self-esteem.
- Explore problem-solving models with the patient, including practicing problem solving. "When you found out the toaster was broken, you threw it against the wall. You said all that did was put a dent in the wall and make a mess for you to clean up. What might you do differently next time that might be more helpful?"
- Help patients to identify resources such as family, community, or friends who can provide support and encouragement in overcoming problems they identify.

Planning for discharge should begin with the first patient contact and is particularly important with hopeless, dependent patients. Help these patients and their families and significant others identify resources in the community they can use to build support systems. Support groups, therapy groups, and social groups can help patients separate from caregivers more readily when the time comes to end therapy.

Evaluation

Patient progress is evaluated based on the ability to meet the expected outcomes. These should be modified based on each patient's unique situation. Some examples of goal-based outcomes for patients with depression include:

- The patient does not express suicidal ideation or a desire to harm self or others.
- The patient is free from vegetative symptoms.
- The patient obtains adequate nutrition and sleep.
- The patient meets daily self-care needs.
- The patient resumes normal activity patterns.
- The patient participates in recreational activities and meaningful social interactions.
- The patient engages in specific steps intended to make him/her feel better.
- The patient adheres to all aspects of the treatment regimen.

Secondary interventions will need to be initiated if goals are not met with the current plan of care. Explore reasons that goals were not met, such as unresolved stressors, lack of adherence to the treatment regimen, or the possibility that a comorbid mental illness or an underlying medical condition has not been identified. If there are no identifiable causes of poor response to treatment, then secondary interventions will need to be implemented. These may include giving the patient additional time to allow the medication to take effect or to meet a goal or working with the treatment team to find a different medication or treatment approach.

Patient Teaching

Increasing Self-Esteem

Patients often believe that *when* they feel better, they will want to engage in activities. For patients who express this belief, implement patient teaching and explain that the patient must begin doing things *in order* to feel better. Being active promotes a more balanced feeling state. Encourage the patient to acknowledge that it takes self-discipline and energy to do something when he does not really feel like it. Other strategies that may help the patient increase self-esteem include helping the patient to set daily, weekly, and monthly goals that are easily achievable, which is likely to improve the patient's self-esteem as each goal is met. As self-esteem improves, the goals should become increasingly harder to meet but still achievable.

Nursing Care Plan

A Patient with Depression

ASSESSMENT	DIAGNOSES	PLANNING
<p>You are the hospice nurse assigned to Pam Allen, who is dying of cancer. During your assessment of her husband, Clifford Allen, he discloses the following:</p> <ul style="list-style-type: none">■ He was diagnosed with depression years ago but is not currently receiving treatment.■ Years ago his brother committed suicide.■ He feels helpless about Pam's situation. He says that he has been a terrible husband and father.■ He is not currently receiving any treatment for depression.■ He has two or three alcoholic drinks every night after Pam goes to bed.■ He is not sure how he is going to cope with caring for their son, Gary, who has Down syndrome, after Pam is gone.	<ul style="list-style-type: none">■ <i>Powerlessness</i>■ <i>Grieving</i>■ <i>Situational Low Self-Esteem</i>■ <i>Caregiver Role Strain, Risk for</i>■ <i>Health Maintenance, Ineffective</i>■ <i>Anxiety</i> <p>(NANDA-I © 2014)</p>	<p>The next day the hospice nurse talks further with Mr. Allen. Together they create a plan of care that will help Mr. Allen:</p> <ul style="list-style-type: none">■ Investigate resources for helping him care for Gary.■ Develop a plan of exercise and recreation.■ Stop drinking.■ Begin treatment for depression as recommended by a mental health professional.
IMPLEMENTATION		
<ul style="list-style-type: none">■ Provide teaching to Mr. Allen about the need to begin treatment for depression again in order to prevent deterioration in mood and affect.■ Refer Mr. Allen to a mental health professional for diagnosis and treatment.■ Encourage Mr. Allen to explore his feelings regarding his wife's terminal condition and what his life will be like after her death.■ Encourage Mr. Allen to talk with his wife about her wishes regarding her death and funeral care in order to take a more active role in meeting her needs.■ Educate Mr. Allen on the effects of alcohol as a central nervous system depressant.■ Educate Mr. Allen on how to implement effective coping skills and identify ineffective coping skills.	<ul style="list-style-type: none">■ Support Mr. Allen's need to grieve for his wife and help him recognize that sadness is a normal part of the process.■ Encourage Mr. Allen to see that maintaining his own health is an important contribution to both Pam's and Gary's care.■ Refer Mr. Allen to agencies serving patients with disabilities to determine what assistance may be available to help him care for Gary.■ Help Mr. Allen develop a plan of exercise and recreation.■ Support Mr. Allen's need to obtain assistance in caring for Pam and Gary to reduce caregiver role strain.■ Provide a list of community resources to Mr. Allen.	
EVALUATION		
<ul style="list-style-type: none">■ Mr. Allen demonstrates improvement by meeting the following expected outcomes:■ He begins seeing a mental health professional to treat depression.■ He is taking medications as prescribed.■ He has quit drinking alcohol.■ He finds a daycare program that specializes in treating adults with Down syndrome.	<ul style="list-style-type: none">■ He discusses his wife's terminal condition with her, her desires for end-of-life care, and her postmortem wishes.■ He learns that his medical insurance will pay for someone to come to the home to provide for Pam's care 4 hours a day and initiates these visits immediately.	
CRITICAL THINKING		
<div><div>1. What expected outcome would you anticipate for Mr. Allen if he fails to obtain treatment for depression?</div><div>2. What community programs might you suggest to Mr. Allen to help him care for Gary and Pam?</div><div>3. What follow-up care can the hospice nurse provide Mr. Allen when making daily visits to Pam?</div></div>		

REVIEW Depression

RELATE Link the Concepts and Exemplars

Linking the exemplar of depressive disorders with the concept of addiction:

1. Why might dependence on alcohol promote depression?
2. What impact might dependence on nicotine have on mood and affect?

Linking the exemplar of depressive disorders with the concept of elimination:

3. What aspects of depression increase the risk for constipation?
4. How might alterations in elimination put an older patient at risk for depression?

READY Go to Volume 3: Clinical Nursing Skills

REFLECT Apply Your Knowledge

Melvin Thomas is a 14-year-old boy whose mother brings him to their family physician's office because this is the third day in a row that

Melvin "hasn't felt well." Melvin has been getting in trouble at school for arguing with teachers, and he has missed a lot of school, complaining of stomachaches. Melvin's mother says that he rarely sees his dad but that her second husband tries to spend time with Melvin when he can. When they do spend time together, they go shooting at the gun range or play video games. Melvin's expression at the physician's office is sullen, and he keeps his arms crossed in front of him. He answers the nurse by giving one-syllable responses or by nodding or shaking his head.

1. What assessment findings would make you suspect Melvin is depressed?
2. What priority teaching would you want to provide Melvin's mother if the diagnosis of depression is confirmed?
3. What impact is depression having on Melvin's ability to meet developmental milestones?

Exemplar 28.B Bipolar Disorders

Exemplar Learning Outcomes

28.B Analyze bipolar disorders and relevant nursing care.

- Describe the pathophysiology of bipolar disorders.
- Describe the etiology of bipolar disorders.
- Compare the risk factors and prevention of bipolar disorders.
- Identify the clinical manifestations of bipolar disorders.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with bipolar disorder.

Overview

The **bipolar disorders** are a group of mood disorders that are characterized by manic, hypomanic, and depressive episodes. Cyclothymic disorder, a related disorder, is characterized by alternating periods of hypomanic and depressive symptoms that are not significant enough to meet the criteria for hypomania or depression. Although less than 2% of the population is diagnosed with bipolar disorders, these types of disorders can have a tremendous impact on those closest to the person with the disorder (APA, 2013).

Pathophysiology and Etiology

Pathophysiology

No definitive cause or specific pathophysiology has been identified for bipolar spectrum disorders. Rather, they are thought to arise from a complex combination of genetic, physiologic, environmental, and psychosocial factors. Studies have not found significant evidence proving that bipolar disorder is localized to a specific area of the brain. However,

- Differentiate care of patients with bipolar disorder across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with bipolar disorder.

Exemplar Key Terms

Bipolar disorders, 1942

Cyclothymic disorder, 1944

Flight of ideas, 1943

Hypomania, 1943

studies in adults have found that the prefrontal cortex tends to be smaller with decreased functioning in those diagnosed with bipolar disorder (Phelps, 2014). Immunologic abnormalities, including unusual patterns of inflammation and glial cell activation, may contribute to the pathophysiology of mania and bipolar disorder (Stertz et al., 2012). Mitochondrial dysfunction and oxidative stress also may be involved in bipolar disorder (Andreazza et al., 2013; Morris & Berk, 2015). Children of parents with bipolar disorders have a 4–15% risk of having a bipolar disorder. Stressful life events (especially suicide of a family member); sleep cycle disruptions; family or caregivers with high expressed emotion; and an emotionally overinvolved, hostile, and critical communication pattern are factors associated with heritability. Bipolar disorders, schizophrenia, and major depressive disorders share biological susceptibility and inheritance patterns. Several genes and loci have been discovered that may be associated with bipolar disorders, including glycogen synthase kinase-3 β (Price & Marzani-Nissen, 2012).

Bipolar I disorder consists of one or more manic or mixed episodes, and the course of illness is usually accompanied

by major depressive episodes. **Bipolar II disorder** consists of one or more major depressive episodes accompanied by at least one hypomanic episode.

Etiology

Bipolar disorders tend to be recurrent and have the unusual tendency to increase in frequency as the individual ages. Many patients return to normal functioning during remission periods, but approximately 30% of those with bipolar disorder will exhibit functional impairment at work. Of patients with bipolar II disorder, at least 15% will continue to experience dysfunction between episodes, and up to 20% will not experience any recovery between alternating episodes of hypomania and depression (APA, 2013). Bipolar disorders typically appear between the ages of 15 and 30.

Risk Factors and Prevention

Risk factors include a family history of bipolar disorders, drug abuse, periods of very high stress, and a major life-altering event. Women and men are at equal risk of having bipolar disorders, although women are more likely to experience rapid cycling and depressive symptoms and are at greater risk for comorbid alcohol abuse than men (APA, 2013). There is no identifiable way to prevent bipolar disorders; however, seeking medical treatment immediately upon presentation of mental illness will assist in minimizing the effects and prevent symptoms from getting worse.

Clinical Manifestations

The manifestations experienced by the individual define the type of bipolar disorder. Nurses must recognize these manifestations, understand how patients respond during various stages, and provide patient and family teaching regarding symptoms and treatments.

Key Diagnostic Criteria

The DSM-5 diagnostic criteria for bipolar disorder include criteria for manic, hypomanic, and major depressive episodes. The criteria for major depressive episodes are the same as the criteria for diagnosing major depressive disorder (see Box 28–2). The DSM-5 characterizes manic episodes as (APA, 2013):

- Lasting most of the day, every day, for at least 1 week, or any duration if hospitalization is required
- Including some combination of symptoms and behaviors to the extent that the individual's changes in behavior are noticeable and impair social or occupational functioning. Examples of symptoms and behaviors characteristic of bipolar disorder include distractibility, racing thoughts (flight of ideas), psychomotor agitation, increase in goal-directed activity, pressured speech, disordered sleep patterns, and grandiosity.

As with MDD (and any other mental disorder), the symptoms cannot be attributed to a medical condition or the effects of a substance. At least one manic episode is necessary to diagnose bipolar I disorder. An individual experiencing hypomania does not experience impairment in functioning or require hospitalization. In the

absence of mania, the individual with hypomania may be diagnosed with bipolar II disorder if other criteria are met (APA, 2013).

Mania and Hypomania

Mania is characterized by an abnormal and persistently elevated, expansive, or irritable mood and increased energy (or activity) present for most of the time, nearly every day, or a week or more and accompanied by specific symptoms as articulated in the DSM-5 and summarized above. **Flight of ideas** (rapidly changing, fragmented thoughts), pressured speech patterns, and increasing goal-directed activities are common during manic episodes. Psychotic symptoms such as delusions or hallucinations may be a feature of severe mania.

Hypomania is a less extreme form of mania that is not severe enough to markedly impair functioning or require hospitalization. Individuals experiencing hypomania feel wonderful, “on top of the world,” and do not recognize changes in themselves. Those who know them well, however, are aware of the changes in mood and behavior. There are no psychotic features in hypomania.

The onset of manic episodes usually occurs in the early 20s but may begin at any age. It often follows a severe disappointment, embarrassment, or other psychic stressor. The mood of patients experiencing a manic episode is euphoric, or “high.” Their behavior is excessive and out of bounds. During mania, individuals typically exhibit overly enthusiastic involvement in projects of an interpersonal, political, religious, or occupational nature. When someone or something gets in the way or appears to put a snag in their way, they become irritable. Moods alternate between euphoria and irritability. Increased sexual behaviors are common, including flirting, making sexual overtures, having inappropriate sexual relationships, and feeling compelled to seduce and be seduced. Women may dress in an uncharacteristically flashy or seductive manner and wear garish makeup. Grandiosity can reach delusional proportions. Patients with mania rarely believe they are sick, even when they are in financial or legal trouble, and may vehemently dispute the need for treatment. The characteristics of a manic episode are illustrated in **Figure 28–5** >>.

Figure 28–5 >> Characteristics of a manic episode.

Depressive Episodes

A diagnosis of bipolar disorder does not always mean that manic or hypomanic behaviors will be manifested in the current episode of illness. Bipolar I and bipolar II disorder are characterized by periods of mania/hypomania alternating with major depressive episodes. Mood stabilizers are the drug of choice, so it is important when assessing patients who present with depression to determine if the patient has ever had a manic or hypomanic episode. Antidepressant medications should be used with care, at low doses, and only during the severe depressive episode to reduce the chance of switching to a manic state.

Many patients with bipolar disorders are not correctly diagnosed in a timely manner. This can mean that an individual loses years to an illness that could have been successfully managed if it had been correctly diagnosed and treated.

Mixed Features

The DSM-5 recognizes certain specifiers for bipolar and related disorders. These include a specifier *with mixed features*, which recognizes that depressive episodes may occur and be accompanied by symptoms of mania or hypomania, and manic or hypomanic episodes may occur and be accompanied by symptoms characteristic of depressive episodes (APA, 2013).

Rapid Cycling

Individuals with either bipolar I or bipolar II disorder may exhibit rapid cycling—four mood episodes occurring within a year with periods of partial or full remission of 2 months or more *or* with immediate alternate periods of mania/hypomania and depression. Individuals can experience episodes more than once a week and even more than once a day (NIMH, 2013b).

Cyclothymic Disorder

When patients have sustained at least 2 years of “chronic, fluctuating mood disturbance involving numerous periods of hypomanic symptoms and numerous periods of depressive symptoms,” they are diagnosed with **cyclothymic disorder** (APA, 2013). They must be free of severe symptoms that qualify for the diagnosis of manic disorder or MDD. These individuals are often considered to be moody, unpredictable, or temperamental, and they may go on to develop an overlay of symptoms that are of major depressive or manic intensity. **Figure 28-6** compares mood in MDD, bipolar disorders, dysthymia, and cyclothymia.

Cyclothymic disorder begins early, usually in adolescence or early adulthood. Although not common, with a lifetime risk of only 0.4–1.0% of the general population, cyclothymic disorder is thought to predispose individuals to other mood disorders. The incidence is approximately equal between males and females (APA, 2013).

Collaboration

Care of the patient with a bipolar disorder requires a multidisciplinary effort that includes the nurse, the patient, the primary care provider, a mental health specialist, a nurse case manager, and possibly a pharmacist as the team works to find a successful therapeutic regimen. The nurse should

Figure 28-6 » Comparison of affect (mood) in major depressive disorder, bipolar disorder, dysthymia, and cyclothymia.

take special care to encourage the patient to track feelings, behaviors, and side effects, especially during the first few weeks of trying a new medication.

Diagnostic Tests

There is no diagnostic test to determine bipolar and related disorders. Diagnosis is made on the basis of clinical manifestations and patient history. A physical examination, which may include drug testing, assists in ruling out the possibility of an underlying medical condition or substance abuse as the source of the patient's symptoms.

Pharmacologic Therapy

Hyperactive and agitated behavior usually responds fairly rapidly to antipsychotic mood stabilizers such as aripiprazole (Abilify), risperidone (Risperdal), and olanzapine (Zyprexa). The atypical antipsychotics, effective as mood-stabilizing medications, are often given in conjunction with anticonvulsive mood stabilizers. Because lithium takes 1–3 weeks before it is effective, atypical antipsychotics are used to help manage the symptoms of mania for individuals prescribed lithium until efficacy is achieved.

Nursing interventions include monitoring patients for adverse side effects of antipsychotic medications. These include extrapyramidal effects such as Parkinson-like symptoms (e.g., rigidity, tremor, or “pill rolling” movements of the fingers); dystonia, which is abnormal tonic contractions of the muscles (muscle spasms); and akathisia (subjective need to move, “jumping out of my skin”). Extrapyramidal symptoms should be reported and are usually treated by administration of an anticholinergic medication such as benztropine (Cogentin), diphenhydramine (Benadryl), or trihexyphenidyl (Artane). Acute dystonic reactions may be severe and require immediate medical intervention. These side effects can be distressing to the patient. The nurse must reassure the patient and explain what is occurring.

Clinical Manifestations and Therapies

Bipolar Disorders

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Mania/manic episode	<p>Characterized by elevated, expansive, or irritable mood and increased activity or energy that significantly impairs social or occupational functioning and is accompanied by at least three of the following:</p> <ul style="list-style-type: none"> Increased self-esteem Decreased need for sleep Pressured speech Flight of ideas Distractibility Increased involvement in goal-directed activities Psychomotor agitation Excessive involvement in pleasurable activities that carry a high risk of painful consequences 	<ul style="list-style-type: none"> Assess for safety. Administer mood stabilizers such as lithium. Remove or limit environmental stimuli. Set limits; teach limit setting. Orient to self, place, and time.
Hypomania	<ul style="list-style-type: none"> Less extreme than mania; individuals describe themselves as feeling “wonderful” and do not recognize changes in their behavior, although friends and family can observe changes. 	<ul style="list-style-type: none"> Assess for safety. Administer mood stabilizers such as lithium. Remove or limit environmental stimuli. Set limits or teach limit setting.
Depressed episode	<ul style="list-style-type: none"> Symptoms of depression 	<ul style="list-style-type: none"> Assess for safety. Administer antidepressant with mood stabilizer.

SAFETY ALERT For patients with bipolar disorder, the orally disintegrating form of olanzapine may be prescribed to reduce instances of “med cheeking,” where patients hide the tablet in their mouth or cheek until they can dispose of it. Valproic acid comes in liquid form, which can also assist with prevention of “med cheeking.”

Several psychopharmacologic agents have proven effective in the long-term treatment of mania. One effective and widely used agent is lithium carbonate.

Lithium Carbonate

Lithium carbonate is an inorganic compound that has been used in the treatment and prevention of acute manic episodes since the 1960s.

Lithium alters neurotransmission in the CNS. It is thought to interfere with the ionic pump mechanism in brain cells, but its exact mode of action is unknown. Its use is not recommended during pregnancy and breastfeeding. Furthermore, it should not be used in patients with impaired renal function, congestive heart failure, sodium-restricted diets, or organic brain disease, as impaired CNS functioning secondary to these conditions places the patient at higher risk for lithium toxicity (Wilson et al., 2016). Administered orally, the onset of action ranges from 1 to 3 weeks. The dosage is gradually increased until the recommended therapeutic blood level of 0.8–1.2 mEq/L is achieved. Once the desired effect is achieved, the dosage is adjusted downward to the maintenance blood level of 0.6–1.2 mEq/L.

Patients who take lithium are at high risk for toxicity, because the difference between harmful and therapeutic

lithium levels is quite small. Thus, patients’ serum lithium levels should be determined prior to beginning drug therapy, then carefully monitored once therapy has begun. Note also that what is considered a therapeutic level for one patient might produce toxic effects in another patient. Accordingly, individual response to specific lithium doses must be carefully documented (Machado-Vieira et al., 2014). For example, individuals of Asian descent may respond to lower doses and blood levels of lithium, and therefore may experience toxicity at lower dosages than Caucasian patients (Quan et al., 2015). Monitor therapeutic effect as well as side effects.

Toxic symptoms begin appearing at blood levels above 1.5 mEq/L. Because there is such a narrow margin of safety, serum concentrations must be closely monitored until stabilized.

Antiseizure Medications

Medications used to treat seizures are often prescribed in combination with lithium or antipsychotic medications. Agents commonly used in the treatment of mania include valproic acid (Depakote, Depakene), lamotrigine (Lamictal), and carbamazepine (Tegretol). Side effects associated with antiseizure medications include drowsiness, fatigue, and weight gain. Typically, these side effects will decrease over time, but blood levels for some drugs must be regularly monitored to ensure that the patient is not experiencing toxicity. Pregnant women should not take these medications unless under the care of a healthcare provider. Caution patients not to discontinue these medications abruptly, but to consult with their prescribing provider regarding how to taper off gradually.

Atypical Antipsychotics

Aripiprazole (Abilify), olanzapine (Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), asenapine (Saphris), and ziprasidone (Geodon) are among the atypical antipsychotics approved for bipolar mania and are becoming first-line treatments for bipolar mania. Olanzapine and aripiprazole come in an injectable form for use in acute agitation. These agents, especially the injectable forms, work quickly to calm the patient.

Lifespan Considerations

The rate of attempted suicide in those with bipolar disorders is high, as is co-occurrence with other disorders such as attention-deficit/hyperactivity disorder (ADHD), anxiety, and substance abuse, all of which complicate diagnosis (NIMH, 2013b).

Bipolar Disorders in Children

Children with bipolar disorders present with mood changes (such as being overly silly or joyful when that is unusual for the child) and behavioral changes (such as sleeping little but not feeling tired, and talking a lot and having racing thoughts) (American Academy of Child and Adolescent Psychiatry [AACAP], 2015). Some children may exhibit lengthy, violent temper tantrums. Older children may take on multiple tasks simultaneously and develop grandiose plans for their projects (APA, 2013). Children must be assessed based on their personal baseline, because children of the same age may be at different developmental stages. Taking into consideration the different developmental stages, it is difficult to define “normal” and “abnormal” behaviors.

Diagnosis of bipolar disorder may be made after other possibilities have been ruled out. Treatment of children with bipolar disorders may include medications to reduce severity of symptoms and psychotherapy to learn how to adapt to stressors and build relationships (AACAP, 2015). It is important that children be prescribed the fewest medications possible at the lowest effective doses.

Bipolar Disorders in Adolescents

The average age of onset of the first episode of mania, hypomania, or major depression is approximately 18 (APA, 2013), and the lifetime prevalence of bipolar disorders in adolescents is 0–3% (NIMH, 2013C). Treatment for adolescents will follow the same guidelines as are used for children. Because teenagers commonly show mood changes, including changes in sleeping and eating patterns, it is important not to mistake typical mood swings for bipolar disorder.

Bipolar Disorders in Pregnant Women

Studies suggest that women diagnosed with bipolar disorder are 5 to 10 times more likely to experience an episode during pregnancy. However, some women do experience their first episode while pregnant (NAMI, 2013). Stopping medications can worsen symptoms; therefore some health-care providers will slowly taper the woman off medications, decrease the dose, or change the medication. If lithium is continued, serum lithium levels must be monitored frequently to prevent toxicity. The fetus should be assessed for potential heart defects, as risk for them

increases with lithium use during the first trimester. In addition, lithium doses should be decreased at the onset of labor to avoid maternal toxicity at delivery. Women taking divalproex (Depakote) should be switched to another mood stabilizer before conception because of the higher-than-average risk for neural tube, cardiac, and craniofacial defects. Carbamazepine (Tegretol) is contraindicated in pregnancy (Freeland & Shealy, 2014).

Close monitoring is necessary for pregnant women with bipolar disorder throughout the pregnancy and during the postpartum period. Ultimately, the decision of whether to continue, begin, or adjust pharmacologic treatment for mood disorders is up to the patient herself. However, health-care providers have a duty to educate pregnant women about the potential risks and benefits of both drug use and untreated mental illness (Kalfoglou, 2016).

Bipolar Disorders in Older Adults

Onset of bipolar disorder may occur at any time during life, including in the 60s or 70s. As with any patients, first episodes of manic symptoms presenting during midlife or late life indicate a need to perform medical testing to verify that there is not a medical or substance-related etiology. Treatment will be the same for older adults as for adults, although doses of medications may be lower. Older adults are also prone to experience more side effects and toxicity, requiring them to be monitored very closely. For example, lithium is contraindicated in older patients with kidney disease and should be used cautiously in patients with thyroid disease.

NURSING PROCESS

Because the nursing care of patients experiencing depressive symptoms is the same whether the diagnosis is a depressive disorder or a bipolar disorder, this section focuses on hypomania and mania, which constitute the other half of the bipolar continuum of behaviors. For all patients, assess personal history of cyclical patterns and triggers. Common triggers include changes in sleep patterns, negative life events (such as breaking up with a partner or losing a job), and use of alcohol or drugs. Early identification of triggers can assist with early identification of helpful interventions and improve patient outcomes (Koenders et al., 2014; Proudfoot et al., 2012).

Assessment

■ **Observation and patient interview.** Assessment of patients with known or suspected bipolar disorder begins with a thorough history and interview. Inquire about any past manic or depressive episodes or behavior, as well as family history of mood disorders. Ask about and observe for the signs and symptoms discussed throughout the Concept section of this module, taking note of their severity, as they may range from mild (in hypomania) to extreme (in a frank manic episode). The nurse should also investigate the speed of onset for any symptoms, noting whether it is gradual or dramatic.

Patients who are experiencing their first manic episode are most likely to be young people in their late teens or early 20s, although adolescents are sometimes affected. Affected individuals may demonstrate or articulate any number of changes in mood and behavior, including:

- Rapid changes in affect, such as going from elation in one moment to anger and irritability in the next.
- Inflated self-esteem, sometimes to the extent of having delusions of grandeur. Delusions of persecution also may be a feature.
- Ignorance or denial of fatigue, hunger, and even hygiene; being too involved in activity to focus on physiologic sensations.
- Rapid, loud, pressured speech.
- Unusual appearance (e.g., dressing inappropriately and using garish makeup or being disheveled and unkempt).
- A surprising sense of well-being. Individuals who are hypomanic and those early in manic episodes feel wonderful and do not understand why people are upset with their behavior.

Cognitive alterations are another frequent feature of mania. Be alert for changes in the patient's thought processes, evidenced by statements such as "I feel like my thoughts are racing." In addition to racing thoughts, other symptoms frequently common during manic episodes include an inability to concentrate and being easily distracted by the slightest stimulus in the environment. Some patients also experience hallucinations, delusions, and other forms of psychosis. Family members may report poor judgment and impulsivity, as evidenced by shopping sprees, drug use, or sexual activity that is out of character with the patient's usual behavior.

With bipolar I disorder, impairments in adaptive functioning are common. This includes difficulties in occupational function, which may result in being laid off from work, being placed on a leave of absence, or being fired because the behavior is disruptive in the workplace. Individuals who have mania cause interpersonal chaos by behaving manipulatively, testing limits, and playing one person against another. If their attempts at manipulation fail, they become irritable or hostile, and such behavior further alienates others.

- **Physical examination.** Assessment of the patient's physical manifestations is also critical. The hallmark of mania is constant motor activity. During a manic episode, patients may not stop to eat. Individuals in a manic state do not rest, have disordered sleep patterns, and may go for days without sleep. Bruises and other injuries sometimes result from the constant activity.

Patients who are in a manic state are not usually able to cooperate fully in the assessment process. In many cases, nurses find it necessary to rely on their own assessment skills and secondary sources, such as family members, to obtain essential assessment data. Family members often can provide detailed information about the onset and progression of symptoms, as well as information about any previous episodes.

Diagnosis

Several nursing diagnoses are common in the care of patients who have mania. These include the following:

- *Injury, Risk for*
- *Social Interaction, Impaired*
- *Impulse Control, Ineffective*

- *Impaired Mood Regulation*
- *Imbalanced Nutrition: Less than Body Requirements*
- *Self-Care Deficit, Bathing, Dressing, and Feeding*
- *Sleep Deprivation*
- *Suicide, Risk for*

(NANDA-I © 2014)

Although the nursing diagnosis *disturbed thought processes* is no longer recognized by NANDA International, some mental health agencies may continue to use it or a similar phrase to organize care for patients experiencing delusions or other disordered thought processes.

Planning

Outcomes for mood disorders include the expectation of a return to normal functioning. While these will vary by patient, appropriate outcomes for a patient with bipolar disorder include the following:

- The patient will remain free of injury.
- The patient will remain oriented.
- The patient will use appropriate behaviors in a variety of social settings.
- The patient will maintain self-care.
- The patient will no longer experience sleep disturbances.

Implementation

With patients who are manic, maintain a calm, relaxed, but firm and matter-of-fact demeanor, particularly when communicating limits. The nurse's behavior serves as a model and can be reassuring to out-of-control patients. As with all patients, building a trusting relationship is important.

Patients experiencing mania may unintentionally engage in behaviors that encroach on or violate boundaries or attempt to manipulate situations or individuals to their advantage. Nursing interventions, such as setting limits, promote patient security and often enable patients to curb their manipulative behavior or give it up entirely. Setting limits also assists in maintaining safety on the unit. Nurses should use self-reflection frequently to make sure they are maintaining their own boundaries of feelings and emotions.

Nurses design activities to facilitate the patient's ability to interact with others by identifying needed behavior changes and assigning tasks that will improve the patient's interactions with others. This may require mediating between the patient and others when the patient exhibits negative behavior. Nursing actions should encourage and demonstrate honesty and respect for others' rights.

Forming a therapeutic alliance with the patient, discovering her expectations, and providing opportunities for interpersonal interactions have been linked with positive long-term outcomes for people with bipolar disorders.

Promote Patient Safety

Taking steps to ensure the safety of patients and others in the environment is a priority.

- Provide the patient with community support by supplying names and phone numbers such as a local crisis

hotline or the National Suicide Hotline (800-273-8255). Having access to support in the time of crisis may be a lifesaving intervention.

- Assist the patient in scheduling appointments with the mental health professional to ensure access has been established.
- Monitor activities. Scheduling a program of appropriate activity interspersed with rest periods helps provide an outlet for tension while protecting patients from exhaustion. Appropriate activities include walking, exercising, or dancing with the supervision of an activity therapist and supervised vacuuming or sweeping chores. Avoid highly competitive activities that bring out hostility and overtly aggressive behaviors.
- Set and enforce limits on unsafe or socially inappropriate behavior when patients are unable to control their impulses. Matter-of-fact intervention rather than angry scolding is the most effective approach. Patients may respond to verbal reminders or redirection to safer and more appropriate activities. Remember to reward appropriate behavior with positive reinforcement such as “I enjoyed our walk today because you were able to walk with me rather than running ahead.”
- Provide a safe environment by reducing environmental stimuli. For hospitalized patients, this means providing a simply furnished private room that has had all unnecessary items removed. It should be in a quiet location to reduce noise stimulation. Low lighting also can be calming to the hyperactive patient.
- Monitor for safety hazards. Agitated patients are more apt to forget or disregard safety considerations such as safe use of smoking materials.

Promote Reality-based Thinking

The patient in a state of mania may demonstrate thinking that is out of touch with reality. It is important to give reality orientation to assist the patient into reality-based thinking.

- Present reality by spending time with patients. Identify yourself, the time and day, the location, and other orienting information as needed. Engage patients in reality-based, somewhat concrete activities (e.g., discussing a current event).
- Consistency is reassuring to patients with altered thought processes. Establish consistency by following a schedule to help patients understand what is expected of them. Consistency also is enhanced by assigning the same caregivers to work with the same patients whenever possible.
- It is not therapeutic to argue or try to reason with patients who are experiencing delusions or other altered thought processes. Arguing with a patient often serves to harden the belief system and can impair the development of trust. Instead, use statements such as “I find that hard to believe” or “That is extremely unusual” to instill reasonable doubt as a therapeutic intervention.
- When patients communicate perceptions of altered reality, reflect their statements back to them for validation. For example, asking “Are you saying that your husband is trying to poison you with monosodium glutamate?”

can help a patient understand how her perceptions sound to others. You will recognize that patients are becoming less delusional when they make statements such as “I know this sounds bizarre, but. . . .”

Promote Improved Self-Care

Self-care may become deficient during an exacerbation of symptoms of bipolar disorder. This includes activities of daily living such as nutrition, hygiene, rest, and elimination.

- Well-being is compromised when patients do not receive sufficient nourishment and fluids for extended periods of time, particularly during periods of hyperactivity. For the inpatient patient, work with a dietitian to ensure that high-calorie finger foods and nutritious liquids are available on the nursing unit until the patient is able to attend regular meals. For outpatient patients or those preparing for discharge, collaborate with the patient and dietitian to determine patient preferences and create a list of easily prepared foods that the patient finds palatable and can make or eat on the go.
- Assist hyperactive patients who are unwilling or unable to bathe, brush their teeth, shave, wash their hair, change clothes, or use the toilet. Autonomy is desirable, so allow patients to do as much for themselves as possible with verbal encouragement. Reinforce any attempts at self-care with recognition; for example, “I see you shaved today, Mr. Adams.”
- During a manic phase, the patient may be awake for days at a time with minimal to no sleep. Sleep deprivation may occur, which impacts cognition and may lead to high blood pressure and cardiac disease. Decreasing stimulation in the milieu will help the patient rest, even if only for short periods of time. While the patient is awake, encourage him to perform tasks that require sitting down, even if only for a few minutes. For more information, see Enhancing Rest and Sleep in this section.
- Incontinence of urine or feces is occasionally seen in severely regressed patients during mania. This can be very disturbing to other patients and staff and insults the dignity of the patient who is experiencing incontinence. Nursing activities include establishing a schedule of frequent, regular toileting. Accompany the patient to the bathroom every hour or half hour until “accidents” no longer occur. A more common elimination problem is constipation. Hyperactive patients suppress the urge to defecate and may become severely constipated.

Set Limits

All staff members must agree on the established limits and enforce them consistently. Violations of limits must have established consequences, also agreed on by all staff members. Patients must know what behaviors are expected and what consequences will result if they exceed the limits. Inconsistent application of consequences will result in a failure to decrease manipulative behavior.

Nurses should expect patients to give charming explanations of why they exceeded this or that limit but should not be disarmed by these explanations. They are another form of manipulative behavior. Matter-of-fact limit enforcement and

the consistent application of consequences are essential in promoting adaptive behaviors.

Enhance Rest and Sleep

Patients in the manic phase of bipolar disorder appear deceptively energetic when they may actually be nearing the point of exhaustion.

- Design nursing activities to facilitate regular sleep–wake cycles. Monitor patients closely for signs of fatigue and make provisions for rest periods. Promote nighttime sleeping by limiting extended daytime naps.
- Sleep may promote the rapid resolution of first episodes of mania. Prior to bedtime, decrease light and noise and encourage quiet activities and pre-sleep routines such as listening to soothing music. A warm bath and a snack may aid relaxation. Administer medications that do not suppress rapid-eye-movement (REM) sleep, such as zolpidem tartrate (Ambien), as prescribed.
- If patients experience extended nighttime wakefulness, avoid engaging them in long conversations or otherwise stimulating them or giving extra attention at night. Firmly encourage patients to stay in their darkened room with the expectation that they will fall asleep. If they will not stay in their room, assign a monotonous, repetitive task such as folding towels or sorting papers to encourage drowsiness.

- When patients are able to sleep, avoid waking them for nonessential care or activities. Allow for sleep cycles of at least 90 minutes.

Evaluation

Specific patient behaviors indicate that nursing interventions have been successful. Outcomes that indicate the patient has improved include:

- The patient remains free from injury.
- The patient is performing adequate self-care.
- The patient is able to sleep through the night.
- The patient is behaving appropriately in social settings.

Secondary interventions will need to be implemented if goals are not met. As with depression, the time frame may need to be extended. Combination pharmacologic therapy may need to be implemented by administering both antiseizure medications (mood stabilizers) and atypical antipsychotic medications. The initiation of clozapine (Clozaril) or ECT may be effective when first-line therapies are not successful. It is important for patients to understand that finding the medication regimen that is effective for them is a process and not to become frustrated when adjustments need to be made.

Nursing Care Plan

A Patient with Bipolar Disorder

Mr. Grey, a 52-year-old engineer, is brought to the emergency psychiatric clinic by two adult sons at 2 a.m. Their mother called them to come help with their father, who has not slept in 3 days. When they arrived at their parents' home, they found their father working

on a large landscaping project in the backyard that involved stonework, a waterfall, a fish pond, and extensive plantings of trees, shrubs, and flowers.

ASSESSMENT

According to the sons, Mr. Grey has had three prior episodes of manic behavior, beginning when he was in the army many years ago. He was stabilized on lithium carbonate for years but stopped taking it about a year ago because he felt so good. The current episode began about 1 week ago, after he was passed over for a promotion at work. He then took a leave of absence from his job to create what he called "the world's first home-based theme park." Any attempt by his wife to talk him out of the project has been met with anger and renewed resolve. Mr. Grey angrily tells the admitting nurse, "I don't know why these boys brought me here. I need to get back to work! I'm going to get millions for this franchise."

DIAGNOSES

- *Sleep Deprivation*
 - *Caregiver Role Strain*
 - *Interrupted Family Processes*
 - *Noncompliance*
- (NANDA-I © 2014)
- Other possible nursing diagnoses may include:
- Disturbed thought processes
 - Nonadherence

PLANNING

Goals for care include:

- The patient will comply with instructions for taking medications as ordered.
- The patient will sleep through the night.
- The patient will be oriented to time and place.
- Family members will return to normal activities.
- Family members will support medication administration.

IMPLEMENTATION

- With Mr. Grey and family members, develop a plan of activity that will help Mr. Grey disperse energy at appropriate times.
- Help family members set and enforce limits. For example, "From 8 p.m. until 6 a.m., Mr. Grey will remain indoors, engaged in sleep-promoting activities or sleeping."
- Refer Mr. Grey and his family to a therapist who can help them learn how to orient Mr. Grey to reality when his mind begins to stray.
- Help Mr. Grey and his wife learn how to promote sleep by decreasing environmental stimuli in the bedroom and engaging in good sleep hygiene.

(continued on next page)

Nursing Care Plan *(continued)*

EVALUATION

Expected outcomes to evaluate the patient's care include:

- The patient maintains therapeutic drug levels indicating compliance with medication regimen.
- The patient and family report that Mr. Grey obtains 6–8 hours of sleep per night.
- The patient demonstrates orientation to time and place.
- The family reports a return to normal daily routine.
- The patient regularly attends counseling sessions.

CRITICAL THINKING

1. What patient teaching can the nurse provide to reduce the risk of medication noncompliance once Mr. Grey feels well and is no longer symptomatic?
2. What teaching will the nurse provide the family to help them cope with the patient's diagnosis?
3. How can the nurse assist the patient to meet his nutritional needs during manic phases of the illness?

REVIEW Bipolar Disorders

RELATE Link the Concepts and Exemplars

Linking the exemplar of bipolar disorders with the concept of family:

1. How might bipolar disorder affect parenting styles?
2. How might different family processes affect a child's treatment for bipolar disorder?

Linking the exemplar of bipolar disorders with the concept of nutrition:

3. How might bipolar disorder affect a patient's nutritional status?

Linking the exemplar of bipolar disorders with the concept of health, wellness, and illness:

4. What consumer education resources are available to patients with bipolar disorders and their families to help them maintain their health during periods of relapse?

REFLECT Apply Your Knowledge

Brittany Mathews, who is 21 years old and attending college, has been diagnosed with bipolar I disorder and is in the manic phase. Since admission 2 days ago, she has been averaging 2 hours of sleep a night. The rest of the night she spends pacing the hallways and talking to staff. She is in constant motion and brags about how much energy she has. Her clothing consists of startling bright miniskirts, low-cut sweaters, and high heels. Every few hours she changes clothes and reapplies her makeup to match.

1. What strategies might the nurse implement to maintain Ms. Mathews's safety at this time?
2. What risks to health does Ms. Mathews face during the manic phase of her illness, and how can the nurse reduce these risks?

Exemplar 28.C Postpartum Depression

Exemplar Learning Outcomes

28.C Analyze postpartum depression and relevant nursing care.

- Describe the processes of maternal role attainment and attachment.
- Identify the clinical manifestations of postpartum depression and psychosis.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with postpartum depression.
- Apply the nursing process in providing culturally competent care to an individual with postpartum depression.

Exemplar Key Terms

Major depressive disorder with peripartum onset, 1951
 Postpartum blues, 1951
 Postpartum depression, 1951
 Postpartum psychosis, 1953
 Puerperium, 1951

Overview

The postpartum period is a time of readjustment and adaptation for the entire family, but especially for the mother. The woman experiences a variety of responses as she adjusts to a new family member, postpartum discomforts, changes in her body image, and the reality that she is no longer pregnant. Alterations in mood may occur at any time during pregnancy. Up to 50% of women identified with major depression during the postpartum period began experiencing depressive symptoms while pregnant. Therefore, clinical recommendations indicate that all pregnant women be assessed early in pregnancy for personal and family history of depressive disorders, bipolar disorders, peripartum or postpartum depression, and postpartum psychosis (see **Figure 28-7** ») (ACOG, 2015).

The **puerperium** is that time immediately following childbirth when physiologic changes that occurred during pregnancy begin to return to normal. **Postpartum blues**, often referred to as “baby blues,” are a common occurrence after childbirth and may affect up to 80% of women after giving birth. Symptoms include mood swings; feeling sad, anxious, or overwhelmed; crying spells (often for no reason); decreased appetite; and problems sleeping. These symptoms are not severe and do not require treatment. They usually resolve within a few days or a week (NIMH, n.d.b). **Postpartum depression**, a depressive disorder associated with pregnancy, is now recognized to begin *during* pregnancy approximately 50% of the time and is called **major depressive disorder with peripartum onset** in the DSM-5. Women who experience a depressive episode during pregnancy typically experience severe anxiety, and panic attacks are not uncommon. Mood and anxiety during pregnancy and postpartum blues are both associated with greater risk for postpartum depression (APA, 2013). This exemplar discusses the psychologic struggles that women face after giving birth and how nurses can support them during this critical time.

Postpartum Blues

As stated previously, the postpartum blues represent a transient period of depression that occurs in as many as 80% of

Figure 28-7 » All women should be assessed for depression during their pregnancies.

women during the first few days following labor (NIMH, n.d.b). Postpartum blues may be manifested by mood swings, anger, weepiness, anorexia, difficulty sleeping, and a feeling of letdown. This mood change frequently occurs while the woman is still hospitalized, but it may occur at home. Changing hormone levels are a factor; psychologic adjustments, an unsupportive environment, and insecurity also have been identified as potential causes. In addition, fatigue, discomfort, and overstimulation may play a role. The postpartum blues usually resolve naturally within 10–14 days, but if symptoms persist or worsen, the woman may need evaluation for postpartum depression. If an assessment was not done previously, the nurse assesses the woman for predisposing factors during labor and the postpartum stay. Several depression scales are available for assessing postpartum depression. Depression screenings should be conducted on all women at least once during the perinatal period. Women with risk factors for perinatal depression should be monitored more closely (American College of Obstetricians and Gynecologists, 2015). For women whose screenings indicate possible depression, mental health treatment should be encouraged and provided (Yazici et al., 2015).

A key feature of postpartum blues is episodic tearfulness, often without an identifiable cause. Often when the woman is asked why she is crying, she responds that she does not know. Cunningham et al. (2010) speculate that several factors contribute to the blues:

- Emotional letdown that follows labor and childbirth
- Physical discomfort typical in the early postpartum period
- Fatigue
- Anxiety about caring for the newborn after discharge
- Depression during pregnancy or previous depression unrelated to pregnancy
- Severe PMS (premenstrual syndrome).

Validating the existence of this phenomenon, labeling it as a real but normal adjustment reaction, and providing reassurance can offer a measure of relief. Assistance with self-care and infant care, rest, good nutrition, information, and family support aids recovery. Encourage the mother's partner to watch for and report signs that the new mother is not returning to a normal mood but is instead slipping into a deeper depression.

The psychologic outcomes of the postpartum period are far more positive when the parents have access to a support network. Women and their partners may find that family relationships become increasingly important, but the increased family interaction itself can be a source of stress. New parents also may have increasing contact with other parents of small children but find that contact with coworkers declines. Of great concern are women and their partners who have no family or friends with whom to form a social network. Isolation at a time when the woman feels an increased need for support can result in tremendous stress and is often a contributing factor in situations of postpartum depression, child neglect, or abuse. New mother support groups are helpful for women who lack a social support system.

Postpartum doulas can be of great help during this critical time. Doulas are professionals trained to help the new

mother after the birth of the baby. As a “mother helper,” a postpartum doula’s services are tailored to help the new mother feel as rested as possible and be well nourished, and to place her household in good order so that she can focus her energy on her new baby.

Postpartum Mood Disorders

Postpartum Depression

Postpartum depression, or major depressive disorder with peripartum onset, is major depression that occurs during or in the first 4 weeks following birth. It has an overall prevalence rate of 3% to 6% in women during pregnancy or in the first 4 weeks following delivery (APA, 2013, p. 186). Postpartum depression may or may not be accompanied by psychotic symptoms.

Many of the symptoms of this major depression are indistinguishable from serious depression at other times in life: sadness, frequent crying, insomnia or excessive sleeping, appetite change, difficulty concentrating or making decisions, feelings of worthlessness, obsessive thoughts of inadequacy as an individual and parent, lack of interest in activities that are usually associated with pleasure (including sexual relations), and lack of concern about personal appearance. Persistent anxiety further contributes to the woman’s feeling of being out of control. Irritability and hostility toward others, including the newborn, may be evident. Women participating in Beck’s qualitative research on postpartum depression described a sense of living their daily life in a sort of fog, from which they believed they would never emerge. Once they improved, they often grieved over the time lost with their newborns while in this “fog.” The duration of symptoms varies, but as many as half continue to be symptomatic at 6 months or longer.

Delayed treatment of major depression is associated with longer duration (Doucet et al., 2009).

Risk Factors and Prevention

Risk factors for postpartum depression include the following:

- History of depression, bipolar disorder, postpartum depression, or other mental illness
- Primiparity (first pregnancy)
- Ambivalence about maintaining the pregnancy
- Lack of social support
- Lack of a stable and supportive relationship with parents or partner
- The woman’s lack of a supportive relationship with her parents, especially her father, as a child
- The woman’s dissatisfaction with herself, including body image problems and eating disorders.

Women with postpartum depression are at risk for suicide, most prominently as they enter or exit the deeply depressed state. In a deep depression, the woman is unlikely to be able to plan and carry out suicide. For that reason, signs of improvement in depression should be celebrated with some caution. Whereas the woman with postpartum psychosis may attempt suicide because of illogical thought processes, the woman with major depression attempts suicide because her suffering is so great that dying seems a more favorable option than continuing to live in such pain. She also may attempt suicide to save her newborn from some perceived or real threat—including the possibility that she herself might harm the baby. The risk of suicide is greater in women who have attempted suicide previously, have a specific plan, and can access the means or weapon identified in the plan. The more specific the plan, the greater the probability of an attempt.

Patient Teaching

Primary Prevention Strategies for Postpartum Depression

Nurses can encourage pregnant women, new mothers, and parents to participate in a number of strategies to help prevent postpartum depression. Providing education to the woman’s partner and primary support persons assists in the prevention or early identification of postpartum depression. Suggestions include the following:

- Celebrate childbirth but appreciate that it is a life-changing transition that can be stressful—at times it can seem overwhelming. Share your feelings with your partner and/or others.
- Consider keeping a journal in which you write down feelings. Not only is it emotionally cathartic, but it also provides a great memory book.
- Appreciate that you do not have to know everything to be a good parent—it is okay to seek advice during this transition.
- Connect to others who are parents—use them as a support and information network.
- Set a daily schedule and follow it even if you do not feel like it. Structuring activity helps counteract the inertia that comes with feeling sad or unsettled.
- Prioritize daily tasks. Decide what must be done and what can wait. Try to get one major thing done every day.
- Remember that you do not have to entertain or care for everyone who drops by. Doing something for someone else, however, often tends to make you feel better.
- If someone volunteers to lend a hand with tasks or baby care, accept the person’s help. While your volunteer is in action, do something pleasurable or get some rest.
- Maintain outside interests. Plan some time every day—even if it is just 15 minutes—to do something exclusively for you that is pleasurable.
- Eat a healthy diet. Limit alcohol. Quit smoking. Get some exercise. (All of these can positively affect the immune system.)
- Get as much sleep as possible. Rest whenever you can, such as when the baby is napping. If you have other young children, bring them onto your bed to read or play quietly while you lie down.
- If things get overwhelming and you feel yourself slipping into depression, reach out to someone for help.
- Attend a postpartum support group if one is available. Also consider an international program such as Postpartum Support International, which provides an emergency contact phone number at 1-800-944-4PPD as well as a website at <http://postpartum.net>.

Focus on Diversity and Culture

Postpartum Depression

Postpartum depression is a universal phenomenon, not restricted to specific cultures. It is seen in both industrialized and nonindustrialized countries (O'Mahony & Donnelly, 2010).

The gender of an infant may influence the development of postpartum depression. In Sweden, births of boys were associated with recall of postpartum sadness in all ethnicities except those from the Middle East (Lagerberg & Magnusson, 2012). In Asia and some Middle Eastern countries, male offspring are highly preferred over female offspring (Grech, 2014; Purnell, 2014). Pakistani women who had already given birth to female children had an increased rate of depression when compared to those who had sons (Waqas et al., 2015).

An alarming cultural consideration in the United States is the disparity of healthcare for postpartum depression in low-income women. A study of more than 29,000 New Jersey Medicaid recipients found that Black and Latina women were significantly less likely than White women to initiate treatment for postpartum depression. Among those who did, Black and Latina women were less likely than White women to receive follow-up care, continue care, or refill antidepressant prescriptions (Kozhimannil et al., 2011).

Genetic Considerations

There is increasing support for the gene and environment interaction theory of depression and postpartum depression. Variants in genes that code enzymes affecting serotonin, dopamine, and noradrenalin (neurotransmitters affecting mood) were associated with development of

depression in the peripartum period (Doornbos et al., 2009). Several studies implicated a serotonin-related transporter genotype in postpartum depression (Binder et al., 2010; Shapiro, Frasier, & Séguin, 2012). Other studies implicated monoamine oxidase-related genes in postpartum depression (Corwin et al., 2010). More research is needed to definitively identify the role of specific genes in postpartum depression.

Postpartum Psychosis

Postpartum psychosis (postpartum mood episodes with psychotic features) occurs in 1 in every 500 to 1000 deliveries (APA, 2013). The risk is increased in first deliveries, in women with prior postpartum depression, and in those with a history of depressive or bipolar disorder. Although relatively rare, postpartum psychosis gains considerable national attention when an incident of infanticide occurs.

Symptoms of postpartum psychosis include agitation, hyperactivity, insomnia, mood lability, confusion, irrationality, difficulty remembering or concentrating, poor judgment, delusions, and hallucinations that tend to be related to the infant. With appropriate treatment, most women experience improvement of symptoms within 2–3 months.

Postpartum psychosis is considered an emergency because of the risk of suicide and/or infanticide (Mayo Clinic, 2015a). The woman who is psychotic may experience delusions or hallucinations that support her perceptions that the infant should not be allowed to live. Illogical thinking or evidence of bonding difficulties may serve as cues to infanticide and suicide risk; however, this assessment is often challenging because of the lucidity seen in some psychotic patients.

Clinical Manifestations and Therapies

Postpartum Depression

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Postpartum blues	<ul style="list-style-type: none"> Mood swings Feeling sad Anxious or overwhelmed Crying spells for no reason Decreased appetite Problems sleeping 	<ul style="list-style-type: none"> Usually resolves without treatment within 3 to 14 days
Postpartum depression	<ul style="list-style-type: none"> Severe depression that occurs within the first year of giving birth, with increased incidence at about the fourth week postpartum, just before menses resumes, and upon weaning 	<ul style="list-style-type: none"> Sertraline (Zoloft) or paroxetine (Paxil) Support groups Assistance with care of the newborn, taking care to promote self-confidence in mothering Mental health counseling Assistance with building self-esteem and self-confidence in mothering skills
Postpartum psychosis	<ul style="list-style-type: none"> Agitation Hyperactivity Insomnia Mood lability Confusion Irrationality Difficulty remembering or concentrating Delusions and hallucinations that tend to be related to the infant 	<ul style="list-style-type: none"> Lithium or antipsychotics Should be supervised at all times when caring for infant or other children Support groups Short-term institutionalization may be required

SAFETY ALERT In all postpartum women, the presence of three symptoms of depression on 1 day or one symptom for 3 days may signal serious depression and requires immediate referral to a mental health professional.

Collaboration

It is not enough to simply refer women with a history of postpartum psychosis or depression or who are otherwise at high risk to a mental health professional for evaluation, counseling, and treatment between the second and sixth week postpartum. Clinical guidelines indicate these women require a detailed plan for psychiatric management during late pregnancy and during the early postpartum period. This plan should be shared (with consent) with the entire maternity team—e.g., obstetricians, nurses, and midwives. The plan should detail supports, contact information, and treatment considerations, including medications and breastfeeding.

Medication, individual or group psychotherapy, and practical assistance with child care and other demands of daily life are common treatment measures for both disorders; however, specific therapies may vary. Treatment of postpartum depression is not unlike treatment of any other significant depression: psychotherapy and antidepressant medications, usually SSRIs. The nurse's responsibilities as

part of the healthcare team are discussed in detail in the Nursing Process section.

Diagnostic Tests

The routine use of a screening tool in a matter-of-fact approach significantly improves the diagnosis. The Edinburgh Postnatal Depression Scale (**Box 28-4** ») and the Postpartum Depression Screening Scale (PDSS) are appropriate tools for use in assessing patients for postpartum depression. The PDSS is a 35-item scale that screens signs of postnatal depression such as cognitive impairment, sleeping and eating disturbances, emotional lability, guilt and shame, and thoughts of self-harm or suicide.

Pharmacologic Therapy

Treatment of postpartum psychosis is directed at the specific type of psychotic symptoms displayed and may include lithium, antipsychotics, or electroconvulsive therapy in combination with psychotherapy, removal of the infant, and social support. It is important for the nurse to realize that many of the drugs used in treating postpartum psychiatric conditions are contraindicated in breastfeeding women. However, systematic review concluded "(1) knowledge of pharmacokinetic characteristics are scarcely useful to assess safety and (2) the majority of antidepressants are

In the past 7 days:

1. I have been able to laugh and see the funny side of things.
As much as I always could
Not quite so much now
Definitely not so much now
Not at all
2. I have looked forward with enjoyment of things.
As much as I ever did
Rather less than I used to
Definitely less than I used to
Hardly at all
- *3. I have blamed myself unnecessarily when things went wrong.
Yes, most of the time
Yes, some of the time
Not very often
No, never
4. I have been anxious or worried for no good reason.
No, not at all
Hardly ever
Yes, sometimes
Yes, very often
- *5. I have felt scared or panicky for no very good reason.
Yes, quite a lot
Yes, sometimes
No, not much
No, not at all
- *6. Things have been getting on top of me.
Yes, most of the time I haven't been able to cope at all
Yes, sometimes I haven't been coping as well as usual
No, I have been coping quite well
No, I have been coping as well as ever
- *7. I have been so unhappy that I have had difficulty sleeping.
Yes, most of the time
Yes, sometimes
Not very often
No, not at all
- *8. I have felt sad or miserable.
Yes, most of the time
Yes, quite often
Not very often
No, not at all
- *9. I have been so unhappy that I have been crying.
Yes, most of the time
Yes, quite often
Only occasionally
No, never
- *10. The thought of harming myself has occurred to me.
Yes, quite often
Sometimes
Hardly ever
Never

Note: Response categories are scored 0, 1, 2, and 3 according to increased severity of the symptoms. Items marked with an asterisk are reverse-scored (3, 2, 1, 0). The total score is calculated by adding together the scores for each of the 10 items. A score above the threshold of 12 to 13 out of 30 indicates with 86% sensitivity that the woman is experiencing postpartum depression.

Source: From Cox, J. L., Holden, J. M., & Sagovsky, R. (1987). Detection of postnatal depression: Development of the 10-item Edinburgh Postnatal Depression Scale. *British Journal of Psychiatry*, 150, 782–786. Users may reproduce the scale without further permission provided they respect copyright by quoting the names of the authors, the title, and the source of the paper in all reproduced copies.

not usually contraindicated: (a) Selective serotonin reuptake inhibitors and nortriptyline have a better safety profile during lactation, (b) fluoxetine must be used carefully, (c) the tricyclic doxepin and the atypical nefazodone should be avoided, and (d) lithium, usually considered as contraindicated, has been recently rehabilitated” (Davanzo et al., 2011, p. 89). Recommendations are that a combination of antidepressants and psychosocial interventions be used regardless of whether or not the woman is breastfeeding. The woman and her partner should be reminded that antidepressants may take several weeks to have an effect. Providers may prefer to start antidepressants before the birth of the baby (usually at 36 weeks’ gestation) so that a therapeutic blood level is achieved before the birth of the baby.

Support Groups

Support groups have proven to be successful adjuncts to pharmacologic treatment. In a support group of postpartum women and their partners, a couple may feel consolation that they are not alone in their experience. Moreover, the group provides a forum for exchanging information about postpartum depression, learning stress reduction measures, and experiencing renewed self-esteem and support. The most effective support groups provide for safe child care to facilitate attendance. If a support group is not available locally, the woman and her family may be encouraged to contact Depression After Delivery (DAD), now a national web-based support network that provides education and volunteers, or Postpartum Support International.

NURSING PROCESS

The priority of nursing care for the patient with postpartum depression is to maintain safety of both patient and family. Nurses may hesitate to assess patients for risk of harm to themselves or others for fear of introducing an idea that had not occurred to the patient. Not only is this not the case, but questioning the patient’s thoughts of harming self or others can actually contribute to saving lives and should be a component of care for any patient experiencing depression.

Assessment

Because depression may occur during pregnancy, assessment of risk factors for depression and psychosis should be made early in the pregnancy and to encourage women who are at risk to seek professional mental health care (Yazici et al., 2015). In addition, pregnant women should be reassessed for manifestations of depression throughout the pregnancy and for up to 3 to 4 months following delivery. Questions designed to detect problems can be included as part of the routine prenatal history interview or questionnaire. Women with a personal or family history of psychiatric disease, particularly postpartum depression or psychosis, need prenatal instructions on the signs and symptoms of depression and may need additional emotional support. If one was not done previously, the nurse assesses the woman for predisposing factors during labor and the postpartum stay.

No matter what approach the nurse uses to assess for postpartum depression, enabling the woman to voice her feelings of maternal role transition and how she is adjusting in this vulnerable time is of inestimable value (Beck, 2008).

Listening to her story provides a critical emic (insider’s) view of her circumstances as opposed to an etic (outsider’s) view.

In providing daily care, the nurse observes the woman for objective signs of depression—anxiety, irritability, poor concentration, forgetfulness, sleep difficulties, appetite change, fatigue, and tearfulness—and listens for statements indicating feelings of failure and self-accusation. Severity and duration of symptoms should be noted. Report behavior and verbalizations that are bizarre or seem to indicate a potential for violence against herself or others, including the infant, as soon as possible for further evaluation.

The nurse needs to be aware that many normal physiologic changes of the puerperium are similar to symptoms of depression (lack of sexual interest, appetite change, fatigue). It is essential that observations be as specific and as objective as possible and that they be carefully documented. Beck and Indman (2005) found that anxiety was a prominent feature of illness for some women and suggested that women be assessed for their level of anxiety, particularly regarding infant care. Because of the strong association of interrupted sleep and postpartum depression and the finding that severe fatigue is an excellent predictor of postpartum depression (Corwin et al., 2005), assessing fatigue level at 2 weeks postpartum by telephone may be helpful in predicting depression risk early. Restorative sleep improves a woman’s ability to cope and make decisions, thereby producing a sense of better self-control.

A central challenge for nursing is identifying women at risk of suicide. Asking the patient directly if she has thoughts of self-harm is best. If the patient responds “yes,” she must be screened by a qualified mental health professional as soon as possible; she is not left alone until this has been accomplished. Family members also should be alert to signals that she may be intent on self-harm and advised that threats are to be taken seriously. Contact information for community mental health and crisis resources should be given to both the patient and family, along with the National Suicide Hotline toll-free number. Family members should be told to be especially vigilant for suicide when the woman seems to be feeling better.

Diagnosis

Possible nursing diagnoses that may apply to a woman with a postpartum psychiatric disorder include the following:

- *Coping, Ineffective*
- *Impaired Parenting, Risk for*
- *Risk for Violence: Self-Directed or Other-Directed.*

(NANDA-I © 2014)

Planning

Appropriate goals for the woman experiencing postpartum depression may include the following:

- The patient and family will remain free of injury.
- Family members and support persons will provide appropriate care for the newborn.
- The patient will articulate feelings and concerns.
- The patient will adhere to the plan of care.
- The patient will integrate the newborn into the family (with assistance as appropriate).

Implementation

Nurses working in antepartum settings (including the pediatrician's office) or teaching childbirth classes play indispensable roles in helping prospective parents appreciate the lifestyle changes and role demands associated with parenthood. Offering realistic information and anticipatory guidance and debunking myths about the perfect mother or perfect newborn may help prevent postpartum depression. Social support teaching guides are available for nurses to use in helping postpartum women explore their needs for postpartum support.

- Alert the mother, spouse, and other family members to the possibility of postpartum blues in the early days after birth and reassure them of the short-term nature of the condition.
- Describe symptoms of postpartum depression and encourage the mother to call her healthcare provider if symptoms become severe, if they fail to subside quickly, or if at any time she feels she is unable to function.
- Encourage the mother to plan how she will manage at home and provide concrete suggestions on how to cope in her adjustment to motherhood.

SAFETY ALERT Make an immediate referral for a mental health evaluation if the mother rejects the infant or makes a threat or an act of aggression against the infant. If any of these occurs, ensure that the infant is not left alone with the mother.

A diagnosis of postpartum depression or other psychiatric disorder poses major problems for the family. Depression interferes with the mother's ability to bond with the baby, which can cause the baby to have problems sleeping and eating and have future behavioral issues (NIMH, n.d.b). The father also often has a difficult time adjusting. The symptoms of these disorders are difficult to witness and may be harder to understand than physical problems such as hemorrhage and infection. The father may feel hurt by his partner's hostility; worry that she is becoming insane; or be baffled by her mood swings and lack of concern about herself, the newborn, or household responsibilities. He may be troubled by their lack of intimacy or deteriorating communication. Certainly, he has cause for concern about how the newborn and any other children are being affected. Very real practical matters—running the household; managing the children, including the totally dependent newborn; and caring for the mother—may be added to his usual routines and work responsibilities. It is not surprising that even in the most supportive families, relationships may suffer in response to these circumstances. It is often the father or another close family member who, in desperation, makes contact with the health-care agency. This is especially difficult when the mother is reluctant to admit she is experiencing emotional difficulty or is too ill to recognize her own needs.

Information, emotional support, and assistance in providing or obtaining care for the infant may be needed. The nurse can assist family members by identifying community

Evidence-Based Practice

Prevention of, Identification of, and Interventions for Postpartum Depression

Problem

How can the risk of postpartum depression be identified early in a pregnancy? What is the most effective way to prevent postpartum depression? When it occurs, how can it be treated?

Evidence

Postpartum depression is a serious condition that occurs in 3 to 6% of women during pregnancy or in the first 4 weeks following delivery (APA, 2013). It often goes undetected, as symptoms may be hidden or misinterpreted. Untreated, the condition may have consequences for mothers, infants, and their families.

But what are the best methods for the prevention, detection, and/or treatment of postpartum depression? A Cochrane review examined this very question, and its results provide useful guidance for nurses and other healthcare professionals. In this review, Dennis and Dowswell (2013) analyzed 28 trials that collectively involved nearly 17,000 women. Some participants in these trials received standard pre- and postnatal care, while others received some sort of psychologic or psychosocial intervention. A variety of interventions were included in the review, including educational programs, CBT, interpersonal psychotherapy, nondirective counseling, and tangible in-person assistance. Some interventions were delivered in group settings, while others were delivered on an individual basis. Similarly, some occurred in the home while others occurred in the clinic, and some were delivered by professionals while others were delivered by laypeople.

In analyzing these interventions, the reviewers hoped to determine which programs and which delivery characteristics yielded the most beneficial outcomes. Their results were somewhat unexpected. In particular, there was no strong evidence indicating that pre- and post-birth classes, postpartum lay-based home visits,

early postpartum follow-up, continuity of care models, in-hospital debriefing, or CBT reduced participants' likelihood of postpartum depression. There was, however, evidence supporting the efficacy of professionally based home visits (e.g., from nurses or midwives), peer-based postpartum support via telephone, and interpersonal psychotherapy. These types of interventions were most successful when they included use of the Edinburgh Postnatal Depression Scale (EPDS) and when they specifically targeted at-risk women rather than the overall population of new mothers.

Implications

Nurses are in particularly good position to identify mothers at high risk for peripartum and postpartum depression. The EPDS should be an important part of these screening efforts. Once high-risk patients and/or patients who present with signs and symptoms of depression have been identified, they should be referred for additional support, ideally in the form of individually based interventions initiated postpartum. In-person interventions are most effective when delivered by a trained professional, whereas telephone interventions are effective when delivered by peers (Dennis & Dowswell, 2013). Some research also suggests that web-based, individualized, interactive interventions may yield beneficial results, but more research is needed before the usefulness of such programs can be confirmed (Haga et al., 2013).

Critical Thinking Application

1. Why do you think prepartum classes have little impact in preventing post-partum depression?
2. What advantages might peer-based postpartum support via telephone offer?
3. Why does postpartum care need to be individualized?

resources, making referrals to public health nursing services and social services, and providing a list of telephone numbers as well as emergency services that the mother may need. Postpartum follow-up is especially important, as are visits from a psychiatric home health nurse.

Evaluation

Expected outcomes of nursing care include the following:

- The patient's signs of depression are identified and she receives prompt intervention.
- The newborn is effectively cared for by the father or other support persons until the mother is able to provide care.

- The mother and newborn remain safe.
- The newborn is successfully integrated into the family unit.

Similar to major depressive disorder, postpartum depression may take time to resolve. The healthcare team will need to provide ongoing care for the mother, infant, and support persons, including integrating a mental health assessment into every postpartum follow-up appointment (O'Hara & McCabe, 2013). Regardless of the treatment provided, the safety of the infant, mother, and family must remain a priority for the healthcare team.

Nursing Care Plan

A Patient with Postpartum Depression

Salma al-Hussein, a 30-year-old woman who was born in Jordan but has lived in the United States for nearly 20 years, is brought to her primary care provider's office by her mother. Mrs. al-Hussein gave birth to her third child nearly 6 weeks ago. Her mother is worried because her daughter is showing almost no interest in the

baby and very little interest in her older children. Mrs. al-Hussein's mother and sister have been providing most of the care for the children. Mr. al-Hussein is a small business owner who works 10 to 12 hours per day, 6 days a week.

ASSESSMENT	DIAGNOSES	PLANNING
At first, Mrs. al-Hussein is slow to answer the nurse's questions and keeps her eyes on the floor during the assessment. Mrs. al-Hussein's mother says that her daughter is not normally like this, that she is usually full of life and outgoing and polite with others, even those she does not know well. With the encouragement of her mother, Mrs. al-Hussein becomes more cooperative. The nurse uses the Edinburgh Postnatal Depression Scale; Mrs. al-Hussein scores 14 out of 30.	<ul style="list-style-type: none"> ■ <i>Parenting, Impaired</i> ■ <i>Powerlessness, Risk for</i> ■ <i>Impaired Social Interaction</i> ■ <i>Coping, Ineffective</i> (NANDA-I © 2014)	<ul style="list-style-type: none"> ■ The patient will commit to safety. ■ The patient will express her feelings. ■ The patient will agree to participate in mental health counseling. ■ The family will continue to provide care for the children and support Mrs. al-Hussein as she begins the treatment process.

IMPLEMENTATION

- Refer to mental health professional.
- Attempt to persuade Mrs. al-Hussein to commit to safety for both herself and the children.
- Teach family to supervise mother's interaction with the infant and other children at all times to promote safety.
- Explain impact of postpartum depression to the family and help them cope with the impact on the family.
- Identify community resources for assisting with treatment.
- Encourage family to continue providing care for the infant and other children.
- Help Mrs. al-Hussein recognize the signs of depression and accept the diagnosis of postpartum depression.
- Explain to both Mrs. al-Hussein and her family members that postpartum depression is not uncommon and can be successfully treated, but risk for reoccurrence is high if she has additional children.

EVALUATION

Mrs. al-Hussein's care is evaluated based on the following expected outcomes:

- The patient begins treatment with a mental health counselor and is taking her medications as prescribed.
- Family members continue to provide supervision and care of the children until Mrs. al-Hussein's condition improves.
- The patient commits to safety for herself and her children.

CRITICAL THINKING

1. How would you persuade Mrs. al-Hussein to commit to safety for herself and her children?
2. What specific questions would you ask to determine if Mrs. al-Hussein is thinking about harming herself or her children?
3. If Mrs. al-Hussein admitted having fantasies of harming her children, how could you advocate for the family?

REVIEW Postpartum Depression

RELATE Link the Concepts and Exemplars

Linking the exemplar of postpartum depression with the concept of development:

1. How might a mother's postpartum depression impact the development of her 3-year-old daughter?
2. What is your priority developmental concern for the newborn when the mother has severe postpartum depression?

Linking the exemplar of postpartum depression with the concept of comfort:

3. What are your concerns for the mother who has postpartum depression regarding sleep and rest?
4. How will fatigue impact postpartum depression and the care of the newborn?

REFLECT Apply Your Knowledge

Jessica Riley is a single 17-year-old new mother of a 1-month-old infant son named Ryan whose father ended his relationship with Jessica when she was 4 months pregnant. Jessica's relationship with her mother has been strained for the past few years and worsened when she became pregnant. Because she was constantly fighting with her mother, Jessica moved to a small apartment when she was 6 months pregnant. Jessica's father left the family when Jessica was 7 years old. She recently completed her GED and is now trying to go to school part time for an associate's degree in cosmetology. She also works nearly full time as a waitress, but because she is supporting herself and her baby, she struggles financially.

1. What information in Jessica's history puts her at risk for postpartum depression?
2. How would you assess Jessica for potential postpartum depression?
3. What interventions can you implement to reduce Jessica's risk of postpartum depression?

Exemplar 28.D Suicide

Exemplar Learning Outcomes

28.D Analyze the nurse's role in preventing and responding to patient suicide attempts.

- Describe the pathophysiology of suicide.
- Describe the etiology of suicide.
- Compare risk and protective factors for suicide.
- Identify the clinical manifestations of suicidal ideation.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual at risk for suicide.

Overview

Suicide is the act of inflicting self-harm that results in death. When the act is not fatal, but the intent of the act was to cause death, it is referred to as a **suicide attempt**. Cases of an individual constantly considering, planning, or thinking about suicide are considered **suicidal ideation**. In the United States, suicide has become the 10th leading cause of death, even higher than homicide. In 2013, more than 41,000 individuals took their own lives, more than 1.3 million attempted suicide, and more than 9.3 million adults considered suicide (CDC, 2015).

Pathophysiology and Etiology

Depression is considered to play a role in many instances of suicide. Approximately half of those who take their own lives were confirmed as being depressed at the time of the incident (American Association of Suicidology [AAS], 2014). Further, an analysis of more than 46,000 responses to the Medical Expenditure Panel Surveys of U.S. Households in

- Differentiate care of patients at risk for suicide across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual at risk for suicide.

Exemplar Key Terms

Suicide, 1958

Suicidal ideation, 1958

Suicide attempt, 1958

2012 and 2013 found that only 28.7% of adults who screened positive for depression received treatment, and that uninsured adults, people of color, and men were less likely to receive treatment for depression than women and individuals with insurance (Olson et al., 2016). Lack of access to mental health care may result in underestimating the relationship between depression and suicide.

Influencing Factors

The majority of individuals who attempt or succeed at taking their own lives often cite a reason for wanting to die. However, suicide is generally influenced by a number of factors, not just one. By understanding the underlying causes of suicide, nurses can better recognize potential warning signs for suicidal behavior as well as identify individuals who are at greater risk.

Genetics and Neurobiology

Studies conducted over the past 15 to 20 years have indicated a familial aspect to suicidal tendencies in a number of

cases. For example, an individual's risk for suicide is 5 times higher if a biological relative has committed suicide. Several neurobiological and genetic studies have proposed that genes and situational stressors work together to create the conditions for suicidal behavior. Parental suicide attempts appear to be among the most important factors contributing to suicidal tendencies, although there are inherent difficulties in teasing out how much of the increased risk is due to genetics and how much is due to dysfunctional family processes (Brent, Melhern, & Oquendo, 2015). Evidence also suggests that early traumatic experiences can lead to changes in gene expression (via epigenetic mechanisms) in the brain that render a person at increased risk for suicidal ideation (Rhodes et al., 2014).

The most commonly studied neurotransmitter thought to be connected with suicide is serotonin, which is also believed to play a central role in major depression. Suicidal individuals have been found to have decreased levels of serotonin, which can cause increased impulsivity and suicidal behavior (Larkin, 2016).

Interpersonal Factors

Individuals contemplating suicide can be influenced by a number of interpersonal factors, such as a history of being abused, a history of being raped, loneliness, a recent separation from a significant other, and grief from the passing of a friend or loved one. Any significant emotional disturbance can cause an individual to become depressed, and if the depression becomes unmanageable, that may lead to suicidal thoughts and behaviors. Loss and grief can be profound influencing factors for suicidal behavior, especially if loss is of significant importance. Individuals who have lost a partner—especially those without other close family ties—should be monitored closely for warning signs of dangerous behavior.

Situations that take away an aspect of an individual's control over life also may increase an individual's risk for suicide. Events such as unemployment and financial difficulties, the loss of a home, or another extremely stressful event can cause some individuals to despair of the possibility that life can improve or that they can feel something other than hopelessness. Feelings of hopelessness such as these are at the root of many cases of suicide. The individual may come to believe that the easiest, and only, way to handle the loss is to kill herself.

Comorbid Disorders

Approximately 90% of those who attempt or commit suicide have a comorbid disorder. Many of these disorders involve an element of depression, and it is estimated that approximately half of individuals who succeed at taking their own lives were experiencing depression at the time, or were in the recovery phase of depression (AAS, 2014). The most common comorbid disorders for suicide are bipolar disorder, borderline personality disorders, conduct disorders, schizophrenia, and drug and alcohol dependency. All of these disorders have aspects of impaired impulse control, depression, and altered consciousness, thus making them the primary disorders associated with suicide attempts and completion (Hooley et al., 2017).

Individuals with bipolar disorder are 15 to 20 times more likely to commit suicide than the general population. It is

estimated that 25–50% of those with the disorder will attempt suicide at some point in their lives. Note that the risk for suicide among individuals with bipolar disorder decreases considerably with active treatment. The most commonly studied treatment associated with decreased suicide risk was administration of lithium (Lewitzka et al., 2015).

Numerous studies have shown that individuals with recurrent mood disorders have the highest risk of suicide. The general population has a 1.4% risk of committing suicide, whereas individuals with schizophrenia are shown to have a 10–13% risk. Those with alcohol dependency carry a 3–4% risk of suicide. Individuals with borderline personality disorder are often plagued with feelings of hopelessness and depression, making the prevalence of attempted and committed suicide quite high within that population. Similarly, conduct disorders and antisocial personality disorders are seen as predictors for suicidal behavior (Hooley et al., 2017).

Social Factors

Recessions, bullies, and/or dominant social beliefs can have an impact on individuals' mental health. Economic recessions can cause financial strain and job loss, which are both stressful events often cited as potential indicators of suicidal behavior. Economic recessions and high unemployment rates often lead to individuals defaulting on mortgages and losing their homes. Research indicates that there is a concealable stigma related to mortgage strain leading to feelings of shame and worthlessness. Concealing the mortgage strain due to the stigma leads to isolation, and isolation appeared to lead to the person's depression, anxiety, and emotional stress (Keene, Cowan, & Baker, 2015).

Bullying is another social factor that increases suicide risk. Bullies in schools or in the workplace are emotionally abusive toward their victims, harassing them to the point where the victims feel worthless or hopeless about life in general. Although many schools and community programs are working to eliminate bullying, it is still present across the country. Dominant social beliefs can also play a role. For example, bullying and discrimination have been linked to an increased risk for suicide among transgender and gender-nonconforming individuals (Haas, Rodgers, & Herman, 2014). Another study found that female refugees from areas sustaining genocide need preventive suicide measures (Levine et al., 2016). Additional groups that the Office of the Surgeon General (2012) reports at risk include individuals in the justice and child welfare settings; lesbian, gay, bisexual, and transgender (LGBT) populations; and members of the armed forces and veterans.

Etiology

A common theme that many suicide-attempt survivors report is that suicidal behavior comes from a feeling that death is the only option that will successfully solve the individual's current emotional strain (SAMHSA, 2015b). It is commonly said that suicide is a "cry for help," and while that may be true some of the time, suicide is a desire for a permanent solution to whatever catalyst has prompted the individual's behavior. Some who attempt suicide do so with the mindset that they would like to die, but if they do not, then at least others will realize how truly unhappy, or

lonely, or desperate they feel. In cases such as these, a mild overdose of pharmaceuticals will often be used, or they will cause an injury that would be life threatening if no one found them in time.

Individuals who have only death in mind will generally use a gun, hang themselves, or jump from a tall building, because these methods are more likely to cause mortal injuries. Assessing lethality is important in determining patient suicide risk. Use of the scale for assessment of lethality of suicide attempt (SALSA) has proven to be useful in determining lethality. This scale has two components, with the first having four items indicating seriousness of attempt and consequences (for example, the method the individual has identified and the degree of medical intervention that will be needed if the patient uses this method). The second component is the global impression of lethality (Kar et al., 2014).

In cases where an individual has a comorbid disorder such as schizophrenia or bipolar disorder, the patient may report having been instructed by voices (e.g., command hallucinations) in their mind to commit suicide. If these voices have been present for the majority of the individual's life, the individual may find it difficult to ignore such commands. However, if some part of the individual's mind still has the desire to survive, he might employ less drastic means of suicide in an effort to both satisfy the voices and get help in stopping them if he is able to survive the suicide attempt.

Risk and Protective Factors

Risk factors for suicide in the United States include depression or other mental disorders; previous suicide attempt; a family history of abuse, violence, or suicide; substance abuse disorders; exposure to suicidal behavior; and firearms in the home. Other factors contributing to suicide risk include (APA, 2015b; Office of the Surgeon General, 2012; World Health Organization, 2016b):

- Social isolation; lack of support systems
- Recent unemployment
- Recent loss of a significant relationship
- Feelings of failure and hopelessness
- Access to lethal means (e.g., presence of a gun in the home)
- History of trauma or abuse
- Chronic physical illness, including chronic pain.

Other risk factors include gender and age. Men in the United States are more likely to die from suicide, whereas women are twice as likely to attempt suicide. Suicide is currently the seventh leading cause of death in males (Heron, 2016, p. 20). From the late 1980s to the early 2000s, older adults were at the highest risk for committing suicide of any age group. In 2014, the highest rate of suicide was among those age 85 and older, whereas the lowest rate of suicide was among those in the age group of 15–24 (American Foundation for Suicide Prevention, 2016).

Protective factors are “factors that make it less likely that individuals will develop a disorder. Protective factors may encompass biological, psychological, or social factors in the individual, family, and environment” (Office of the

Surgeon General, 2012). Examples of protective factors include the following:

- Strong family connections
- Community support
- Access to mental health providers
- Young children to care and provide for
- Strong ties to religions that denounce suicide.

Additional protective factors include caring for pets and use of healthy coping and decision-making skills (APA, 2015b; CDC, 2016a).

Clinical Manifestations

Although the clinical manifestations of suicidal ideation and behavior vary by age, culture, individual psychology, and life history, a few common factors underlie most suicidal behavior. Experts frequently cite impulsivity, aggression, pessimism, and an overall negative affect as personality traits associated with the condition. As stated earlier, negative events such as interpersonal crisis and financial catastrophe can play a role. The sense of a loss of meaning in life produces the painful, hopeless mental state conducive to suicide. Factors that predict suicidal behavior in the short term include major depression, psychic anxiety, delusions, and alcohol abuse. The fundamental clinical manifestation of suicidal ideation is the domination of the patient's consciousness by an unrelenting stream of painful thoughts. The suicidal person feels that death is the only possible solution to escape a mental life of unrelenting stress, anxiety, and depression (Hooley et al., 2017).

Behavior

Behavioral cues provide a window into the mind of an individual who may be contemplating suicide. Though not all people who commit suicide behave abnormally beforehand, many people provide clues that an attempt is imminent. An individual contemplating suicide may mention feeling helpless in the face of stress and may discuss life after death. He may also provide verbal cues such as “It won't matter for long” or “I can't take this much longer.” Some behaviors may also demonstrate suicidal ideation, such as giving away personal possessions, withdrawing from relationships, and obtaining a means to end life such as purchasing a gun (Mayo Clinic, 2015b). It is important to note that some individuals may not demonstrate overt behaviors when suicidal. For example, data suggests that older adults may not report suicidal ideation (Cukrowicz et al., 2013).

The American Association of Suicidology (2016) developed a mnemonic device for the short-term indications of suicidal intent with the phrase **IS PATH WARM**. The letters in the phrase indicate the following terms:

Ideation	Purposelessness	Withdrawal
Substance abuse	Anxiety	Anger
	Trapped	Recklessness
	Hopelessness	Mood Changes

All of these terms are indicators of possible suicidal behavior, and concern for the patient's condition should increase if

she exhibits more than one of these behaviors. An individual at immediate risk for suicide will often display the warnings signs of acute risk. These include talking of wanting to hurt herself; looking for access to firearms, pills, or other means of suicide; and talking or writing about death. If these symptoms are observed, the individual should not be left alone and a mental health professional should be contacted.

Cognition

Individuals who attempt suicide are more likely than their peers to experience distortions in cognition. Common distortions include (but are not limited to) unusually rigid thinking, dichotomous thinking, magnification, overgeneralization, externalization of self-worth, and “fortune telling,” or predicting negative outcomes without considering the possibility of other, more positive outcomes (Jager-Hyman et al., 2014). After an unsuccessful suicide attempt, an easing of emotional stress typically takes place, especially if the attempt was expected to be lethal, and cognitive distortions often abate. Without appropriate treatment, however, this reduction in stress and distorted thinking is only temporary, and suicidal behavior frequently recurs. In fact, the year after an attempt, repetition of suicidal behavior occurs in 15–25% of cases, and there is an increased likelihood that the second or third attempt will be fatal. Long-term studies have shown that 7–10% of individuals who seriously attempt suicide will eventually kill themselves, a risk that is about 5 times greater than the average risk of 1.4% (Hooley et al., 2017).

Social Isolation

A common precipitant to suicidal behavior is social stress or isolation. An individual may become suicidal when he becomes alienated from family and friends, or even when he has difficulty adapting to the demands of new social roles. Loss of a loved one is a contributing factor related to suicide, as well as the loss of the ability to participate in once enjoyable activities. For older adults, the loss of autonomy, including a reliance on others to get around (e.g., loss of a driver's license or loss of mobility) and feeling like they are a burden to others, contributes to the sense of social isolation and increases suicide risk (SAMHSA, 2015b).

Regardless of an individual's age, a stable social situation is essential to healthy mental functioning. The early 20th-century sociologist Emile Durkheim related the differences in suicide rates to differences in group cohesiveness and concluded that the best deterrent to suicide is a sense of involvement and identity with other people. Durkheim's thesis is confirmed by the prevalence of suicide among people living in disorganized families and people experiencing social isolation (Hooley et al., 2017). The link between suicide and weak group organization is also corroborated by the relationship between unemployment and suicidal ideation: Unemployed individuals are cut off from both their sense of purpose and their social network.

Cultural Considerations

Also within the United States, the various ethnic groups exhibit substantial differences in suicide rates. For example, American Indians and Alaska Natives have the highest rate of suicide, followed by non-Hispanic Whites. African Americans

Focus on Diversity and Culture

Suicide and LGBT Culture

Lesbian, gay, bisexual, and transgender (LGBT) individuals are at higher risk for suicide, in part, due to discrimination that they experience regularly from family, friends, colleagues, and society. Fear of non-acceptance may be a precipitant to depression and, if severe enough, has been known to lead to suicide.

- LGBT individuals are 2 times more likely to attempt suicide than heterosexual individuals.
- Gay and bisexual men are 4 times as likely to attempt suicide compared to heterosexual men.
- LGBT individuals are more likely to participate in suicide attempts and ideation compared to completed suicides.
- Increased risk for suicide in this population can be attributed to the presence of prejudice, stigmas, and discrimination.
- Adolescent LGBT individuals demonstrate a particularly high rate of suicide, attempted suicide, and suicidal ideation (CDC, 2017).

have the second lowest suicide rate, and the lowest rate is in the Hispanic population (NIMH, 2015). Suicide rates also vary significantly among national cultures. The United States currently has a suicide rate of about 13 per 100,000 (CDC, 2016b), whereas Greece, Spain, and the United Kingdom have rates of about 9 per 100,000. Hungary has a rate of about 40 per 100,000, the world's highest. Other European nations like Switzerland, Finland, Austria, Sweden, Denmark, and Germany have high rates due to a variety of cultural factors (Hooley et al., 2017).

Another cultural difference in the prevalence of suicide worldwide is gender disparity. Women are more likely to attempt suicide and men are more likely to complete suicide in the United States, but in India, Poland, and Finland, men are more likely to engage in nonfatal attempts. In China, India, and Papua New Guinea, women are more likely to complete suicide than men (Hooley et al., 2017).

Adherence to religious beliefs is considered to be a protective factor for suicide. Faiths such as Catholicism and Islam strongly forbid suicide, and rates of suicide in nations that follow these religions are accordingly low. Many societies have strong cultural taboos against suicide in addition to formal declarations. However, some nations provide cultural exceptions to the rule outlawing suicide. Japanese culture is one of the few societies in which suicide has been approved as a socially acceptable solution to certain problems of disgrace or social cohesion. The suicidal zeal for a political and religious cause has found a new form in the suicide bombings of Muslim extremists in the Middle East. Across cultures, suicide can be a violent expression of inner turmoil, or an act motivated by national or religious fervor (Hooley et al., 2017).

Collaboration

Suicide attempts and suicidal ideation, if caught early enough, can be addressed in a number of ways. The most common and effective method of treatment is to combine pharmaceutical interventions with talk or group therapy or counseling. For individuals who are also experiencing a

comorbid disorder, the underlying disorder will need to be treated in addition to the suicidal behavior because the two conditions may exacerbate each other. Nurses will work with the patient, physicians, and therapists to create an effective plan of care.

Pharmacologic Therapy

Depending on the individual patient’s manifestations and the presence of comorbid disorders, pharmacologic therapy may be appropriate for patients who are suicidal. The most likely choices of medications are antidepressants and mood stabilizers.

Antidepressants

The antidepressants most often used to treat depression (the underlying cause of the majority of suicide attempts) are fluoxetine (Prozac), citalopram (Celexa), sertraline (Zoloft), paroxetine (Paxil), and escitalopram (Lexapro). All five of

these drugs are SSRIs and are used to balance and stabilize the neurotransmitters in the brain that affect mood and emotional responses. Although all of these medications are used to treat depression, they also have the potential side effect of causing suicidal tendencies. The use of antidepressants after a patient has attempted or seriously considered suicide should be combined with nonpharmacologic therapy.

Mood Stabilizers and Antipsychotics

Mood stabilizers commonly prescribed for bipolar disorder have the ability to moderate extreme shifts in emotions between mania and depression. Some antiseizure drugs are also used for mood stabilization in bipolar patients. For more on drugs for bipolar disorder, see the exemplar on Bipolar Disorders earlier in this module.

Antipsychotics (medications used in the treatment of schizophrenia) may be prescribed for patients who experience hallucinations and delusions or those with major

depressive disorder with psychotic features. The treatment of these symptoms of the disease can help the suicidal patient immensely by eliminating one of the underlying causes of self-destructive thoughts. For more information about schizophrenia and antipsychotic medications, see the exemplar on Schizophrenia in the module on Cognition.

Nonpharmacologic Therapy

Therapeutic approaches to suicide prevention can be quite effective in many cases. The type of therapy employed will depend on both the patient and the therapist, but the three most common forms of therapy used for suicidal patients are group therapy, individualized therapy, and family therapy. All three of these forms can be combined to further help the patient work through her suicidal thoughts and behaviors. Family therapy will generally be used in tandem with either group or individualized therapy. The presence of the family can be very helpful in supporting the patient, especially because most individuals who are truly contemplating suicide will work to isolate themselves from friends and family before the event. Family therapy can also help the patient's family to understand what she is feeling and why she considered suicide, which can ultimately aid the family in taking an active role in supporting the patient's recovery.

Cognitive behavior psychotherapy for suicide prevention (CBT-SP) is sometimes used with adolescents who display serious suicidal ideation or have recently attempted suicide. CBT-SP works to help the individual develop skills to prevent suicidal behavior in the future. The therapy works with the adolescent patient to develop and employ healthy coping mechanisms and avoid all forms of self-harm (O'Connor et al., 2014).

Patients who are at risk for suicide or who have attempted suicide often benefit from therapeutic interventions addressing healthy coping mechanisms. Writing therapy can be employed to help the patient work through any suicidal thoughts or fantasies; similarly, a preoccupation with death and dying can be addressed through writing and keeping a journal. The journal will also serve to allow the patient to see the progress that has been made from the start of therapy until its completion, with the goal that the writing will change tone from potentially hopeless at the start to more positive and hopeful at the end.

Lifespan Considerations

In the United States in 2014, males were 3.6 times more likely to commit suicide than females. For adults, men between the ages of 25 and 44 committed suicide at a rate of 24.3 deaths per 100,000 individuals, and this increased to 29.7 deaths per 100,000 men between the ages of 45 and 64. Women between the ages of 25 and 44 committed suicide at a rate of 7.2 deaths per 100,000 individuals, and this increased to 9.8 deaths per 100,000 women between the ages of 45 and 64. Women between the ages of 45 and 64 had the highest suicide rate of any female age group (CDC, 2016b). Suicide rates for other age groups are provided in the following sections.

Firearms, suffocation, and poisoning are used for over 90% of all suicides. However, the preferred method of suicide

Figure 28-8 » Methods of suicide differ between men and women.

differs between males and females (see **Figure 28-8** »). For the years in which the most recent data is available, 34.1% of females chose poisoning, 31.0% chose firearms, and 26.2% chose suffocation. In contrast, males predominantly used firearms (55.4%) compared to suffocation (26.8%) or poisoning (10.6%) (CDC, 2016b).

Suicide in Children

In 2014, boys between the ages of 10 and 14 committed suicide at a rate of 2.6 per 100,000 individuals, and girls in this age range committed suicide at a rate of 1.5 per 100,000 individuals. The increase from 0.5 (in 1999) to 1.5 (in 2014) suicides per 100,000 individuals represented the greatest increase in the suicide rate for females of any age group (CDC, 2016b). Children are at an increased risk for suicidal ideation if they have lost a parent, have been physically or sexually abused, have an unstable family, experience humiliation in school, or have lost a loved one. Psychopathology in childhood—including depression, antisocial behavior, ADHD, and impulsivity—is a strong predictor of childhood suicide. Suicide is the third leading cause of death in children age 10 to 14 (CDC, 2015). The most common means is hanging or strangulation. Statistics indicate that suicide is more common among Black children, especially Black males, than members of other ethnic and racial groups. Furthermore, more than a quarter of children who committed suicide discussed their intent to do so with someone else prior to their death. These findings highlight the importance of targeted prevention efforts, as well as not discounting the words of children who mention a desire to die (Sheftall et al., 2016).

Suicide in Adolescents and Young Adults

In 2014, males between the ages of 15 and 24 committed suicide at a rate of 18.2 per 100,000 individuals, and females in this age range committed suicide at a rate of 4.6 per 100,000 individuals (CDC, 2016b). Suicidal cognition in adolescents increases dramatically, most likely because of the collision of depression, anxiety, drug use, and conduct disorders in the teenage years. Adolescents and young adults may also attempt suicide because of a lack of meaningful relationships, sexual problems, and/or acute problems with parents

or significant others. Exposure to the dramatic suicides of role-model celebrities also plays a role in the cognition of adolescents, who are highly susceptible to imitative behavior (Hooley et al., 2017). Similarly, suicide has an element of “contagion” among teenagers, meaning that adolescents are more likely to attempt suicide after learning of the suicide of a friend or acquaintance. In recent years, bullying and harassment via “new media” such as text messaging and the internet has also been linked to a rise in suicide attempts (Hawton, Saunders, & O’Connor, 2012). College students have additional risk factors, including anxiety about academics, new social situations and responsibilities, and anxiety about their place in the world. Suicide is the second leading cause of death among individuals age 15 to 34 (CDC, 2015).

Suicide in Pregnant Women

Suicide during pregnancy is not a common occurrence, despite the fact that pregnant women are at risk for depression with peripartum onset. The Centers for Disease Control and Prevention’s Violent Death Reporting System indicates that there were approximately 43 women who committed suicide while pregnant between the years 2003 and 2007 (Georgia Health Sciences University, 2011). Relationship issues appeared to be contributing factors to more than half of these suicides. Older, White women were reported to be at greatest risk. Women are far more likely to attempt suicide in the postpartum period than during pregnancy, especially if they are experiencing postpartum depression or psychosis or if they have a history of mood disorders. In fact, suicide is believed to account for about 20% of deaths in women during the first year postpartum (Gentile, 2011).

Suicide in Older Adults

For older adults, men between the ages of 65 and 74 committed suicide at a rate of 26.6 deaths per 100,000 individuals, and this increased to 38.8 deaths per 100,000 men age 75 and older. Women between the ages of 65 and 74 committed suicide at a rate of 5.9 deaths per 100,000 individuals, and this decreased to 4.0 deaths per 100,000 women age 75 and older (CDC, 2016b). Men age 75 and older had the highest suicide rate of any other age group, and though older adults attempt suicide less often than individuals in other groups, they have a higher rate of completion because they use more lethal means. Further, many are not as resilient as younger adults. White men over the age of 65 make up 80% of those who commit suicide in late life (NIMH, 2015). One of the leading causes of suicide in the older population is depression, often undiagnosed, and the negative events that frequently come with long life: death of a loved one, illness, and isolation. Although most of the suicide attempts in this population are associated with mental illness, terminal illness increases the risk of depression and suicidal ideation or suicide. Terminal illness that causes pain and suffering is known to be a precursor to successful suicides. Suicide is the seventh leading cause of death in persons over the age of 65 (CDC, 2015). Interestingly, although older adults have higher suicide rates than younger populations, they are less likely to

mention suicidal ideation to their healthcare provider (Kiosses, Szanto, & Alexopoulos, 2014).

NURSING PROCESS

Appropriate, nonjudgmental nursing care of the patient who is suicidal is imperative. Nurses will work to ensure the patient’s safety while helping empower the patient’s need to refrain from self-harm. Every situation involving suicide is different, and nurses evaluate patients based on their individual cases and without any personal judgment or biases.

Assessment

Nurses working with patients who are considering suicide, or who have recently attempted suicide, should be direct but respectful when evaluating the patient and asking questions. It is a common misconception that talking about suicide directly can cause the patient to act in a suicidal manner. Individuals who are experiencing suicidal ideation respect direct acknowledgment of the situation as opposed to a restrained approach.

During assessment, obtain a full patient and family history, focusing in particular on any personal or family history of mood disorders. Inquire whether the patient has a history of suicide attempts or ideation, and if anyone in the patient’s family has ever committed suicide.

Next, a thorough assessment to determine suicidality will need to occur. During this assessment, the nurse should evaluate the patient’s mood and affect, behavior, cognition, and patterns of social interaction, looking specifically for the manifestations of suicidality described earlier. The nurse should also consider the various risk factors and protective factors outlined near the start of the exemplar. Questions to ask to assess suicidality may include (APA, 2016; Columbia University Medical Center, n.d.; Potter & Moller, 2016):

- Have you wished you were dead or that you could go to sleep and not wake up?
- Have you had any thoughts of killing yourself?
- Have you been thinking of how you might do this?
- Do you have any intent of acting on these thoughts?
- Have you started to work out the details of how you intend to carry out this plan?
- Do you have access to a means of suicide (e.g., gun, pills, vehicle)?
- Have you told anyone of your plan?
- Have you attempted to end your life in the past?
- What is happening in your life that makes you feel like you don’t want to live?
- Has anyone in your family ever attempted or succeeded with suicide?

Once the presence of suicidality has been established, the nurse must assess the patient’s level of intent and lethality. One frequently used tool in this area is the Columbia-Suicide Severity Rating Scale (C-SSRS), which has been administered

to millions of individuals and has demonstrated success in reducing rates of patient suicide (The Joint Commission, 2016). The scale comes with a list of questions, many of which appear above, and recommendations for triage depending on the severity of the individual's suicidality. For example, a patient who has thought about killing himself or wished he was dead but does not express any intent to harm himself requires, at minimum, mental health referral at discharge. However, the patient who expresses intention to kill himself, with or without a plan, requires immediate safety monitoring and psychiatric consultation. For patients with a history of previous suicide attempt, interventions are determined by the amount of time that has lapsed since the previous attempt. These range from immediate monitoring for safety with a psychiatric consultation for the patient who attempted suicide within the last week to a referral to a mental health provider for the patient who attempted suicide more than a year ago (Columbia University Medical Center, n.d.). See Box 28-1 for an overview of safety precautions to reduce the risk of patient suicide in inpatient settings.

» Stay Current: To download a copy of the C-SSRS and for more information, go to <http://cssrs.columbia.edu>

Another valuable tool for evaluating suicidality is the Suicide Assessment Five-Step Evaluation and Triage (SAFE-T). This assessment helps the nurse both determine the patient's risk level and select appropriate care interventions. The five steps involved in SAFE-T assessment are as follows:

1. Assess the patient's risk factors.
2. Assess the patient's protective factors.
3. Directly ask the patient about intent to commit suicide. This means the nurse should pose specific questions regarding the patient's thoughts, plans, behaviors, and intent.
4. Determine the patient's risk level and intervention. This determination should be based on the nurse's clinical judgment after completion of steps 1–3. Use of C-SSRS can also be helpful. Ultimately, the nurse should assign a risk level of low, moderate, or high.
5. Document the patient's risk level and treatment plan, along with the rationales for both.

Low-risk patients can be treated in an outpatient setting, while high-risk patients require immediate hospitalization and support. Following evaluation, individuals with a moderate level of risk can usually be treated in an outpatient setting or with partial hospitalization, but only if they can elaborate a plan for seeking immediate help should their desire to commit suicide increase. Note that the SAFE-T assessment should be conducted upon first contact with the patient and in subsequent contacts as appropriate, but particularly with any additional suicidal behaviors, increase in suicidal ideation, or pertinent clinical change. In addition, patients in inpatient settings should be assessed before increasing unit privileges and at discharge (SAMHSA, n.d.; Potter & Moller, 2016).

Diagnosis

The diagnoses for patients who demonstrate suicidal behavior or ideation or who have attempted suicide will change

greatly depending on the assessment. Nurses recognize that each patient is an individual case. Some nursing diagnoses for patients are as follows:

- *Suicide, Risk for*
- *Self-Directed Violence, Risk for*
- *Vascular Trauma, Risk for*
- *Knowledge Deficit*
- *Hopelessness*
- *Powerlessness*
- *Self-Esteem: Situational Low or Chronic Low.*

(NANDA-I © 2014)

Planning

Involving the patient in the planning process can be beneficial depending on the individual's current emotional outlook. Empowering the patient to take control of the goals of his care can be a small step in working toward those goals. Some potential goals are:

- The patient will remain free from injury.
- The patient will ask for help when needed.
- The patient will discuss any extreme feelings of depression or hopelessness.
- The patient will participate in regularly scheduled meetings with his therapist.
- The patient will demonstrate healthy coping mechanisms.
- The patient will begin to demonstrate a desire to live.

Implementation

The majority of suicidal individuals are also depressed. Nurses will need to develop a therapeutic rapport with the patient, which will assist with adherence to the treatment plan. Prioritization of interventions is extremely critical, given the potentially lethal nature of the patient's condition. This means the nurse's first actions should focus on reducing the patient's risk for self-directed violence. After that, other interventions may be carried out as appropriate. These include encouraging patients to verbalize emotions and concerns; encouraging patients to attending individual, family, and group therapy sessions as scheduled; teaching effective coping skills; and teaching patients how to seek help when needed. Some agencies use no-harm contracts as an intervention (see **Box 28-5** »).

Many patients at risk for suicide lack help-seeking behaviors, and feelings of hopelessness can skew perceptions and prevent patients from asking for help. Nurses can help patients identify sources for help and support and then provide opportunities for practice through role playing with the nurse, peers, or family members.

Promote Immediate Safety

- Ensure that patients who are actively experiencing suicidal ideation do not have access to any sharp objects, weapons, or modes that could be used to harm themselves.
- Ensure that the patient at high risk for suicide is never left alone. A nurse, healthcare professional, or other health-

Box 28–5

No-Harm Contracts and Safety Plans

Some agencies employ the use of no-harm contracts (sometimes referred to as behavioral contracts or individualized safety plans) to assist patients in identifying options other than self-harm when they experience feelings of suicide. Although there is a lack of evidence to support the use of no-harm contracts (APA, 2010), practice guidelines and competencies developed by The Joint Commission (2007), the American Psychiatric Nurses' Association (2015), and the U.S. Veterans' Administration (2013) include the development of individualized safety plans in collaboration with the patient. Individualized safety plans may help nurses and other clinicians to empower the patient, manage the suicidal crisis, strengthen the therapeutic alliance, provide an opportunity to educate the patient about warning signs and review coping strategies, and provide options for help and support (U.S. Veterans Administration, 2013; The Joint Commission, 2007). It is important for nurses and other providers to recognize that no-harm contracts and safety plans may be useful in these areas, but may not in and of themselves reduce a patient's risk for suicide. There is no guarantee that a patient who enters into a no-harm agreement will not attempt suicide. Further, no-harm contracts or safety plans should be used alongside, and not be substituted for, other essential nursing and clinical interventions.

care worker should be with the patient at all times until the risk for suicide decreases.

- Within the healthcare setting, instruct guests as to what objects they cannot have while visiting the patient, including knives, razor blades, and large quantities of pills.
- In homes, outpatient, or community settings, if a patient expresses that she is considering suicide, alert the appropriate people per agency protocols and applicable state laws: that can be the patient's family, the patient's primary healthcare provider, or a mental health service provider.

Increase Patient Knowledge

- Provide patient and family teaching about symptoms of depression, including feelings of helplessness, worthlessness, and lack of energy. Reassure patients that it takes time for feelings associated with depression to dissipate.
- Provide education to patients who have other comorbid disorders, especially bipolar disorder and schizophrenia.
- Provide medication education, including how the medication works; its intended purpose; how long it may take to experience the full, intended effect; and potential side effects.
- Education of family members and concerned individuals should include the telephone numbers of the National Suicide Prevention Lifeline: 1-800-273-TALK (8255),

1-800-799-4TTY (4889). Links to state websites can be found through the Suicide Prevention Resource Center (SPRC) at <http://www.sprc.org>.

SAFETY ALERT An individual who is contemplating suicide will generally not ask for help in obvious ways. However, the person's behavior will include clues associated with suicide, such as talking about wanting to die, giving away prized possessions, or saying that he will not be around much longer. These warning signs are the patient's way of asking for help, and nurses should be able to recognize them and respond effectively.

Assess and Monitor for Self-Injury Behaviors

Patients may present with **non-suicidal self-injury behaviors (NSSI)**. These are intentional self-inflicted acts of harm to body tissue without the intent of suicide. Self-mutilation and self-injury are used synonymously; however, currently, the preferred term is self-injury or NSSI (Kara et al., 2015). NSSI generally occurs during periods of painful moods, including guilt, sorrow, flashbacks, and depersonalization to physical pain. Additional reasons attributed to NSSI include self-punishment, attention seeking, imposing guilt, and adaptation to peers who also participate in NSSI (Kara et al., 2015). Patients demonstrating NSSI will need to be monitored closely and may be asked to sign a no-harm contract. Examples of NSSI include cutting, bruising, burning of the skin, trichotillomania, interfering with wound healing, and extreme nail biting (Emelianchik-Key, Byrd, & La Guardia, 2016).

Evaluation

The outcomes for patients demonstrating suicidal behavior can be varied. If the patient is responsive to treatment, then the outcome has a chance of being favorable. Some potential outcomes for the patient who is receiving treatment for suicidal ideation or attempted suicide include the following:

- The patient remains free from injury.
- The patient verbalizes emotions and concerns.
- The patient participates in all scheduled meetings with therapists and counselors.
- The patient demonstrates effective coping skills.
- The patient seeks help when needed.

If the patient remains actively suicidal, extreme caution must be taken, including the aforementioned steps to prevent self-directed violence.

Although many interventions can be employed when a patient demonstrates an unwillingness to live, none of these will prove successful if the individual does not have the desire to help himself. If a patient dies while in a nurse's care and there is an emotional or guilt response, then the nurse should find someone with whom to discuss her feelings in regard to this event. Other nurses, physicians, therapists, or counselors are good sources of support for nurses who have lost a patient.

Nursing Care Plan

A Patient Who Is Suicidal

Brandon Lewis, age 45, is admitted to the behavioral health unit after having threatened to attempt suicide. He was severely intoxicated at the time of his admission. Mr. Lewis is withdrawn and hesitant to speak to anyone who approaches him.

Mr. Lewis is withdrawn and hesitant to speak to anyone who approaches him.

ASSESSMENT	DIAGNOSIS	PLANNING
<p>Danielle Serrano, an RN in the psychiatric department, enters Mr. Lewis's room to obtain a health history and suicide risk assessment. A nursing assistant is sitting in the room with Mr. Lewis. The hospital initiated suicide precautions when Mr. Lewis arrived, because his daughter reported that she had walked in on him trying to kill himself.</p> <p>Mr. Lewis does not readily respond to the nurse's questions, so Ms. Serrano waits and begins talking to the patient about mundane topics such as the weather, a documentary she saw on television the evening before, and the lunch menu at the hospital for today. Eventually Ms. Serrano notices that Mr. Lewis seems to be more relaxed, so she asks him again if he would like to talk about what happened. When he does not reply, Ms. Serrano calmly explains that the patient's daughter told the nurse she found him with a large knife and a bottle of painkillers, and then called 911. Mr. Lewis asks if his daughter is still at the hospital, and the nurse responds that she will be back this evening.</p> <p>The patient begins to explain that his wife left him 2 months ago, and then shortly after that he lost his job. Mr. Lewis has been drinking heavily for the past month. The night of his suicide attempt, he wanted all of the pain to stop, so he tried to kill himself. Mr. Lewis's daughter walked in and got the knife away from him, then called for help. The patient claims that he probably would not have tried to kill himself if he had not been intoxicated. Mr. Lewis has no previous history of suicide, depression, or any other comorbid disorders. Mr. Lewis denies any current thoughts of or intent to kill himself.</p>	<ul style="list-style-type: none"> ■ <i>Suicide, Risk for</i> ■ <i>Self-Directed Violence, Risk for</i> ■ <i>Hopelessness</i> <p>(NANDA-I © 2014)</p>	<p>Identified outcomes for Mr. Lewis include:</p> <ul style="list-style-type: none"> ■ The patient will remain free from injury. ■ The patient will discuss emotions and concerns. ■ The patient will ask for help. ■ The patient will demonstrate healthy coping mechanisms. ■ The patient will participate in treatment for alcohol dependence.

IMPLEMENTATION
<ul style="list-style-type: none"> ■ Assist Mr. Lewis to decrease or eliminate self-abusive behaviors. ■ Facilitate development of a positive outlook for the future. ■ Provide for safety, stabilization, recovery, and maintenance until Mr. Lewis's depression improves. ■ Administer antidepressants as ordered. ■ Teach visitors about restricted items (razors, scissors, and so forth). ■ Involve family, as patient allows, in discharge planning. Encourage creation of a family safety plan. ■ Educate patient and family about signs of increased suicidality, as well as available resources (e.g., suicide prevention hotlines, emergency psychiatric care).

EVALUATION
<p>Mr. Lewis agrees that he needs help to abstain from alcohol and agrees to be admitted to an alcohol rehabilitation facility. He says he probably would never have tried to harm himself if he had not been drinking, but agrees counseling is required and talks with a psychologist.</p>

CRITICAL THINKING
<ol style="list-style-type: none"> 1. If you are the nurse caring for Mr. Lewis on the behavioral health unit, what actions will you take to keep the patient safe? 2. Will you notify Mr. Lewis's wife of his admission? Explain your answer. 3. What strategies would you promote to Mr. Lewis to reduce hopelessness and have hope for the future?

REVIEW Suicide

RELATE Link the Concepts and Exemplars

Linking the exemplar of suicide with the concept of health, wellness, illness and injury:

1. Explain the relationship between suicide and disrupted sleep pattern.
2. Explain the relationship between suicide and terminal illness.

Linking the exemplar of suicide with the concept of comfort:

3. Explain why the patient with chronic pain should be assessed for risk of suicide.
4. How will you assess the patient living with chronic pain for suicide risk?

REFLECT Apply Your Knowledge

Jenny Vasquez, age 14, presents to the emergency department after having consumed a box of diphenhydramine (Benadryl) tablets. Her left wrist has also been cut horizontally; the amount of blood loss is unknown. Upon ED arrival, Jenny is lethargic. A security guard is present in the examination room. The physician begins to perform a physical assessment on Jenny.

Jenny's vital signs include temperature 96.2°F tympanic; pulse 118 bpm; and BP 152/96 mmHg. Respirations are 14 per minute, and Jenny does not appear to be in any acute respiratory distress. The ED physician quickly assesses Jenny's left wrist wound; there is no active bleeding and the wound is superficial with no deep tissue damage. A dressing is applied to the wound. Gastric lavage is performed immediately to remove the drugs from Jenny's stomach. Afterward, her wrist laceration is cleaned and sutured, and a sterile dressing is applied to the site.

Upon reassessment of Jenny, she speaks quietly and makes eye contact with the nurse. She explains that the teenagers at her school have been bullying her for the past year. Jenny is unsure about her sexual orientation, but was caught kissing another girl at the winter formal last year. Ever since then, she has been ostracized and teased constantly at school. The day of the suicide attempt, she arrived at her locker to find that someone had spray painted the words "queer," "freak," and "spic" in red paint. Seeing no other way to stop the abuse, Jenny tried to kill herself.

1. Based on the information provided about Jenny's situation, do you believe she is at especially high risk for attempting suicide again? Please explain your answer.
2. Do you believe that Jenny was actually trying to kill herself, or was this incident more of a "cry for help"? Justify your answer with evidence from the case study.
3. Identify three nursing diagnoses that are appropriate for inclusion in Jenny's plan of care.

Module 29

Self

Module Outline and Learning Outcomes

The Concept of Self

Normal Presentation

29.1 Analyze the psychosocial processes related to self-concept.

Psychosocial Development Across the Lifespan

29.2 Differentiate considerations related to the development of self across the lifespan.

Alterations from Normal

29.3 Differentiate alterations in self-concept.

Concepts Related to Self

29.4 Outline the relationship between self-concept and other concepts.

Health Promotion

29.5 Explain the promotion of healthy self-concept.

Nursing Assessment

29.6 Differentiate common assessment procedures used to examine the individual's self-concept.

Independent Interventions

29.7 Analyze independent interventions nurses can implement for patients with alterations in self-concept.

Collaborative Therapies

29.8 Summarize collaborative therapies used by interprofessional teams for patients with alterations in self-concept.

Self Exemplars

Exemplar 29.A Feeding and Eating Disorders

29.A Analyze feeding and eating disorders and how they relate to self.

Exemplar 29.B Personality Disorders

29.B Analyze personality disorders and how they relate to self.

>> The Concept of Self

Concept Key Terms

Body image, 1976		Personality disorder (PD), 1980	Purging, 1981	Role performance, 1977
Bulimia nervosa (BN), 1980	Global self-esteem, 1978	Prader-Willi syndrome (PWS), 1980	Real self, 1976	Role strain, 1977
Erik Erikson, 1978	Ideal body image, 1977	Psychoanalytic theory, 1978	Role, 1977	Self-awareness, 1978
Feeding and eating disorders, 1980	Ideal self, 1976		Role ambiguity, 1977	Self-concept, 1976
	Introspection, 1978		Role conflicts, 1977	Self-esteem, 1978
			Role development, 1977	Specific self-esteem, 1978

At the simplest level, caring for patients requires the nurse to be physically present in the care setting. Physical presence in the workplace requires adhering to a work schedule and honoring a commitment to an employer and to patients. However, the energy needed to maintain employment and to care for others requires that the nurse obtain adequate nutrition and rest. Likewise, the knowledge needed to apply the nursing process first requires education in the field of nursing.

On a deeper level, to assess and care for patients from a holistic perspective and to establish therapeutic relationships, the nurse must draw from psychosocial resources that include caring, empathy, and compassion, psychosocial resources whose attainment is far more personal than the attainment or use of time, energy, or knowledge. Nurses recognize that caring for others is not one dimensional in nature; that is, caring for a patient extends beyond the treatment of injury or illness. For example, treatment of a

pediatric patient who has sustained a forehead laceration incorporates far more than ensuring physiologic stability and providing wound care. Along with these priority concerns, other facets of nursing care include addressing the wounded child's pain, anxiety, and fear, as well as recognizing and addressing the concerns of the injured child's family or loved ones. Just as patients are not one-dimensional beings, neither are nurses. Needs of nurses also extend beyond the physiologic domain.

To promote health and wellness in others, nurses must first recognize and understand their own thoughts, emotions, perceptions, abilities, and limitations. Recognition of one's own needs requires an understanding of the concept of self. *Self* can be described as the entirety of an individual's being, including body, sensations, emotions, and thoughts, as well as a conscious awareness of one's own being. Within the self are all personal traits, characteristics, beliefs, and behaviors. Accurate assessment of a patient's degree of psychosocial health requires that the nurse be capable of recognizing signs and symptoms of impairments and alterations. In addition, the nurse must be able to identify evidence-based interventions that are effective in the promotion of psychosocial well-being.

Both personally and professionally, wellness promotion requires the nurse to understand and apply principles related to the concept of self, which includes an individual's overall self-image and self-perception. This module explores the concept of self, as well as its various components.

Normal Presentation

Physiologic alterations often produce visible findings or manifestations that can be discerned through laboratory and diagnostic tests. The use of established parameters or guidelines can simplify the process of identifying abnormal findings.

In contrast, identification of abnormal psychosocial function requires a different approach. Rather than following objective algorithms and guidelines, normal parameters within the psychosocial realm often range along a continuum. Moreover, to identify what is normal or abnormal, the nurse must assess the degree to which the psychosocial concern is affecting the patient. *Normal* is more easily defined within the physiologic realm, whereas *healthy* is the term that more readily applies to the psychosocial realm.

Development of self is a dynamic process that is influenced by interpersonal interactions throughout an individual's lifetime. Numerous theorists, including famed psychologists Erik Erikson and Jean Piaget, proposed theories to describe the processes of human growth and development, including specific stages and tasks associated with each phase of life. From a broad standpoint, principles of growth and development apply to mastery of numerous tasks, as well as to achievement of milestones related to physiologic, cognitive, psychosocial, spiritual, and moral development. For many developmental tasks throughout the lifespan, successful task completion is rooted in interpersonal interaction.

Although this module offers an overview of the development of self, the primary focus includes exploring and describing the impact of self on patient health, as well as its

importance to nursing care. (For in-depth discussion of theories related to psychosocial development, see the module on Development.)

Self-concept

Self-concept, which is integral to psychosocial development, is the personal perception of self that forms in response to interactions with others and the environment throughout the course of an individual's lifetime. Self-concept affects an individual mentally, physically, and spiritually. A negative self-concept can lead to struggles with adapting to change and building interpersonal relationships. In addition, a negative self-concept can increase an individual's susceptibility to physical and psychologic illnesses. Within the psychosocial domain, effective nursing care includes assessing patients' self-concept and assisting them with the development of a healthy, positive self-perception (Berman, Snyder, & Frandsen, 2016). Because each individual's self-concept impacts the nature and efficacy of her interpersonal interactions, including nurse-patient relationships, the nurse is responsible for exploring and optimizing her own self-concept. In nursing, components of self-concept are often considered to include personal identity, body image, role performance, self-esteem, and self-awareness, each of which will be discussed.

Personal Identity

Personal identity can be evaluated from the standpoint of three aspects of self: the ideal self, the real self, and the public self. The **ideal self** reflects qualities an individual believes he should possess, as well as those he aspires to develop. The **real self** represents the perceived true self (Ciccarelli & White, 2013). The real self may include observations about self or self-perceived qualities that the individual hides from others or does not readily share. For example, the real self may house perceptions such as "I am greedy" or "I am judgmental." The **public self** is formed on the basis of how the individual wishes to be perceived by others. For example, in the workplace, an individual's public self may lead to behaviors that inspire others to deem him as being friendly, competent, and team-oriented. While the ideal self reflects "who I should be and who I want to be," the real self represents "who I really am." The public self reflects "who I believe others think I am."

Characteristics that make up personal identity include objective descriptors, such as name, age, gender, marital status, and occupation. In addition, personal identity can include an individual's cultural background and ethnic origin. Values, beliefs, and self-expectations also shape personal identity. When an individual chooses values that he believes to be important and acts accordingly, his personal identity becomes stronger. This has a direct impact on nursing care, as congruence of the nurse's behavior with his own personal character and values impacts the extent to which patients and coworkers find him to be trustworthy (Riffkin, 2015).

Body Image

Body image is an individual's mental picture of her physical self. How an individual perceives the appearance and size of her body and emotional reaction to those perceptions are

TABLE 29–1 Elements of Body Image

Element	Description
Perceptual	Mental image of the body; includes perception of physical appearance and how one perceives his or her body when viewing it in a mirror.
Cognitive	Includes beliefs and attitudes about one's body, as well as the degree to which body image is valued and the individual's level of investment in physical appearance.
Behavioral	Encompasses behavioral manifestations that may reveal cues about an individual's feelings and perceptions about his or her body; for example, indicators may include wearing revealing clothing and engaging in activities that require physical exposure (e.g., wearing a swimsuit to the swimming pool).
Affective	Represents feelings about one's body, in terms of both appearance and function. May be negative (e.g., shame or embarrassment) or positive (e.g., pride or satisfaction).
Subjective satisfaction	Reflects an individual's degree of satisfaction with his or her body, both as a whole and in terms of individual parts or regions.

components of body image. However, the impact of an individual's body image extends far beyond these two components. Elements of body image include those within the perceptual, cognitive, behavioral, affective, and subjective satisfaction dimensions (see **Table 29–1** ») (Ginis, Bassett-Gunter, & Conlin, 2012). Body image takes into account prosthetic devices, including hairpieces and artificial limbs, as well as assistive devices, such as wheelchairs, walkers, eyeglasses, and hearing aids (see **Figure 29–1** »). The individual's perception of her need to use assistive devices is also part of body image.

Culture and society significantly impact body image, including the **ideal body image**, which is a mental representation of what an individual believes her body should look like. In particular, visual media—such as movies and magazine images—are viewed by some as promoting an unrealistic

Source: Mezzotint_fotolia/Fotolia.

Figure 29–1 » Body image is the sum of a person's conscious and unconscious attitudes about his or her body. How do you think the runner pictured here views his body image?

ideal body image. For example, in the United States, the modeling and advertising industries often feature women who are extremely thin, which is an issue that has sparked cultural debate with regard to the effects of this practice on the development of ideal body image among young females. Typically, the more congruent an individual's perceived body image is with her ideal body image, the greater her level of satisfaction with body image will be.

Role Performance

A nursing student is also a son or daughter, perhaps a brother or sister, and may be a father or mother as well. Each of these positions or roles—student, offspring, sibling, and parent—is associated with certain behavioral expectations.

A **role** encompasses a grouping of behavioral expectations associated with a specified societal or organizational position. Role expectations may be defined by numerous entities, including society, culture, religion, tribal leadership, an employer, or any organization of which the individual is a member. The demonstration of behaviors or actions associated with a given role is called **role performance**.

Teaching and modeling the behaviors needed to successfully assume a role are part of **role development**, which is essential for effective role performance. Role development also includes socialization of the individual who is preparing to assume a given role. For example, a graduate nurse who accepts a position in a medical–surgical hospital unit will most often complete an orientation program, which includes exposure of the newly employed nurse to basic aspects related to working in that clinical setting, such as institutional protocols and charting requirements. After orientation, the nurse usually will be assigned a preceptor who models expected nursing behaviors and assists the nurse with continued role development.

Ineffective role development can lead to **role ambiguity**, which occurs when an individual lacks clarity regarding the expectations, behaviors, or demands associated with fulfilling a given role. Individuals who feel incapable of fulfilling a role may experience **role strain**. In some cases, role strain may be the result of sexual stereotyping. For example, a female firefighter who is told or given the impression by male colleagues that she is physically incapable of handling the rigorous demands associated with a male-dominated occupation may experience role strain. Both role ambiguity and role strain can negatively impact self-concept.

When role-related expectations clash or are incongruent, **role conflicts** may occur. If needs for recognition, accomplishment, and independence are not met, the role conflict can produce embarrassment, increased stress, and decreased self-esteem (Berman et al., 2016). Conflicts may occur between one or more individuals (interpersonal) or within one individual (intrapersonal), as well as between groups and organizations. Forms of role conflict include the following:

- **Interpersonal conflict.** Occurs when individuals hold varying or conflicting expectations about tasks and behaviors associated with a specific role; for example, a husband and wife may have conflicting expectations about who is responsible for completing household chores and preparing meals.

- **Interrole conflict.** Occurs when roles create competing demands; for example, in the case of an individual who is balancing college courses with parenting, the demands associated with being a student may impinge on the demands of raising a child.
- **Person–role conflict.** Occurs when role expectations are in opposition to the values and beliefs of the one who fills the role; for example, despite the Western healthcare practice of promoting truth telling and autonomy, in some instances a family may ask that their family member not be informed that he has been diagnosed with a terminal illness (Coolen, 2012).

Role mastery occurs when an individual's behaviors within a role meet or exceed predetermined expectations. The inability to achieve role mastery can lead to stress, internal conflict, and impaired self-esteem (Berman et al., 2016).

Self-Esteem

Self-esteem, which is separate from self-concept, is an individual's opinion of himself. In essence, self-esteem describes the degree to which an individual approves of, values, or likes himself (Blascovich & Tomaka, 1991; Brown, 2014).

While self-concept reflects how an individual perceives himself, self-esteem, which is the evaluative component of self-concept (Berk, 2013), describes the individual's judgments and opinions about those perceived characteristics. Positive or high self-esteem is associated with greater levels of achievement, increased financial prosperity, and decreased incidence of depression (Orth & Robins, 2014).

Researchers have proposed two categories of self-esteem: global and specific. **Global self-esteem**, or the **global evaluative dimension of the self**, is the degree to which an individual likes herself overall, as a whole being. **Specific self-esteem**, however, reflects an individual's positive regard for certain aspects of herself (Brown, 2014; Gentile et al., 2009), such as physical appearance, athletic ability, parenting skills, or academic achievement.

Specific self-esteem influences global self-esteem (Berman et al., 2016). For example, if an individual who highly values athletic ability possesses exceptional athletic skills, that individual's athletic performance will impact his global self-esteem. However, if that same individual assigns little value to academic achievement, his global self-esteem will be minimally influenced by failing a college course.

In their landmark study, DeHart, Pelham, and Tennen (2006) identified early parent–child interactions as significantly influencing the development of self-esteem. Young adult children who reported exposure to greater levels of parental nurturing also reported higher self-esteem, while parental overprotectiveness was linked to lower self-esteem (DeHart et al., 2006). In addition, both behavioral and neural studies (using MRI scanning) have identified a link between an individual's perceived experience of rejection and the expression of a sense of low self-esteem (Kashdan et al., 2014; Leary, 2006). In studies of individuals between the ages of 14 and 30, high risk-taking behaviors, low sense of mastery, and poor health status effectively predicted lower levels of self-esteem. In older adults, self-esteem was higher among individuals who had completed more education (Orth & Robins, 2014).

Self-Awareness

For an individual to develop a reality-based perception of his real self requires **self-awareness**. Development of self-awareness begins in infancy, as infants learn to distinguish themselves from other individuals and objects in their environment. With the ability to differentiate his own voice and body from the voices and bodies of others, the infant's self-awareness increases (Berk, 2013). Developing self-awareness is an ongoing process that requires intense examination of one's personal perspectives, beliefs, and values. Moreover, self-awareness includes identifying relationships that connect actions to self. By establishing connections between past experiences and current actions or choices, the individual who is self-aware gains insight into the meaning of his behaviors. As opposed to viewing life experiences as being isolated events, many of which are perhaps inexplicable, development of self-awareness requires that actions and behaviors are viewed within the context of the individual's deep-seated values and beliefs (Demetriou & Kazi, 2013; Eckroth-Bucher, 2010). Essentially, the individual who is self-aware understands why he does what he does, and his behaviors and actions can be linked to his core beliefs and values.

The process of developing self-awareness requires **introspection**, which is personal exploration and evaluation of one's own thoughts, emotions, behaviors, and values. Introspection also incorporates both verbal and nonverbal feedback from others (Demetriou & Kazi, 2013; Eckroth-Bucher, 2010). While the process of introspection is intimate and personal in nature, the outcome of this process is greatly influenced by a number of external factors. In many ways, an individual's view of himself is significantly shaped by how others perceive him.

Development of Personality

Numerous behavioral theorists and scientists have proposed theories to describe the development of personality as a component of self. Among the most famous developmental theories are those originated by Sigmund Freud and Erik Erikson. Freud (1856–1939) is considered the founder of **psychoanalytic theory**, which provided the earliest framework for personality development and emphasized the presence of unconscious impulses and their influence on behaviors and the formation of self. Whereas Freud's theory is grounded in psychosexual elements and the human response to impulses, Erikson's theory incorporates social, cultural, and interpersonal components (Kneisl & Trigoboff, 2013).

The theory of psychosocial development originated by German-born psychologist and psychoanalyst **Erik Erikson** (1902–1994) is still widely taught today. Erikson (1950, 1963) developed the primary theory on psychosocial development in humans. His ideas were greatly influenced by Freud's theory regarding the structure and topography of personality (McLeod, 2013). Whereas Freud concentrated on internal conflicts, Erikson emphasized the role of culture and society and the conflicts that can influence personality. According to Erikson, the self develops as it successfully resolves crises that are distinctly social in nature. Three overriding themes in Erikson's theory are establishing trust in others, developing a sense of identity in society, and

helping the next generation prepare for the future. Erikson extended Freudian theory by focusing on the adaptive and creative characteristics of the self and by expanding the notion of the stages of personality development to include the entire lifespan (McLeod, 2013). For more discussion of Erikson's developmental theory, see Table 25-2 in the module on Development.

Psychosocial Development Across the Lifespan

Early childhood experiences and brain circuitry development influence the child's developing central nervous system and have been linked to both risk and resiliency for psychopathology in adulthood (Potter & Moller, 2016). Environmental factors, such as toxins, early childhood maltreatment, diet, and stress can change gene activity and increase the risk for developing psychopathology later in life. Because approximately 75% of adult psychiatric disorders have their onset in childhood and adolescence, mental health promotion interventions that target these factors can change the course of development for children at risk for psychiatric disorders and alter the course of development along the psychologic, biological, sociologic, cultural, and spiritual domains (Potter & Moller, 2016). For example, interventions that promote healthy nutrition in pregnant women and in young children can reduce the risk for disorders or dysfunction in multiple areas of growth and development.

An important influence on psychosocial development is the occurrence of trauma at any life stage. The frequency and number of abusive and traumatic events, referred to as *complex trauma*, influence the severity of psychologic distress and can hinder development. Emotional experiences of trauma can be particularly overwhelming for children, especially if the home environment is the source of maltreatment (Potter & Moller, 2016). Interpersonal violence (IPV) is the primary source of trauma in adult women. Trauma can affect people of every race, ethnicity, age, sexual orientation, gender, psychosocial background, and geographic region (Substance Abuse and Mental Health Services Administration [SAMHSA], 2014).

Other key considerations at each developmental stage are discussed below.

Newborns and Infants (Birth to 1 Year)

During the first year of life, infants are uncertain about their environment and look to the primary caregiver for stability and consistency of care as they adjust to life outside the womb. If infants receive consistent, predictable, and reliable care, they will develop a sense of trust, which they will expect to occur in other relationships (McLeod, 2013). They will feel secure even in threatening situations and develop a sense of hope that other people will provide support.

Infants who do not feel secure will become fearful when dealing with new people and situations. They may mistrust others and lack confidence in the world around them or in their abilities to influence events. Lack of trust may result in anxiety, heightened insecurities, and a pervasive feeling of uneasiness (McLeod, 2013). Three influential theorists were Erikson (discussed below), who advanced strong views on

the importance of trust for infants, and Bowlby (1969) and Ainsworth (1973), both of whom outlined how the quality of the early experience of attachment can affect relationships with others in later life (McLeod, 2013).

Toddlers (1 to 3 Years)

During this period, children are developing physically and becoming more mobile. Children will begin to assert their independence, develop skills, and engage in activities that promote growing independence and autonomy. Parents need to allow toddlers active exploration within an encouraging environment that is tolerant of failure, such as allowing children to don their own clothes without interference unless assistance is requested. The primary parental task at this stage is to foster independence while avoiding criticism of failures. By bolstering toddlers' self-esteem, parents will help children be supported in acquiring increased independence, thus becoming more confident and secure in their own ability to navigate in the world (McLeod, 2013).

Preschool Children (3 to 6 Years)

Around age 3 and continuing to age 5, children begin to assert themselves more frequently. They begin regularly interacting with other children and playing, which provides children with the opportunity to explore their interpersonal skills through initiating activities (McLeod, 2013). Children begin to plan activities, create games, and initiate activities with others, which help them begin to develop a sense of initiative and feel secure in their abilities to lead others and make decisions. However, if during this period children are overcontrolled or over-criticized, they may develop a sense of guilt and lack self-initiative (McLeod, 2013).

Children also begin to ask many questions to grow their knowledge base. If parents do not allow children to question and treat them as a nuisance, children may develop a sense of guilt that will influence interpersonal interactions and inhibit creativity. The parental balance at this point is to impose enough restriction on children that they begin to develop a conscience and self-control (McLeod, 2013).

School-Age Children (6 to 12 Years)

At age 6 to 12 years, the primary tasks of children are learning to read and write, to do math, and to perform activities on their own. Teachers begin to take an important role as they teach the specific skills (McLeod, 2013). At this stage, the child's peer group will gain greater significance and will become a major source of the child's self-esteem. The child now feels compelled to win approval by demonstrating specific competencies that are valued by society and begins to develop a sense of pride in acquired accomplishments (McLeod, 2013). Children age 5 to 9 exhibit increased control of emotions, form peer groups, and begin to understand how their actions affect others (Mental Health America [MHA], 2015).

Preteen adolescents of age 10 to 12 years commonly have emotional swings (feeling wonderful one minute, and sad or irritable the next). They begin to believe peer acceptance means being liked. They still rely on bonds with their parents but may not demonstrate closeness. They question rules and values, often saying things are "unfair." They may begin

to focus more on their looks and dress (MHA, 2015). For pre-teens, it is important for parents and teachers to support their interests and their desire to acquire abilities and achieve goals. If this initiative is not encouraged or if it is restricted by parents or teacher, then the preteen begins to feel inferior, doubting his or her own abilities, and therefore may not reach full potential.

Adolescents (12 to 18 Years)

The major task of this life stage is to learn the roles required to become an adult. During this stage, the adolescent will reexamine personal identity, including sexual orientation and occupational roles (McLeod, 2013). Adolescents explore possibilities and begin to form their own identities based on the outcome of their explorations. Failure to establish a sense of identity within society can lead to role confusion, where the adolescent is uncertain regarding his or her place in society. In response to role confusion or identity crisis, an adolescent may begin to experiment with different lifestyles in such areas as work, education, drugs/alcohol, or political views (McLeod, 2013). Adolescents who are pressured into an identity have the potential to become unhappy and often rebel by establishing a negative identity.

Adolescents struggle with their sense of identity, worrying about being normal or “fitting in.” They feel awkward about themselves and their body image and maintain high expectations for themselves. Although adolescents still rely on connectedness with their parents, they may complain that their parents interfere with their independence or behave rudely to their parents in front of others. Young teens begin testing rules and limits. As they develop more friendships with peers of both genders, they try to find a group of peers with whom they fit in and are accepted. Exposure to sex and drugs increases in adolescence. Moodiness is common, and young teens may return to childish behaviors when stressed. Intellectual efforts become more important (MHA, 2015).

Adults

In young adulthood (age 18 to 40 years), adults begin to share themselves more intimately with others, exploring relationships that lead toward longer term commitments with someone other than a family member. Successful completion of this stage can lead to comfortable relationships and a sense of commitment, safety, and care within a relationship (McLeod, 2013). Avoidance of intimacy and fear of commitment and relationships can lead to isolation, loneliness, and sometimes depression.

Researchers Erol and Orth (2011) studied levels of self-esteem in males and females between the ages of 14 and 30. Overall findings suggested that self-esteem increases during adolescence and, to a lesser degree, into young adulthood. Regardless of age, participants who were extraverted, emotionally stable, and conscientious reported higher self-esteem than did those participants who were deemed introverted, emotionally unstable, and less conscientious. In addition, among all ages studied, low risk-taking behaviors, high sense of mastery, and better health status reliably predicted higher levels of self-esteem.

During middle adulthood (age 40 to 65 years), adults establish careers, settle down within relationships, begin their own families, and develop a sense of being a part of the

bigger picture. Adults give back to society through raising children, being productive at work, and becoming involved in community activities and organizations (McLeod, 2013). If adults fail to achieve these objectives, they become stagnant and feel unproductive.

As adults grow older (age 65+ years) and become senior citizens, they tend to slow down productivity and explore retirement options. If older adults see their lives as unproductive, feel guilty about the past, or perceive that they did not accomplish their life goals, they may become dissatisfied with life and develop despair, often leading to depression and hopelessness (McLeod, 2013).

In 2010, Orth, Trzesniewski, and Robins published findings of a study designed to evaluate the development of self-esteem between young adulthood and old age. Participants ranged in age from 25 to 104 years. Study findings included an apparent increase in self-esteem during young and middle adulthood, with self-esteem levels ultimately peaking around 60 years of age. After age 60, self-esteem declined. Higher self-esteem was reported by participants who had completed more education. Overall, results suggested that the declining self-esteem reported by older adults was primarily caused by changes in physical health and socioeconomic status (Orth et al., 2010).

Alterations from Normal

Alterations in self may stem from a variety of factors, including issues pertaining to the primary components of self-concept, self-esteem, and self-awareness. Within the component of self-concept, some researchers suggest that conflicts related to body image may lead to the development of feeding and eating disorders. Alterations in one or more components of self may manifest through the development of personality disorders.

Alterations and Manifestations

Feeding and Eating Disorders

Feeding and eating disorders are marked by chronic disturbances in eating or eating-related practices that result in impairment in food consumption or absorption to the extent that daily functioning is affected and physical and psychologic health are significantly impaired (American Psychiatric Association [APA], 2013). Feeding and eating disorders cause low self-esteem, self-hatred, fear, and hopelessness, and they put the individual at risk for a variety of physiologic problems. Affected individuals often also have other mental disorders such as anxiety disorders, substance abuse, or depression (National Institute of Mental Health [NIMH], 2014). Feeding and eating disorders can be fatal. Nurses should not underestimate the significance of these disorders.

The most common feeding and eating disorders include **anorexia nervosa**, **bulimia nervosa**, and binge-eating disorder, each of which is discussed in detail in the exemplar later in this module. The characteristic features of these three disorders are presented in **Table 29-2** ». Other disorders that may impact body image include nocturnal sleep-related eating disorder and Prader-Willi syndrome. Additional disorders often clustered with the more prevalent feeding and eating disorders include pica, rumination disorder, and avoidant/restrictive food intake disorder.

TABLE 29–2 Characteristic Manifestations of Common Feeding and Eating Disorders

Eating Disorder	Characteristics
Anorexia Nervosa (AN)	<ul style="list-style-type: none"> ■ Obsessive focus on weight and body size ■ Abnormally low body weight (usually 85% or less of the normal/expected weight) ■ Extreme fear of weight gain ■ May include purging behaviors (e.g., vomiting, diuretic use, laxative abuse) ■ Average age of onset 19 years
Bulimia Nervosa (BN)	<ul style="list-style-type: none"> ■ Obsessive focus on weight and body size ■ Classified by presence or absence of purging behaviors ■ Purging type: includes episodes of binge eating followed by purging through self-induced vomiting or use of diuretics or laxatives ■ Nonpurging type: includes episodes of binge eating followed by fasting, intense and frequent exercise, or restrictive dieting ■ Average age of onset 20 years
Binge-Eating Disorder (BED)	<ul style="list-style-type: none"> ■ Episodic compulsive consumption of excessive amounts of food within a 2-hour time period ■ Overeating typically conducted in private/secretly ■ Not associated with purging behaviors ■ Average age at onset 25 years

Retrieved from <https://www.nimh.nih.gov/health/publications/eating-disorders-new-trifold/index.shtml>; Osborn, K. S., Wraa, C. E., Watson, A., & Holleran, R. S. (2013). *Medical-surgical nursing: Preparation for practice* (2nd ed.). Upper Saddle River, NJ: Pearson.

Nocturnal sleep-related eating disorder (NSRED) is characterized by an initial period of insomnia, followed by an episode of sleepwalking or semiconsciousness, during which time the affected individual consumes unusual foods or nonfood items. Primary manifestations associated with NSRED include obesity and difficulty losing weight. This sleep-related eating disorder is more common in women and typically starts when individuals are in their 20s. It often occurs in those who have restless leg syndrome and may be a related condition. NSRED may also be linked to other sleep disorders, such as obstructive sleep apnea, and has been associated with use of short-acting sleep medications, such as zolpidem (Mayo Clinic, 2014a). For these patients, interventions include referral to a nutritionist, evaluation of mood and stress, and screening for sleep-related disorders.

Pica refers to a continuing pattern of behavior in which the individual consumes nonnutritive, nonfood substances (e.g., chalk, paper, soap, dirt, metal, string, hair). Pica is more commonly reported in children, although it may appear in adults with intellectual disability or mental disorders. Pica may manifest in pregnancy related to cravings for nonfood substances (APA, 2013).

Rumination disorder describes the repeated regurgitation of food outside the presence of a medical condition (e.g., pyloric stenosis, gastroesophageal reflux). Onset may occur at any age, but if rumination begins in the first year of life, it may result in a medical emergency if it does not resolve spontaneously or if treatment is not initiated (APA, 2013).

Avoidant/restrictive food intake disorder is characterized as a disturbance in a eating patterns manifested by failure to meet nutritional needs. Significant weight loss, nutritional deficiency, and dependency on enteral feeding or nutritional supplements may be observed along with impairment of psychosocial functioning. This disorder is seen more commonly in children and may result in impaired family functioning because of the increased stress related to meals and around functions including meals (APA, 2013).

Prader-Willi syndrome (PWS) is a chromosomal disorder that usually manifests at about 2 years of age. The characteristic features include mental retardation, poor muscle tone, and an incessant desire to eat (Mayo Clinic, 2014b). Obesity occurs as a result of indiscriminate and excessive food consumption (Osborn et al., 2013). Because individuals with PWS have a constant sense of hunger and desire to eat, treatment includes ensuring good nutritional habits and providing the patient with the proper amount of food intake. Because of hormonal deficiencies, these patients exhibit impaired physical growth and hypogonadism (underdevelopment of the sex organs). Treatment for patients with PWS may include hormonal therapies, as well as mental health services to address comorbid conditions. Speech, physical, and occupational therapy may also be of benefit to these patients (Mayo Clinic, 2014c).

Personality Disorders

A **personality disorder (PD)** manifests as a pervasive pattern of behaviors, personal perceptions, and internal experiences that are significantly incongruent with an individual's cultural expectations. This persistent pattern of behaviors, perceptions, and experiences is relatively inflexible and causes distress or functional impairment (see **Figure 29–2** »). Manifestations of the PD frequently lead to disruption of the individual's personal, social, and professional interactions. Typically, the onset of PDs is during adolescence or early adulthood (APA, 2013). At present, the American Psychiatric Association recognizes the following 10 forms of PD, each of which is discussed in the exemplar on Personality Disorders in this module (APA, 2013). Of these, borderline personality disorder (BPD) and antisocial personality disorder (ASPD) are the most challenging for patients, family members, and clinicians.

See the Alterations and Therapies feature for a summary of the manifestations and therapies for feeding and eating disorders and personality disorders.

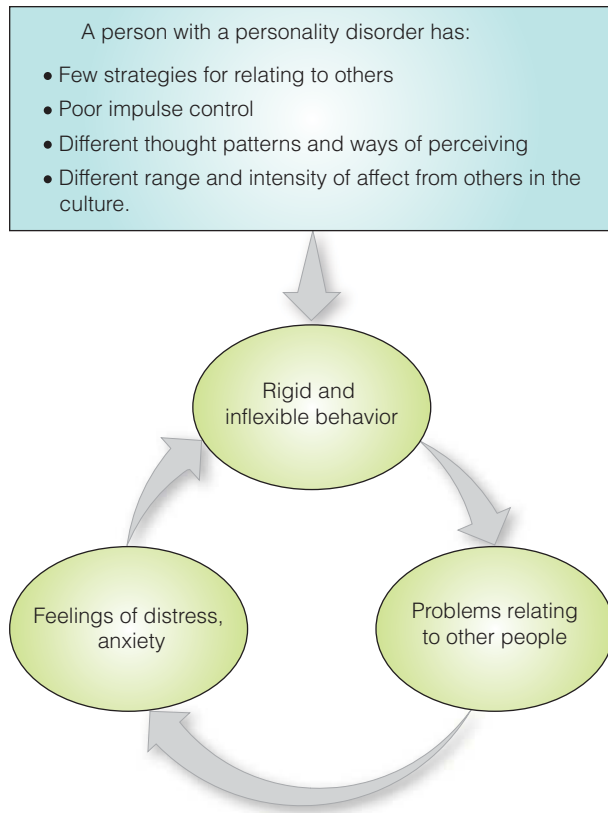

Figure 29–2 » Vicious cycle of personality disorders.

Prevalence

Although feeding and eating disorders can impact individuals at any age, from the standpoint of patients who are officially diagnosed with an eating disorder, these conditions are reportedly more common among adolescents and young adults. In the United States, among adolescents between the ages of 13 and 17, an estimated 2.7% have an eating disorder. Bulimia nervosa is most prevalent among Hispanic adolescents, whereas anorexia nervosa is most prevalent among non-Hispanic White adolescents (Perez & Warren, 2013; Swanson et al., 2011). Bulimia nervosa (BN) is more common than is anorexia nervosa (AN) (APA, 2013). Lesbian, gay, and bisexual (LGB) identity has been associated with substantially elevated odds of purging and diet pill use in both male and female high school students, while bisexual females and males were also at elevated odds of obesity compared to same-gender heterosexuals (Austin et al., 2012).

Among individuals 18 years and older, an estimated 15% of all adults in the United States have at least one personality disorder (APA, 2013). Prevalence associated with specific PDs is discussed in the exemplar on Personality Disorders in this module.

Genetic Considerations and Nonmodifiable Risk Factors

Compared to boys, girls are more than twice as likely to develop an eating disorder (Swanson et al., 2011). Gender prevalence varies with regard to specific PDs.

Research suggests there is a genetic component in PDs, and selected PDs with paranoid and delusional features

may have a link with schizophrenia (APA, 2013). Certain personality characteristics can reflect the development of PDs, such as pervasive anxiety, fear, and aggression. Being a victim of childhood trauma or sexual abuse may promote the development of BPD. Adverse socioeconomic factors such as poverty and sociocultural factors such as migration can influence the development of a PD. A PD may be exacerbated following the loss of a significant support person, such as a spouse, or previously stabilizing social situations such as a job (APA, 2013).

Case Study » Part 1

Jocelyn LeMandre, a 28-year-old woman, is transported to the emergency department (ED) by a friend. Although Ms. LeMandre is alert, oriented, and denies any complaints, her friend reports that Ms. LeMandre “passed out during an aerobics class” and also notes Ms. LeMandre has been complaining of being light-headed for the past few weeks. Ms. LeMandre reports she is finishing her doctoral degree in chemistry and currently teaches university courses.

When questioned about her symptoms, Ms. LeMandre admits to “feeling a little light-headed” but also notes that she hasn’t been drinking enough fluids lately. She reports that she exercises daily for 2 hours prior to teaching her first course and occasionally exercises for another hour before going to bed. When asked about her dietary habits, Ms. LeMandre quietly replies, “I eat almost anything I want to eat. I might as well—I’m still going to be fat,” and then looks away. When asked, Ms. LeMandre reports her height and weight as 5’7” tall and 154 pounds. By observation, Ms. LeMandre’s weight is relatively proportionate to her height. Upon assessment, Ms. LeMandre’s vital signs, which are within normal limits, include temperature 97.8°F oral; pulse 89 bpm; respirations 20/min; and BP 92/52 mmHg.

Clinical Reasoning Questions Level I

1. Considering the report provided by Ms. LeMandre’s friend and Ms. LeMandre’s statements, what may be the cause of her light-headedness?
2. Based on Ms. LeMandre’s educational background, occupation, and exercise regimen, what aspects of her personality are apparent?

Clinical Reasoning Questions Level II

3. At this time, what nursing diagnoses may be appropriate for inclusion in Ms. LeMandre’s plan of care?
4. Based on the available information, what additional assessment data might you expect the primary healthcare provider to order for Ms. LeMandre?

Concepts Related to Self

An individual’s self-concept and self-esteem may be affected by alterations in other systems. For example, someone who is challenged by alterations in mobility may experience difficulty with accomplishing simple tasks associated with daily living. Loss of independence and autonomy may negatively impact self-concept or self-esteem. Similarly, a positive self-concept and high self-esteem may help motivate the individual to move beyond the impairment and learn to adapt and function independently.

As discussed earlier, family plays a role in the development of healthy self-esteem. Overprotective parenting has been associated with lower self-esteem (McLeod, 2013). Authoritative parenting, interfamilial violence, and the loss of a close family member may also impact an individual’s self-esteem.

Alterations and Therapies

Feeding and Eating Disorders and Personality Disorders

ALTERATION	DESCRIPTION	MANIFESTATIONS	INTERVENTIONS AND TREATMENTS
Feeding and eating disorders ■ Body image distortion	Impaired perception of body size and/or shape; e.g., a thin individual perceiving herself to be obese when she is excessively thin	<ul style="list-style-type: none"> ■ Refusal to eat ■ Verbalized self-perception of obesity ■ Verbalized negative perception of body image 	<ul style="list-style-type: none"> ■ Cognitive-behavioral therapy (CBT) ■ Pharmacologic therapy for management of comorbid disorders or to treat acute symptoms of depression or anxiety
Feeding and eating disorders ■ Absence or loss of appetite	Extreme restriction or prohibition of oral intake through self-imposed starvation	<ul style="list-style-type: none"> ■ Absence of appetite ■ Emaciation ■ Potential nutritional deficiencies, dehydration, and electrolyte imbalances ■ Potential death 	<ul style="list-style-type: none"> ■ CBT ■ In extreme cases, forced nutritional supplementation and hydration (e.g., through nasogastric feeding tube)
Feeding and eating disorders ■ Binge eating	Unrestrained consumption of excessive amounts of food within a 2-hour time period; eating continues even after sensing satiation	<ul style="list-style-type: none"> ■ Weight exceeds recommended guidelines ■ If obesity is present, may have secondary physiologic alterations 	<ul style="list-style-type: none"> ■ CBT ■ Nutritional counseling and weight management programs
Feeding and eating disorders ■ Purging	Self-induced expulsion of food and/or products of digestion through use of forced vomiting, laxatives, enemas, and/or diuretics	<ul style="list-style-type: none"> ■ Dental caries (cavities) and damage to tooth enamel due to caustic effects of stomach acid if frequent vomiting is occurring ■ Potential nutritional deficiencies, dehydration, and electrolyte imbalances; potassium and chloride levels due to frequent vomiting can lead to metabolic alkalosis ■ Relatively stable weight patterns ■ Relatively normal weight and body mass index (BMI) 	<ul style="list-style-type: none"> ■ CBT ■ Nutritional counseling, including encouragement to eat foods that provide replacement of electrolytes lost through vomiting (e.g., bananas, nuts, and dried cereals, and potatoes for potassium replacement)
Personality disorders <ul style="list-style-type: none"> ■ Absence or reduction of insight as to effects of behaviors ■ Externalized stress response ■ Failure to accept consequences of behaviors ■ May include egocentricity, grandiosity, or perfectionism 	<ul style="list-style-type: none"> ■ Pervasive pattern of behaviors, personal perceptions, and internal experiences that are significantly incongruent with an individual's cultural expectations ■ Behaviors, perceptions, and experiences are relatively inflexible and cause distress or functional impairment 	<ul style="list-style-type: none"> ■ Impaired function and disruption within personal, social, and professional realms ■ Impulsivity with disregard for consequences of actions ■ Outbursts of emotion, including anger and frustration ■ Attempts to control external environment, including other individuals ■ Potential self-directed violence ■ Potential suicidal ideations and suicide attempts ■ Potential other-directed violence ■ Potential psychosis 	<ul style="list-style-type: none"> ■ CBT ■ Dialectical behavioral therapy (DBT) ■ Schema-focused therapy (SFT) ■ Family-focused therapy ■ Expressive therapy ■ Pharmacologic treatment with antidepressants (e.g., selective serotonin reuptake inhibitors [SSRIs], such as fluoxetine) for management of obsessive-compulsive, aggressive, and self-destructive behaviors ■ Antipsychotics for cognitive-perceptual symptoms ■ Pharmacologic mood stabilizers for control of impulsive behavior and anger

Sources: Based on Potter, M. L., & Moller, M. D. (Eds.). (2014). *Psychiatric-mental health nursing: From suffering to hope*. Upper Saddle River, NJ: Pearson Education; Wilson, B. A., Shannon, M. T., & Shields, K. M. (2013). *Pearson nurse's drug guide*. Upper Saddle River, NJ: Pearson.

Decreased self-esteem has been associated with an increased risk for depression. Alterations in mood and affect influence an individual's level of resilience and coping abilities. Patients with personality disorders who have difficulty adhering to treatment regimens may experience negative consequences, including shame and stigmatization, as a result of their behaviors.

Nurses have an ethical responsibility to engage in self-care, as outlined by the American Nurses Association (ANA). In

particular, Provision 5 of the ANA Code of Ethics for Nurses requires the nurse to provide the same level of self-care as that which he provides to others (Blum, 2014). Effectively caring for others requires first recognizing and adequately fulfilling one's own personal needs, including those within the physiologic, psychosocial, and spiritual realms.

The Concepts Related to Self feature links some, but not all, of the concepts related to Self. They are presented in alphabetical order.

Concepts Related to Self

CONCEPT	RELATIONSHIP TO SELF	NURSING IMPLICATIONS
Advocacy	Being a member of a vulnerable and underserved population (e.g., the chronically mentally ill, the poor, LGBT populations, the homeless, certain ethnic groups) → ↓ access to healthcare services → poorer quality of life and ↓ health outcomes	<ul style="list-style-type: none"> ■ Educate yourself on vulnerable and underserved populations in your region. ■ Join professional and community groups that try to address these issues. ■ As a nurse, advocate for outreach efforts to include these populations in healthcare services. ■ Advocate for increased funding and research to better serve these populations.
Development	Missed development stages → ↓ fulfillment of life roles and ↓ cognitive, physical, and psychosocial development → ↓ self-esteem	<ul style="list-style-type: none"> ■ Screen patients for developmental delays and refer to appropriate healthcare community resources. ■ Develop appropriate accommodations for nonmodifiable disorders or presentations. ■ Educate the family on how to assist the family member with developmental delays and refer to appropriate community agencies for support.
Ethics	Nurses are required to administer self-care that is at the same level as that which they provide to others	<ul style="list-style-type: none"> ■ Perform self-assessment and strive for self-awareness both personally and professionally. ■ Identify and meet personal needs in order to promote optimal physical, psychosocial, and spiritual self-wellness.
Family	↑ parental nurturing → ↑ self-esteem ↑ parental overprotectiveness → ↓ self-esteem	<ul style="list-style-type: none"> ■ Interview the patient regarding his perception of his familial style of parenting. ■ Assess patient's level of self-esteem.
Mobility	Mobility → independence in daily living → ↑ self-esteem Impairment of mobility → increased dependence on others → may ↓ self-esteem and negatively impact self-concept High self-esteem and positive self-concept → greater resilience → increased likelihood for adaptation and achievement of optimal independence despite impairment	<ul style="list-style-type: none"> ■ Assess self-concept and self-esteem in the patient with alterations in mobility. ■ Collaborate with other healthcare providers, including physical therapists and occupational therapists, to assist the patient with achieving maximum independence and autonomy. ■ Encourage the patient to focus on strengths and abilities, as opposed to limitations.
Mood and Affect	↓ self-esteem linked to ↑ risk for depression	<ul style="list-style-type: none"> ■ Assess patients who exhibit low self-esteem for presence of signs and symptoms of depression. ■ In the clinical setting, report signs and symptoms of depression to the patient's primary care provider. ■ Facilitate referrals to mental health professionals for patients at risk for depression.
Stress and Coping	↑ stress → biogenic and psychosocial manifestations of stress → impaired physical and mental health	<ul style="list-style-type: none"> ■ Assess patients for signs and symptoms of ineffective coping. ■ Refer patients for short-term pharmacologic interventions and CBT. ■ Refer patients to appropriate resources in the community.

Health Promotion

Promotion of healthy self-concept varies according to the individual. Early recognition of negative self-concept and poor self-esteem can assist nurses in identifying strategies that may promote healthy self-concept and self-esteem in individual patients. Because eating disorders and personality disorders have complex and multifactorial etiologies, there is no single way to prevent their development.

School-Based Interventions

With eating disorders, some experts recommend implementation of school-based interventions because schools play a vital role in promoting the intellectual, physical, social, and emotional development and well-being of children and adolescents (National Eating Disorders Collaboration [NEDC], 2014). Some of the suggested interventions include providing a body-image friendly environment and celebrating diversity; prohibiting appearance-related teasing, including cyber-bullying in school policy; ensuring no weighing, measuring, or anthropometric assessment of students in any context; providing an opportunity for all students to engage in regular physical activity in a noncompetitive, non-weight-loss focused, and safe environment; providing a balance of food options in the cafeteria; and displaying public material/posters including a wide diversity of body shapes, sizes, and ethnicities (NEDC, 2014).

Other school-based interventions include training all relevant teaching staff in the early identification and referral of students with serious body image concerns and suspected eating disorders. Training teachers, especially athletic coaches, on risk factors that are reinforced by social environments and to use body-friendly language in their interactions with students is also recommended (NEDC, 2014).

Promoting Healthy Self-Esteem

Although there is increasing research regarding the influence of genetics on the development of eating disorders and personality disorders, clinicians agree that a stable home environment, lack of exposure to trauma, and thoughtful parenting are protective factors. The promotion of healthy self-esteem throughout childhood and adolescence is also helpful in creating a stronger sense of self. Children with low self-esteem see temporary setbacks as permanent, intolerable conditions and maintain a sense of pessimism, which can increase their risk for experiencing stress, mental health problems, and difficulty with problem solving and meeting challenges (New, 2012). Children with healthy self-esteem tend to enjoy interacting with others and are comfortable in social settings. When challenges arise, they can work toward finding solutions and voice discontent without belittling themselves or others (New, 2012). These children are more likely to accept their strengths and weaknesses and are more optimistic.

Strategies nurses can offer to parents to promote healthy self-esteem in children include the following (New, 2012):

- Praise children not only for a job well done, but also for effort.
- When children lack certain skills, help them to use learning these skills as an opportunity to learn about themselves and appreciate what makes them unique.

- Be a role model by not being excessively harsh on yourself or pessimistic. Children mirror what they see.
- Identify and redirect inaccurate beliefs children have about themselves.
- Be spontaneous about giving affection, hugs, and praise. Give praise honestly without overdoing it. By praising children when they make good choices, you reinforce the good choices and encourage them to continue making good choices.
- Create a safe, loving home environment. Children exposed to parents who fight and argue repeatedly may feel they have no control over their environment and become helpless or depressed.
- Encourage children to participate in activities that require cooperation with others.

Screenings

Identification of manifestations associated with personality disorders and medical diagnosis of such is guided by the fifth edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) (APA, 2013). Screening for eating disorders may include administration of the SCOFF questionnaire (Morgan, Reid, & Lacey, 1999). The **SCOFF** questionnaire was developed in England and has been found to reliably identify core elements of early-stage anorexia nervosa and bulimia nervosa (Sim et al., 2010).

- S:** Do you make yourself Sick because you feel uncomfortably full?
- C:** Do you worry you have lost Control over how much you eat?
- O:** Have you recently lost more than One stone (14 pounds) in a 3-month period?
- F:** Do you believe yourself to be Fat when others say you are too thin?
- F:** Would you say that Food dominates your life?

One point for every "yes"; a score of 2 or higher indicates a likely case of anorexia nervosa or bulimia and the need for referral to a mental health specialist.

Nursing Assessment

Assessment of the patient with suspected impairments related to self requires giving priority consideration to establishing and maintaining a safe environment. Because certain PDs are associated with impulsive or aggressive behavior, the nurse should ensure that the patient, the nurse, or anyone else in the area is not at risk for physical injury throughout the patient's care. The second priority is establishing a therapeutic relationship, which requires the nurse to build trust and apply principles of therapeutic communication.

After establishing trust, the nursing assessment begins by tactfully interviewing the patient regarding components related to self-concept, self-esteem, and self-awareness. Although it is important to complete a thorough assessment, the nurse should avoid asking personal questions that are unlikely to substantially add to the assessment data. For examples of basic components of a psychosocial assessment, see **Table 29-3** >>.

TABLE 29–3 Sample Psychosocial Assessment Criteria

Dimension	Sample Assessment Criteria
Personal identity	Name Age Gender Marital status Occupation Cultural background, practices Ethnic origin Religious or spiritual affiliation, practices Self-perception: “How do you describe yourself?” Perceived image viewed by others: “How do others describe you?” Values: “In your life, what is most important to you?”
Physical history	Current physical illness History of physical illness Level of energy Disabilities
Communication skills and behaviors	Emotional tone Ability to follow conversation Verbal expression of emotion Verbal and nonverbal cues
Role performance	Current roles Presence of role conflicts, or recent changes (e.g., retirement, death of spouse) Level of congruence between current developmental life stage and role performance Past behaviors used in management of role conflict
Body image	<i>Perceptual</i> : “What do you think when you look at your body in a mirror?” <i>Cognitive</i> : “How important is physical appearance to you?” <i>Behavioral</i> : “Are you comfortable in clothing that exposes more of your body, such as a swimsuit?” <i>Affective</i> : “In one or two words, how do you feel about your body?” <i>Subjective satisfaction</i> : “Overall, how satisfied are you with your body? Which is your favorite body part or region? Which is your least favorite body part or region?”
Self-esteem	(Global) “How satisfied are you with yourself?” (Global) “Overall, do you feel you’re the person you should be?” (Specific) “What do you like most about yourself?” (Specific) “What do you like least about yourself?”

L., & Moller, M. D. (Eds.). (2016). *Psychiatric-mental health nursing: From suffering to hope*. Upper Saddle River, NJ: Pearson Education.

limbs. Conversely, a patient who has bulimia or binge-eating disorder (BED) may present as overweight (BMI >25 to 30) or meet criteria for obesity (BMI >30) (Potter & Moller, 2016). When performing a patient history, the nurse may note that patients with anorexia display signs of reduced alertness and concentration and cognitive deficits as well as multiple physiologic characteristics, including poor sleep, sensitivity to the cold, and decreased energy (Potter & Moller, 2016). These signs and symptoms are discussed more fully in the exemplar on Feeding and Eating Disorders.

During the patient history, the nurse will assess the content of the patient's thinking patterns. In particular, patients with eating disorders exhibit distorted thinking regarding eating, calories, exercise, and body image. Patients with higher acuity will be unable to engage in normal activities and maintain productive relationships. A comprehensive nursing assessment also should determine the level of impairment and functioning within the family, relationships with peers, and performance in school or work (Potter & Moller, 2016). Any evidence of pica should be further investigated. In women, pica can lead to iron deficiency anemia. Ice pica may be indicative of an obsessive-compulsive or developmental disorder (Mesa, 2016).

It is less likely that a nurse will observe visible signs of a personality disorder upon initially meeting a patient. Because of the nature of PDs, clinicians are cautioned not to hurry a diagnosis. Although a single interview may confirm a prior assessment of a PD in a patient, clinicians are urged to assess the stability of personality traits over time across different situations (APA, 2013). Furthermore, assessment is complicated because patients often do not see personality characteristics reflecting psychopathology as problematic (APA, 2013).

Despite these considerations, some features of PDs may be apparent during an initial conversation. For example, patients with Cluster A traits, which include paranoid, schizoid, and schizotypal PDs, may appear odd or eccentric. Patients with Cluster B traits, which include antisocial, borderline, histrionic, and narcissistic PDs, may display dramatic, emotional, and erratic behaviors. Finally, patients with Cluster C traits, which include avoidant, dependent, and obsessive-disorder PDs, may appear as anxious or fearful (APA, 2013). During the assessment, careful attention to cultural considerations is necessary to prevent inadvertent mislabeling of behaviors (see the Focus on Diversity and Culture feature).

As part of the assessment, it may be necessary to interview family members or coworkers (with the patient's permission) to more fully assess the patient's perceptions of reality and behaviors as well as what manifestations or behaviors family members or coworkers find most challenging.

Physical Examination

When dealing with patients with eating disorders, the nurse should always remember that even though the etiologies of eating disorders are often psychologic, eating disorders have serious physiologic complications. For example, morbidity and mortality rates of anorexia are among the highest for all mental disorders (Potter & Moller, 2016). Thus, the assessment of patients with feeding and eating disorders requires thorough and ongoing medical monitoring. This includes

Observation and Patient Interview

For many patients with alterations of self, observation may not yield visible clues. Exceptions do occur with patients who have eating disorders. For example, a patient with a restrictive eating disorder such as anorexia nervosa may appear skeletal, with downy hair (lanugo) on the face and

Focus on Diversity and Culture

Culture and Personality Disorders

Behaviors influenced by sociocultural contexts or specific life circumstances may erroneously be labeled as abnormal during the mental health assessment phase. For example, immigrants and political and economic refugees may display guarded or defensive behaviors that are interpreted as paranoid because of the healthcare provider's unfamiliarity with the language or customs in the United States and/or because of previous negative experiences with the U.S. healthcare system (Paniagua & Yamada, 2013; Spector, 2017). For example, men from the Swat Pukhtun society, a tribe living in mountainous north Pakistan, own firearms and are extremely vigilant in protecting personal honor, family members, and personal property. These behaviors are normal in their natural environment, but could be considered maladaptive in the United States unless the cultural context is discovered and interpreted (Paniagua & Yamada, 2013).

frequently assessing vital signs, measuring height and weight, and repeating diagnostic tests such as complete blood count (CBC) and electrolytes and cardiac studies (e.g., electrocardiogram [ECG]).

A physical examination of a patient with a suspected PD is less likely to yield valuable clues, especially given that the treatments are primarily psychologic. If the patient has had a recent physical exam and any medical comorbidities are being managed by a healthcare provider, mental health clinicians will likely defer the physical exam. If a physical exam is conducted, it will include vital signs, assessment of the patient's appearance, and evidence of self-injurious behaviors (e.g., cutting), which are indicative of some Cluster B diagnoses.

Diagnostic Tests

In the diagnosis and treatment of patients with alterations in self, there are no specific laboratory diagnostics that can be used to conclusively confirm a diagnosis. For these patients, laboratory and diagnostic tests are initially used to rule out physiologic causes that might be the source of associated signs and symptoms.

For patients diagnosed with feeding and eating disorders, laboratory and diagnostic testing may be used to assess for additional impairments that have occurred as a result of the primary disorder. For example, in the care of a patient with anorexia nervosa who is severely dehydrated and malnourished, laboratory studies may include a CBC and electrolyte studies, as well as tests to assess kidney function, such as blood urea nitrogen (BUN) and creatinine, and liver function tests. Other diagnostic exams may include ECG, thyroid screening, arterial blood gas (ABG), and urinalysis.

Case Study » Part 2

After assessing Ms. LeMandre, the ED physician orders a CBC and serum electrolytes, as well as administration of intravenous fluids for treatment of acute dehydration. When you return to insert Ms. LeMandre's IV catheter, she asks if she can first use the restroom. You respond that she is welcome to use the restroom; however, because of her recent loss of consciousness and history of light-headedness, policy dictates that she must be transferred to the restroom by wheel-

chair. Ms. LeMandre replies, "That's ridiculous. I'm perfectly capable of walking to the restroom!" Against your wishes, Ms. LeMandre quickly rises from the ED gurney and proceeds to ambulate to the restroom with you following at her side. She staunchly refuses to allow you to assist her. As you wait outside the restroom door, you hear water running, followed by retching sounds. When you knock on the door and ask if she is okay, Ms. LeMandre replies, "I'm fine—I'll be out shortly."

Less than a minute later, Ms. LeMandre emerges with what appears to be a small amount of emesis on the front of her hospital gown. When you ask if she vomited, she replies, "I just ate too much before I worked out this morning. Sometimes, when I eat too much, I get an upset stomach."

Ms. LeMandre denies any further complaints and, at your insistence, she agrees to allow you to return her to her ED room via wheelchair. You insert her IV catheter without incident and begin infusion of 500 mL of lactated Ringer's solution, as ordered. Per Ms. LeMandre's request, you provide her with magazines to read while she awaits her lab draw and further assessment.

Clinical Reasoning Questions Level I

1. How does Ms. LeMandre's initial refusal to allow you to assist her to the restroom coincide with other aspects of her personality?
2. Does Ms. LeMandre's vomiting episode seem congruent with her explanation? How might Ms. LeMandre's vomiting contribute to her light-headedness?

Clinical Reasoning Questions Level II

3. Based on all available data, including nursing observations, what nursing diagnoses may be appropriate for inclusion in Ms. LeMandre's plan of care?
4. What actions should the nurse take next? What information should be reported to the primary care physician?

Independent Interventions

In the promotion of psychosocial wellness, nurses have the unique opportunity to build trusting relationships with patients and to create a safe environment in which the patient can openly discuss both positive and negative aspects of himself as a holistic being. Through assessment of a patient's psychosocial wellness, the nurse can assist patients with identifying areas of strength and weakness, which enhances the patient's level of self-awareness.

Establishing the Therapeutic Relationship

Establishment of trust and application of therapeutic communication techniques require the nurse to exercise authenticity. The principle of authenticity includes remaining committed to promoting the patient's health and well-being (Watson & Browning, 2012). In particular, for patients with alterations in self, trust and respect are keys to both assessment and treatment. When caring for these patients, building a therapeutic relationship can be especially challenging. Patients with PDs may already be impacted by the stigma and shame often associated with mental illness, and they may have limited social support systems. For patients with feeding and eating disorders, many of whom maintain their condition and behaviors in secrecy, speaking openly about their self-perceptions and eating patterns may be especially difficult. Recovery rates are poor and dropout rates are high among patients who receive inpatient treatment for feeding and eating disorders (Halmi, 2013).

Interventions for Patients with Eating Disorders

Interventions that focus on reducing stress and not specifically addressing the problematic eating behaviors may help initially to create a therapeutic nurse–patient relationship. At this stage, patient education about possible stressors that contribute to eating disorder behavior is also appropriate. While this approach does not directly confront the problem behavior, it does address the stressors that can lead to problem behaviors (Potter & Moller, 2016). Nursing interventions include decreasing exposure to environmental stress; decreasing anxiety by eliminating caffeine and other stimulants; helping patients increase social and familial connectedness through improving communication skills; and assessing and teaching coping strategies. As patients develop a therapeutic relationship and become more open to change, they can be referred to treatment using established methods such as CBT (Potter & Moller, 2016).

Patients with eating disorders often are paralyzed by low self-esteem. Nurses can promote self-worth and positive self-regard in these patients through a variety of interventions. When nurses provide positive reinforcement to patients who adhere to treatment and make efforts to meet goals, patients begin to view their efforts more optimistically (Potter & Moller, 2016). Helping patients set short-term, realistic goals helps patients to see and measure their treatment progress. Encouraging patients to reconnect with activities and experiences that they enjoy helps them begin to regain control over their own behaviors and begin to reexperience positive emotions (Potter & Moller, 2016).

Interventions for Patients with Personality Disorders

For patients with PDs, the priority interventions are directed to safety. Once safety is ensured, the nurse turns the focus toward building the therapeutic relationship, which, in turn, supports other nursing interventions in the areas of medication management, facilitating coping skills, strengthening reality orientation, maintaining professional boundaries, and milieu management (Potter & Moller, 2016). These interventions help patients begin to feel hopeful that they can progress in their treatment and improve their ability to function on a daily basis.

Regarding safety, the nurse will assess patients for suicidal ideation, history of suicide attempts, and desire and history of self-injurious behaviors (for detailed information, see the exemplar on Suicide in the module on Mood and Affect). If a patient does self-injure in some way, it is important for the nurse to remain objective and matter-of-fact. The nurse responds first with the necessary medical attention. Then, when the crisis is over, the nurse will process the event with the patient, looking for cues and feelings that may have contributed to or triggered the patient's desire to self-harm (Potter & Moller, 2016).

Self-awareness is an essential component of the therapeutic relationship when working with patients with PDs. Nurses must have a strong sense of identity, must be willing to set limits and reinforce boundaries, and should have supervision or collaborative relationships with colleagues with whom they can process their relationships with patients

(Potter & Moller, 2016). Nurses working with these patients should frequently examine their patient relationships in order to maintain a consistent and therapeutic effect.

Nurses working with patients who have PDs should help reconnect patients with coping behaviors they have employed successfully in the past and teach patients new adaptive coping skills. For example, patients who act impulsively and aggressively may be taught to count until less angry, employ deep breathing exercises, and eventually to express anger verbally (Potter & Moller, 2016). Self-management, taking responsibility for one's own behavior and well-being, is another coping technique that can help bring a sense of order and empowerment to patients. Self-management behaviors promote social interaction and reduce disruptive behaviors and include adhering to the treatment plan and using appropriate social skills (Potter & Moller, 2016).

Collaborative Therapies

One problem among collaborative clinicians, especially when dealing with patients with personality disorders, is creating a therapeutic relationship that provides firm, consistent boundaries. Individuals diagnosed with PDs, especially BPD, often require limit setting to reinforce those boundaries (Potter & Moller, 2016). A consistent, firm approach reinforcing elements of the care plan and institutional policies is necessary. If reinforcement is inconsistent, a patient will often engage in splitting by playing one staff person against another (Potter & Moller, 2016). Therefore, nurses and other members of the treatment team need to consistently enforce interventions and boundaries and confront patients who are testing them. Specific interventions nurses and other members of the interprofessional team can take toward developing a therapeutic relationship include maintaining consistent staffing, following through on all agreements and promises, setting limits on inappropriate behavior, maintaining appropriate professional boundaries, and processing patient interactions with trusted colleagues (Potter & Moller, 2016).

Pharmacologic Therapy

Pharmacologic therapy normally is not the primary course of treatment for alterations in self, although it may be used to treat specific manifestations and/or comorbid conditions. For example, antipsychotic medications may be indicated in the care of patients with PDs who are experiencing delusions, hallucinations, or other manifestations associated with psychosis. Similarly, patients with feeding and eating disorders who experience comorbid anxiety or depression may also benefit from pharmacologic therapy.

Nonpharmacologic Therapy

For many patients with feeding and eating disorders or PDs, counseling and therapy are the mainstays of treatment. In particular, CBT, which emphasizes focusing on immediate problems and developing solutions through activities such as repatterning the patient's thinking or developing healthy coping behaviors to replace maladaptive ones, has been deemed useful in the treatment of the patients with feeding and eating disorders (NIMH, 2012). Other forms of therapy include DBT and SFT; these are discussed in the exemplar on Personality Disorders in this module.

Case Study » Part 3

You report Ms. LeMandre's vomiting episode to the ED physician. Shortly thereafter, Ms. LeMandre's CBC and serum electrolyte findings are available; all findings are within normal limits, although both her potassium level (3.7 mEq/L) and chloride level (99 mmol/L) are on the low end of the normal range. The physician diagnoses Ms. LeMandre with dehydration. However, in light of her laboratory results, rigorous exercise regimen, statements about her eating patterns, expressed body image, and vomiting episode, the physician is concerned that Ms. LeMandre's signs and symptoms may be manifestations of an eating disorder. He asks you to accompany him while he speaks with Ms. LeMandre. After speaking with her for several minutes about her dietary patterns and what she now describes as "occasionally getting sick when my stomach is too full," the physician asks Ms. LeMandre if he may ask her a few questions about her overall physical health and her views about food. Reluctantly, Ms. LeMandre agrees.

The physician proceeds to administer the SCOFF Questionnaire. Ms. LeMandre responds "yes" to two of the questions contained in the questionnaire: "Do you make yourself sick because you feel uncomfortably full?" and "Do you worry you have lost control over how much you eat?" Subsequently, the ED physician requests that Ms. LeMandre speak with the on-call psychiatrist.

Once again, Ms. LeMandre reluctantly agrees. Following the consultation, the psychiatrist diagnoses Ms. LeMandre with bulimia nervosa and schedules her for a follow-up appointment in 3 days for further evaluation and treatment.

Clinical Reasoning Questions Level I

1. What is the SCOFF Questionnaire? What criteria suggest the potential presence of anorexia nervosa or bulimia nervosa?
2. If Ms. LeMandre does have an eating disorder, why do you think her weight is within normal limits?
3. How does anorexia nervosa differ from bulimia nervosa?

Clinical Reasoning Questions Level II

4. Based on all available data, including nursing observations, what nursing diagnoses may be appropriate for inclusion in Ms. LeMandre's plan of care?
5. What is the most likely cause of Ms. LeMandre's near-hypokalemia (low serum potassium) and near-hypochloremia (low serum chloride)? In light of these deficiencies, what dietary recommendations might be appropriate for her?
6. What long-term risks are associated with feeding and eating disorders? How might Ms. LeMandre's personality traits affect her willingness to follow treatment protocols?

REVIEW The Concept of Self

RELATE Link the Concepts

Linking the concept of self with the concept of fluids and electrolytes:

1. Explain how alterations in self may affect fluid and electrolyte balance. Which personality disorders might lead the patient to be most vulnerable to alterations in fluid and electrolyte balance?
2. Describe at least three independent and collaborative nursing interventions that are appropriate for implementation in the plan of care for a patient with an alteration in fluid and electrolyte balance due to an eating disorder. Include discussion of diagnostic testing that may be useful for evaluating fluid and electrolyte balance in these patients.

Linking the concept of self with the concept of ethics:

3. Describe ethical considerations related to the nurse's self-care. How might a nurse's self-concept affect the ethical aspects of his behavior, both personally and professionally?
4. Describe ethical considerations that impact the care of a patient who is known or believed to be at risk for self-injury.
5. In the course of caring for a patient with an eating disorder who refuses to eat, what ethical considerations might the nurse face?

REFLECT Apply Your Knowledge

The family nurse practitioner (FNP) is seeing Caitlin Smith, a 26-year-old woman, who has come in for her annual checkup, primarily to renew her prescription for birth control pills. Caitlin is very well dressed and obviously overweight. She is 5'4" tall and weighs 188 pounds. The exam goes routinely until the FNP addresses Caitlin's weight, pointing out that her BMI of 32.3 makes her technically obese. Caitlin angrily explodes, saying loudly to the FNP, "When I want your opinion I will ask for it!" The FNP soothes Caitlin by saying she needs to discuss the weight because of the possible adverse health effects. Caitlin then starts crying. During additional questioning when Caitlin has calmed, the FNP finds out that Caitlin has a high-stress job in real estate management. She enjoys her job but feels that patients unfairly judge her because of her weight. Caitlin is vague about her dietary habits, but admits to being a stress eater and having a weakness for chocolate and sweets. "I can eat an entire chocolate cake at one sitting and not even be aware of it," she says. Sometimes after a stressful day, she goes home from work and eats snack foods continually until bedtime. She denies vomiting or overuse of laxatives. Caitlin also admits that her boyfriend recently broke up with her "because of my moods and anger. . . . I just think it is raging hormones." However, this is the fourth romantic relationship that has broken off abruptly since Caitlin graduated from college. Caitlin also worries about losing control or becoming angry at work.

1. Given Caitlin's statements and findings, she likely has which eating disorder?
2. The FNP will probably make which referrals for Caitlin's weight issue?
3. In a later visit, Caitlin discloses that she was sexually abused by an uncle during her preteen and early teen years. Caitlin's mother stopped the abuse when she found out about it, but it was never reported and Caitlin never received any counseling. Given her history of emotional lability, Caitlin may have or be at risk for developing which personality disorder?

Exemplar 29.A

Feeding and Eating Disorders

Exemplar Learning Outcomes

29.A Analyze feeding and eating disorders and how they relate to self.

- Describe the pathophysiology of feeding and eating disorders.
- Describe the etiology of feeding and eating disorders.
- Compare the risk factors and prevention of feeding and eating disorders.
- Identify the clinical manifestations of feeding and eating disorders.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with feeding and eating disorders.
- Differentiate care of patients with feeding and eating disorders across the lifespan.

Overview

Food is essential to life. The body requires an adequate supply of **nutrients** to meet energy requirements such as thermoregulation, cellular regulation, and metabolism. Feeding and eating disorders are complex conditions that stem from myriad social, cultural, and psychologic causes and that culminate in the disruption of the body's nutrient supply. These disorders can cause either under- or overnutrition, both of which have negative physiologic effects. In the absence of a food source to use for energy, the body digests body fat and muscles. When it has excess food in proportion to energy use, weight gain and obesity result. Feeding and eating disorders produce biochemical and physiologic interruptions of the metabolism that endanger the whole body. **Metabolism** is the complex process by which the body breaks down and converts food and fluids into energy sources.

The three disorders discussed in this exemplar are anorexia nervosa, bulimia nervosa, and binge-eating disorder. Anorexia nervosa (AN) is a condition characterized by an extreme aversion to gaining weight, as well as physiologic and mental consequences associated with food restriction. Bulimia nervosa (BN) is characterized by a pernicious cycle of bingeing and purging. Binge-eating disorder (BED) is characterized by the consumption of large amounts of food and a feeling of loss of control during binges. These three conditions create biological, physiologic, and social imbalances that ravage an individual's health and self-concept. For individuals with feeding and eating disorders, the irregular supply of the nutrients necessary for physical health is compounded by psychologic states such as depression, isolation, and self-destructive tendencies.

» See Chart 29-1: *Clinical Manifestations and Therapies: Other Feeding and Eating Disorders* at **Pearson MyLab Nursing and eText**. See the clinical manifestations and clinical therapies for pica, rumination, avoidant/restrictive food intake disorder (ARFID), and night eating syndrome (NES).

Feeding and eating disorders are not defined by body weight and external appearance, but rather by the psychologic states that give rise to inadequate nutrition. There are

many causes for feeding and eating disorders that are outcomes of biological, psychologic, and social processes. At present, researchers believe that an individual's family, social context, and culture provide triggers, but that hormones, brain chemicals, and genetics cause individuals to push themselves to starvation or obesity.

Pathophysiology

The biological aspects of eating disorders are complex and not fully understood. During active illness, there are known disturbances in neuroendocrine, neurochemistry, and neurotransmission circuitry and signal pathways (Monteleone & Maj, 2013). Investigators have found disturbances in serotonin and neuropeptide systems that modulate appetite, mood, cognitive function, impulse control, energy metabolism, and hormonal systems. As a result of their malnourished and emaciated state, individuals with AN have alterations of brain structure that are related to the course of the illness (Fonville et al., 2014), metabolism (Kaye, Bailer, & Klabunde, 2014), and neurochemistry. In contrast, those with BN have shown brain atrophy in imaging studies (Westmoreland, Krantz, & Mehler, 2016).

The genetic heritability of feeding and eating disorders is comparable to other biologically based mental illnesses. Twin studies in AN, BN, and BED estimate that 40 to 60% of the variance is accounted for by genetic factors (Fairweather-Schmidt & Wade, 2015; Trace et al., 2013). Furthermore, these studies revealed that puberty has a powerful impact in activating the genes of etiologic importance in feeding and eating disorders (Klump et al., 2012). Molecular genetic studies are beginning to identify chromosomal genes and regions that may contribute to the etiology of eating disorders. Areas on chromosomes 1, 4, and 10 may maintain risk genes for AN and BN (Trace et al., 2013). Additional risk for AN may be in the genes involved in the serotonin and opioid systems (Sestan-Pesa & Horvath, 2016).

The regulation of feeding behavior involves a complex integrative central and peripheral signaling network system of positive and negative feedback mechanisms that work to maintain energy homeostasis (Solon-Biet et al., 2014). Positive

feedback signals are initiated by feeding behavior. In response, inhibitory or negative feedback signals, requiring greater potency, terminate an episode of eating (Halford & Harrold, 2012). In the case of binge eating, if there is a dysregulation in the relative potency of the negative feedback signaling mechanism, meal size and eating duration can be increased. Thus, binge eating may reflect a relative dysregulation in the negative feedback system. During meals, satiety-signaling neuropeptides—cholecystokinin (CCK) and glucagon-like peptide (GLP-1) from the gut (stomach and intestine)—generate sensory nerves impulses to the hindbrain. These satiation signals connect with neurons in the brain stem via synapses, where they influence meal size and duration (Potter & Moller, 2014).

Ghrelin, a gut peptide that increases appetite, acts on the vagus nerve and stimulates neurons in the hypothalamus. Short-acting satiation signals from the gut to the hindbrain also interact with the long-acting adiposity hormones, leptin and insulin, which are then released and circulate in the blood (Potter & Moller, 2016). These hormones gain access to the hypothalamus in response to the amount of fat stores and energy needs to maintain weight regulation, metabolism, and homeostasis. This higher-order integration evaluates inhibitory signals and metabolic state to determine energy storage needs for regulation, whereas the nucleus tractus solitarius in the caudal brainstem primarily controls the amount of food eaten. During food deprivation or restriction, the sensitivity of the short-acting satiation signals decreases. Therefore, it takes larger amounts of food to generate adequate signaling to terminate a meal (Halford & Harrold, 2012). These hormones can affect satiety by either increasing or decreasing the amount of food eaten.

Research has shown that in comparison to individuals without weight issues, those with feeding and eating disorders experience blunted or attenuated functioning in both the short- and long-acting signaling processes responsible for appetite and weight regulation. When individuals cease eating-disordered behaviors, these hormones may return to a normalized state. However, in some individuals these hormones may remain dysfunctional, indicating a trait-related phenomenon. Therefore, it remains to be determined whether these dysfunctions are a cause, consequence, or maintenance factor in eating disorders (Potter & Moller, 2016). When individuals who stop engaging in eating-disorder behaviors experience normalization of a hormone (such as CCK), this may indicate an adaptive response (Hannon-Engel, Filin, & Wolfe, 2012). It may be that a recalibration begins to effectively regulate and control the input of neuronal and hormonal signals to the hindbrain. As a result, homeostasis and the stability of the hormone system feedback loops are restored. The resulting responses are the absence of debilitating behaviors, such as bingeing or vomiting.

What is unclear is which adaptive mechanism(s) must be present and properly functioning for hormonal response to return to normal and for this behavior to remit. Understanding which biological adaptations must occur before remission and how these can be promoted and maintained is essential to the development of effective treatment strategies and relapse prevention, and it merits further investigation.

Etiology

Although many studies on the causes of feeding and eating disorders have been performed and published, there is no medical consensus on the etiology of these conditions. Biological and cognitive-behavioral theories are relevant to the development of these alterations. An understanding of these theories allows the nurse to take a holistic approach when caring for patients with feeding and eating disorders.

It seems clear that biology—including genetic and neurologic factors—plays a large part in the development of feeding and eating disorders. Research shows that relatives of patients with feeding and eating disorders are 5–10 times more likely to develop a disorder. Studies of twins have demonstrated that feeding and eating disorders occur for both twins at a rate of 40–60%, indicating that a genetic predisposition may play into the development of these conditions. Neurologic factors include neurotransmitter dysregulation. The neurotransmitter in question is 5-HT, or serotonin, which is synthesized partially of carbohydrates. A low level of 5-HT typically reduces an individual's satiety and increases the consumption of nutrients; a high level of the neurotransmitter increases satiety and decreases food intake. A current theory of binge eating holds that repeated binge episodes may result from a deficiency in serotonin, and that the tendency of individuals with bulimia to binge carbohydrate-rich foods is a manifestation of the body's attempt to replenish serotonin. However, 5-HT is not the only neurotransmitter involved in feeding and eating disorders. Norepinephrine and neuropeptide Y increase food consumption, while dopamine inhibits eating. In addition, endogenous opioids, such as endorphins, increase food intake and elevate mood. Individuals who are significantly underweight typically have significantly lower endorphin levels than individuals of normal weight. The fact that endorphin levels return to normal when weight returns to normal outlines the complex relationship between biology, nutrition, and psychology in feeding and eating disorders (Kneisl & Trigoboff, 2013).

Cognitive-behavioral theories view feeding and eating disorders as learned patterns of behavior based on irrational thought and beliefs. These theories look at the affected individual's cognition and behavior to stimuli, whether physiologic, psychologic, or social, and attempt to help the patient with the disorder by changing the maladaptive behavior and replacing it with a healthier response. An essential element of cognitive-behavioral theory is that the individual's thought patterns give rise to destructive behavioral patterns, and that irrational thoughts are at the heart of the network of problems that leads to feeding and eating disorders (Kneisl & Trigoboff, 2013; Potter & Moller, 2016).

Risk Factors

Because the origination of feeding and eating disorders is so complex, the risk factors for feeding and eating disorders are closely related to their etiologies. Biology, sociocultural factors, and family systems all contribute to the psychologic conditions that prime an individual for an eating disorder.

Increasingly, research is pointing to genetic factors as a major risk factor for feeding and eating disorders. Contemporary genetic research works with the behavioral, neurobiological, and temperamental variables that are core features

of disorders. Behavioral conditions that may be related to genetics are perfectionism, orderliness, low tolerance for unfamiliar situations, low self-esteem, and high anxiety. The genetic underpinnings of these conditions can cause individuals to develop an eating disorder even when their culture does not commonly induce feeding and eating disorders (Kneisl & Trigoboff, 2013; Potter & Moller, 2016).

Sociocultural risk factors are elements of an individual's social and cultural context that exert the pressure that initiates an eating disorder. In the American culture, portrayals of men's and women's bodies in the media and a pervasive cultural understanding of a trim body as the "ideal" lead to the unrealistic expectation that everyone should have a low weight. In addition to glamorizing an unrealistically trim body shape, the cultural obsession with thinness leads to a bias against those who are overweight. These social factors diminish the self-esteem of those who believe they do not fit the "ideal" body shape and enhance self-worth for those who are deemed attractive. Girls and women are hardest hit by the cultural emphasis on thin bodies. Magazines targeted at adolescent girls present dieting as a sensible solution to the crises of adolescents and contain 90% more articles promoting weight control than magazines targeted at teenage boys. For many young women, self-esteem becomes centered on concerns about weight (Potter & Moller, 2016).

In recent years, the American ideal of male attractiveness has also shifted toward the unhealthy. Men and boys are confronted every day with images of male beauty that center on muscle-bound figures defined by their strength. The use of anabolic steroids is common among men with feeding and eating disorders, because in addition to seeking thinness they also seek improved muscle tone (National Association of Men With Eating Disorders, 2016). Because of the pressure that the media, social, and cultural expectations exert, feeding and eating disorders like anorexia and bulimia can be considered culture-reactive syndromes in the United States and the rest of the Western world. Negative body image, degraded self-worth, and body dissatisfaction create the stress that leads to feeding and eating disorders (Kneisl & Trigoboff, 2013; Potter & Moller, 2016).

Family systems theories do not necessarily hold that harmful family patterns cause feeding and eating disorders, but rather that the family enables maladaptive behaviors. Some individuals with feeding and eating disorders are survivors of childhood and adolescent abuse—including sexual abuse—much of which occurs in immediate and extended family systems. In addition to abuse, many families of patients with eating disorders have impaired conflict resolution skills. Another factor that enables the development of feeding and eating disorders is a family-wide emphasis on achievement and performance, with ambition for the family's success being one of the principal goals of the parents. Body shape frequently is related to success in these families, and an emphasis on fitness combined with a desire for control may become obsessive.

In addition to the family system impacting the development of an eating disorder, the appearance of a disorder can disrupt the fragile order of a family unit. After the diagnosis or appearance of a disorder such as anorexia, certain families become enmeshed: The boundaries between members become weak, interactions intensify, members become more

dependent, and autonomy decreases. When these patterns occur, each family member becomes less stable and more involved with the other members' private concerns. The parents become overprotective, and food can take on extreme importance. A family's system of interpersonal relations influences the development of an eating disorder, and the presence of an eating disorder impacts the way a family conducts itself in a harmful cycle (Kneisl & Trigoboff, 2013; Potter & Moller, 2016).

Prevention

Prevention is a systematic attempt to change the circumstances that facilitate feeding and eating disorders. Prevention can involve reducing negative risk factors such as body dissatisfaction, depression, and basing self-esteem on appearance. Prevention also involves increasing protective factors

Patient Teaching

Sports and Eating Disorders: Warning Signs

Disordered eating behavior (DE) and eating disorders (EDs) frequently occur in children and adolescents participating in competitive sports. The reported prevalence of DE and EDs in athletic populations ranges from 18 to 45% in female athletes and up to 28% of all male athletes (Melin et al., 2014). The most common sports-related ED is **anorexia athletica**, a condition in which individuals seeking a lean body type engage in excessive exercise and calorie restriction. The condition may also be known as obligatory exercise or hypergymnasia because of excessive and compulsive exercise. Athletes experiencing sports anorexia overexercise to give themselves a sense of having control over their bodies.

Sports-related EDs have been associated with physical and mental health risks as well as impaired performance.

Warning signs of EDs associated with sports participation include the following findings (KidsHealth, 2016). The child or adolescent:

- Will not skip a workout, even if tired, sick, or injured.
- Seems anxious or guilty when missing even one workout.
- Is constantly preoccupied with weight and exercise routine.
- Does not like to sit still or relax because of worry that not enough calories are being expended.
- Has lost a significant amount of weight.
- Increases exercises after eating more.
- Skips seeing friends, gives up activities, and abandons responsibilities to make more time for exercise.
- Seems to base self-worth on the number of workouts completed and the effort put into training.
- Is never satisfied with own physical achievements.

Parents and coaches should be sensitive to encouraging restrictive eating behaviors to improve athletic performance and should practice using weight-neutral language when communicating with younger athletes. Parents and coaches should also be careful about putting too much pressure on young athletes, who have not yet developed effective coping mechanisms (KidsHealth, 2016).

such as basing self-esteem on factors other than appearance, and replacing unhealthy dieting with an appreciation for the body's natural functionality. A broad-based cultural emphasis on prevention is essential for the global reduction of the suffering associated with feeding and eating disorders (National Eating Disorders Association [NEDA], 2013).

Healthcare providers should target two types of audiences when implementing eating disorder prevention. Universal prevention, the first type, should be aimed at the general public, even at those individuals who show no signs of feeding and eating disorders. This type of prevention aims to promote healthy development and understanding of the many complex issues that cause these disorders, as a way of spreading the information that can cut them off before they begin. Targeted prevention, the second type of prevention, educates individuals who are beginning to show symptoms of feeding and eating disorders. These individuals may have high levels of body dissatisfaction. The goal of targeted prevention is to provide enough information to stop an eating disorder from developing (NEDA, 2013). Both universal and targeted programs have had success in preventing feeding and eating disorders, though targeted programs seem to be more effective.

Instruction and interventions interwoven and scaffolded by age throughout all years of K–12 education also seem to hold promise because teachers and coaches play an important role in promoting health and well-being within the school environment (see the Patient Teaching feature). Education about body image, disordered eating, and the risks of dieting and eating disorders are all important topics that should be addressed to help prevent an eating disorder from developing, ease the suffering of a young person in the early stages of an eating disorder, and reduce the stigma and misconceptions that surround eating disorders (NEDC, 2014). Proactive efforts to promote positive body image and healthy lifestyle choices should be integrated across the curriculum with the aim of helping to prevent eating disorders rather than simply responding reactively to existing issues (NEDC, 2014).

Clinical Manifestations

Clinical manifestations of the different feeding and eating disorders vary, but similarities include body image disturbance, anxiety, and ineffective coping skills. Commonly occurring feeding and eating disorders include anorexia nervosa, bulimia nervosa, and binge-eating disorder.

» An overview of clinical manifestations and therapies associated with less prevalent feeding and eating disorders can be found in Chart 29–1 at [Pearson MyLab Nursing and eText](#).

Anorexia Nervosa

Anorexia nervosa (AN) is a potentially deadly ED that compels individuals to lose more weight than is healthy for their age and height. Patients with anorexia have an intense fear of gaining weight, even when they show the symptoms of being dangerously underweight. Individuals with anorexia engage in dieting and exercising to the point of dangerous malnutrition to avoid gaining weight (PubMed Health, 2012a). Information related to the severity of anorexia nervosa and criteria for hospitalization are summarized in **Box 29–1** ».

Box 29–1

Severity of Anorexia Nervosa and Criteria for Hospitalization

Clinical signs are important indicators of the severity of anorexia nervosa for two reasons: (1) Patients with anorexia nervosa often hide their symptoms and behaviors, and therefore may not always report reliably about the extent to which symptoms interfere with function or the duration of the symptoms; and (2) as the illness becomes more acute, the patient is at increased risk for physiologic dysfunction and even organ damage.

The DSM-5 identifies BMI (the weight in kilograms divided by the square of the height in meters) as an important clinical indicator of the severity of AN (APA, 2013):

Mild: BMI ≥ 17

Moderate: BMI 16–16.99

Severe: BMI 15–15.99

Extreme: BMI < 15

Providers with patients who have symptoms of anorexia nervosa with severe to extreme BMI deficits may determine a need for hospitalization based on the patient's BMI and other clinical signs, such as arrhythmia, systolic BP < 90 mmHg, and heart rate below 40 to 50 beats per minute (Harrington, Jimerson, Haxton, & Jimerson, 2015). Although specific clinical markers may vary by clinician or healthcare agency, the following indicators will likely necessitate admission (Harrington et al., 2015; Herpertz-Dhalman et al., 2015):

- Acute medical complication(s) requiring stabilization
- Refusal to eat
- Risk of self-harm or suicide
- Failure to respond to outpatient treatment

Anorexia nervosa typically begins during the teen years, and it is more commonly diagnosed in females. In particular, AN is more prevalent among White females with a history of high academic achievement. See the Evidence-Based Practice feature in the Collaboration section for a discussion of how those with feeding and eating disorders are affected by the internet. These women frequently have goal-oriented families or personalities, and they develop rigid “rules” that they use to control weight. These rituals can be simple, such as cutting food into tiny pieces, or elaborate, such as preparing lavish dinners for friends or family without consuming any food themselves. Criteria for diagnosis of AN include possessing an intense fear of weight gain, refusing to maintain a healthy weight, and perceiving a distorted body image. In previous years, amenorrhea (absence of menstruation for 3 or more months) was also a diagnostic criterion for AN; however, this is no longer the case. In order to maintain low body weight, individuals with anorexia severely limit food consumption and offset consumption with excessive exercise. Other behaviors include self-induced vomiting; refusing to eat in the presence of others; using diuretics, laxatives, and diet pills; and cutting food into small pieces as a way of pretending to eat (PubMed Health, 2012a).

Anorexia nervosa takes a toll on the entire body (see the Multisystem Effects feature). As an individual loses body weight and becomes malnourished, hair and nails become

Multisystem Effects of Anorexia Nervosa

Integumentary

- Brittle skin
- Dry, yellow, scaly skin
- Lanugo
- Brittle hair
- Loss of hair
- Brittle nails

brittle, skin becomes dry and yellow, and a fine layer of hair called *lanugo* appears on previously hairless parts of the body. Individuals with anorexia may constantly feel cold, as the body loses its ability to retain heat. The starvation resulting from anorexia can cause damage to vital organs such as the brain, kidneys, and heart. Pulse rate and blood pressure drop, and irregular heart rhythms can cause heart failure. Loss of nutrients can lead to brittle bones and even changes in the brain, which in turn lead to impaired thinking. In the worst cases of anorexia, patients can starve themselves to death. The condition has the highest mortality rate of any mental illness, due to the complications of malnutrition and the high rate of suicide in the population (National Alliance on Mental Illness [NAMI], 2013a).

Bulimia Nervosa

Bulimia nervosa (BN) is a condition in which individuals binge on food or have episodes of overeating in which they feel a loss of control. After periods of bingeing, the individuals use methods such as vomiting or laxative abuse to prevent weight gain. Bingeing may also be followed by periods of extreme exercise. Many individuals who have bulimia also have anorexia nervosa. Individuals with bulimia are obsessed with their body appearance and engage in the destructive pattern of bingeing and purging to control weight (PubMed Health, 2012b). For diagnosis of bulimia nervosa, the individual must demonstrate binge eating in association with unhealthy compensatory behaviors (e.g., purging or excessive exercise) at least once per week over a 3-month period (APA, 2013).

Binge eating is the rapid consumption of an uncommonly large amount of food in a short amount of time, for example, over a 2-hour period (APA, 2013). Individuals who binge-eat feel out of control during the episode, and although eating binges may involve any kind of food, they usually consist of junk foods, fast foods, and high-calorie foods. Bingeing may be pleasant initially, but the individual who is bingeing quickly becomes distressed. A binge usually ends only when abdominal pain becomes powerful, when the individual is interrupted, or when the individual runs out of food. After the binge, the individual with bulimia feels guilt and engages in purging activities to rid the body of excess calories (NAMI, 2013b).

Purging behaviors are frequently dangerous and include a wide variety of activities that are meant to remove all food from the body, such as self-induced vomiting, enemas, or diuretics. Restrictive dieting and extreme exercising also are common. For many with bulimia, purging becomes a purification ritual and a means of regaining self-control in addition to a mechanism for emptying the body of nutrients (NAMI, 2013b).

Bulimia nervosa is frequently underdiagnosed because many of those who have the condition are either overweight or of normal weight. The typical age at onset is late adolescence or early adulthood. The disorder mainly affects females, although at least 1 in 10 individuals with the condition is male. BN is more common than anorexia, and it occurs in approximately 3% of the population. In addition, BN is often comorbid with other psychiatric

disorders, such as mood disorders, anxiety disorders, substance abuse, and disorders of self-injurious behavior (NAMI, 2013b).

The principal indicator of BN is an incessant obsession with food and body weight. Other important indicators are physical signs of bingeing and purging. These include the trash produced by the large quantity of food required for bingeing, and the products—enemas and laxatives—used in purging. Individuals affected by BN may also experience menstrual irregularity and depressed mood, in addition to the unexplained stomach pain and sore throat that bingeing and purging produce. The signs of self-induced vomiting—unexplained damage to teeth, scarring on the backs of fingers, and swollen cheeks due to the damage to parotid glands—often indicate to doctors and dentists that there is a problem. Individuals who engage in chronic ingestion of syrup of ipecac (available over the counter and online) can experience toxicity, with the most serious adverse effects being lethal cardiac arrhythmias, low blood pressure, and heart failure.

Behaviors associated with BN can lead to severe physiologic damage, even if the individual's weight remains normal. Bingeing and purging cause unhealthy nutritional patterns, and self-induced vomiting can cause serious injury to the digestive tract. Tooth decay, esophageal and stomach injury, and acid reflux are all common in individuals with the condition.

Purging behaviors can lead to dehydration and changes in the body's electrolytes. Because stomach acid contains potassium and chloride, electrolyte disturbances associated with purging include low potassium (hypokalemia) and low chloride (hypochloremia). Frequent vomiting, diuretic use, or laxative abuse may cause hypokalemia; in each case, metabolic alkalosis may result (Potter & Moller, 2016). Bloating and slowed peristalsis (movement of gastric contents through the intestines) also may accompany BN. Complications stemming from electrolyte disturbances, severe dehydration, and undernutrition associated with BN may include cardiac arrhythmias, heart failure, and even death (NAMI, 2013b).

Binge-Eating Disorder

Persons with **binge-eating disorder (BED)** experience periods of rapid food consumption, episodes during which they are unable to stop eating. Individuals with the disorder may continue to eat until long after they are full, and they may experience embarrassment about their behavior. For some individuals with BED, bingeing can produce a sense of relief or fulfillment that gives way as the episode progresses into feelings of disgust, guilt, worthlessness, and depression (NAMI, 2013c).

There is no specific test that can diagnose someone with BED. Rather, a diagnosis is made by a mental health practitioner based on an assessment that includes a formal history and collateral information. Any patient diagnosed with the condition should have a full physical exam performed in order to screen for complications of the illness. These complications include obesity, high cholesterol, type 2 diabetes, and heart disease. In cases of

extreme weight gain, complications can include arthritis, obstructive sleep apnea, and other weight-related conditions (NAMI, 2013c).

Collaboration

Feeding and eating disorders are diagnosed through a combination of laboratory tests to detect the effects of irregular nutrition and consultation with a medical professional. Once a disorder is diagnosed, reestablishment of adequate nutrition, cessation of binge-purge behaviors, and reduction of excessive exercise are the essential points of treating feeding and eating disorders. These goals are accomplished through a combination of pharmacologic and nonpharmacologic therapies, including psychotherapy. Treatment plans are tailored to individual needs but include counseling, medication, and, in extreme cases, hospitalization. Some patients require hospitalization to treat problems caused by severe malnutrition. An inpatient stay at a hospital can also be used to ensure that the patients are eating if they are severely underweight and to establish new eating patterns in a supportive environment (NIMH, 2012).

Diagnostic Tests

Laboratory tests can reveal the physiologic hallmarks of feeding and eating disorders. Screening for anorexia may

include tests for albumin, total protein, electrolyte levels, CBC, and a bone density test to check for signs of osteoporosis. Other diagnostic exams include an electrocardiogram; kidney, thyroid, and liver function tests; and urinalysis. These exams determine whether there is a severe deficiency of any nutrients or any wasting of the body as a result of malnutrition (PubMed Health, 2012a).

Diagnostic tests for bulimia nervosa consider many more visible symptoms of disease than do the tests for anorexia because of the physical damage induced by purging. The dentist is often the first medical professional to identify signs of bulimia, including cavities and gum infections. The enamel of teeth may be worn or pitted because of exposure to the acid in vomit. Loss of stomach acid can lead to metabolic alkalosis. A physical exam may discover broken blood vessels in the eyes (from the stress of vomiting), a dry mouth, pouchlike cheeks, rashes and pimples, and cuts and calluses on the finger joints. Laboratory tests may show an electrolyte imbalance or dehydration from purging (PubMed Health, 2012b).

In order to diagnose a BED, a clinician typically conducts a physical exam, followed by blood and urine tests. A psychologic evaluation is necessary to complete the evaluation, including a discussion of the patient's eating habits. Following diagnosis, the other tests should be performed to check for the common health implications of

Evidence-Based Practice

Feeding and Eating Disorders and the Internet

Problem

For a patient coping with an ED, the internet can be perilous territory. Not only does the internet offer websites dedicated to encouraging and celebrating feeding and eating disorders, but some research suggests that sites provide erroneous diagnostic criteria that can be detrimental to patients and their families. Especially for adolescent patients who spend hours every day engaged with media, information on the internet can both prompt and exacerbate disordered eating behaviors.

Evidence

Approximately 92% of teens report daily internet use, with more than half (56%) of teens age 13 to 17 going online several times a day (Pew Research Center, 2015). Nearly three quarters of teens have or have access to a smartphone. African American teens are the most likely of any group of teens to have a smartphone, with 85% having access to one, compared with 71% of both White and Hispanic teens (Pew Research Center, 2015). African American and Hispanic youth report more frequent internet use than White teens. Among African American teens, 34% report going online almost constantly, as do 32% of Hispanic teens and 19% of White teens.

The overwhelming majority, 84%, of teens turn to the internet for health information (Center on Media and Human Development [CMHD], 2015). Teens report using online sources to learn more about puberty, drugs, sex, depression, and other issues. Nearly a third of teens (31%) visit medical websites for health information, with smaller numbers also relying on social media sites such as YouTube and Facebook. Forty-two percent of teens have researched fitness/exercise, followed by diet/nutrition (36%) and stress and anxiety (19%), with nearly one in three teens (32%) saying they have changed their behavior due to digital health information or tools (CMHD, 2015).

Digital media have become an important source of the social pressure, cultural expectations, and health misinformation that contribute to the development of feeding and eating disorders in adolescents. Many teens come across negative health information online, including drinking games (27%), getting tobacco or other nicotine products (25%), how to be anorexic or bulimic (17%), and how to get or make illegal drugs (14%) (CMHD, 2015).

With the prevalence of adolescent internet use, it is essential to consider that **more than 100** pro-eating-disorder websites not only encourage feeding and eating disorders, but also offer specific advice on anorexic and bulimic techniques, with pro-anorexia content composing almost 30% of the content on certain social

media platforms (Rodgers et al., 2016). These pro-eating-disorder websites offer advice on bingeing, purging, and extreme forms of weight control, and they provide interactive resources such as message boards. Research indicates that the sites are alarmingly easy to access and understand (Rodgers et al., 2016). Pro-eating-disorder websites are readily accessible communities with dynamic, user-distributed content.

In addition to sites that provide information that explicitly promotes feeding and eating disorders, websites that purport to provide medical information can spread damaging information to individuals of all ages. Research shows that the quality of medical content related to the diagnosis and treatment of feeding and eating disorders is relatively low. Few sites fully describe the criteria for diagnosis, complications, and treatment options of any ED, and some provide a good deal of erroneous information. Some sites use inaccurate “diagnostic” terms—“bulimexia,” for example—as well as multiple “optimal” treatment options for each of the feeding and eating disorders. Inaccurate information is particularly dangerous for adolescents with disordered eating, and it may interfere with the family’s decision to seek medical treatment (Smith et al., 2011).

Implications

The fact that almost all adolescents have easy access to the internet and its variety of viewpoints creates a new set of problems for parents and nurses. The web offers an interactive way for impressionable adolescents and young adults to engage with unhealthy cultural expectations of thinness. In addition, the myriad viewpoints expressed online include pathologic websites that support the damaging behaviors associated with anorexia and bulimia. Even sites that purport to present medical information and treatment options for EDs often contain flawed and medically inadequate information.

Critical Thinking Application

Consider a consultation with an adolescent female patient who has been exhibiting the behaviors associated with AN for the past 3 years. This patient has also been taking part in pro-anorexia message boards online for the past 2 years. She knows that anorexia is unhealthy but embraces the damage she deals her body by fasting and exercising, partly because she learned most of what she knows about the condition from websites full of incorrect “information.” Identify a communication strategy that will enable you to correct her misconceptions about AN while attempting to communicate the grim reality of her disorder.

BED, including heart problems and gallbladder disease (Mayo Clinic, 2012).

Pharmacologic Therapy

There is currently no surgical treatment, aside from bariatric surgeries for extremely overweight patients, indicated as primary treatment for any of the feeding and eating disorders. Treating AN involves restoring the patient to a healthy weight, treating underlying psychologic issues, and eliminating behaviors that might lead to malnutrition and relapse. Research suggests that antidepressants, antipsychotics, or

mood stabilizers may be modestly effective in treating patients with anorexia. Medications can treat some of the psychologic states that undergird the ED, but it is not yet clear whether medications are effective in preventing relapse. No medication has yet been shown to be effective in assisting weight gain.

The antidepressant fluoxetine (Prozac) is the only medication approved by the U.S. Food and Drug Administration for treating bulimia. This and other antidepressants may help individuals for whom depression and anxiety are at the root of bulimic behavior. Fluoxetine appears to lessen bingeing

and purging behaviors, reduce the likelihood of relapse, and improve attitudes toward eating.

SAFETY ALERT Selective serotonin reuptake inhibitors (SSRIs), such as fluoxetine, which can be prescribed used to treat underlying depression in patients with EDs, carry an FDA-mandated black box warning regarding increased suicidality. The risk of suicide is especially increased in pediatric, adolescent, and young adult patients 18 to 24 years old. Parents should be made aware of this risk, know the symptoms of suicidal ideation, and know to contact the prescribing clinician immediately if symptoms present.

The pharmacologic options for treating BED are similar to the treatments for bulimia nervosa. Antidepressants, particularly fluoxetine, have been found to reduce binge-eating episodes and help ease depression (NIMH, 2012).

Nonpharmacologic Therapy

Although pharmacologic treatments may play a role in the treatment of feeding and eating disorders, therapies that do not make use of medication have proven to be more consistently effective. In the treatment of AN, individual, group, and family-based psychotherapy can address the psychological reasons for the illness. A therapy called the *Maudsley approach* has been shown to be particularly effective in the treatment of adolescents with anorexia. In the Maudsley approach, the parents of the affected adolescent take responsibility for feeding the patient. Research shows that for patients with anorexia, a combined approach of medical attention and psychotherapy produces more complete recoveries than psychotherapy alone. There is no cure-all approach for AN, but evidence indicates that individualized treatment programs frequently achieve success and that specialized treatment may help reduce the risk of death.

The nonpharmacologic treatment of bulimia nervosa frequently involves a combination of options and depends on the needs of the individual patient. The most effective psychotherapy for patients with bulimia is CBT, which helps individuals focus on their present problems and how to solve them. CBT may be individualized or group-based, and it is effective in changing binge-and-purge behaviors and attitudes to eating. Systemic family therapy and family-based therapy are family-systems approaches that focus on family strengths and family narratives (Espie & Eisler, 2015). Family-based therapies are often used with adolescent anorexic patients, mobilizing the family as the primary resource in feeding and restoring health to an undernourished child.

Nonpharmacologic treatment options for BED are very similar to the options for bulimia nervosa. Psychotherapy, especially CBT that is individualized, has been shown to be effective in many cases with adolescent and adult patients (NIMH, 2012).

Treatment Settings

Day-patient programs are considered to be the first-line treatment approach when more a more structured program is needed for an anorexic patient. Day programs have advantages over inpatient programs in allowing continued engagement with the patient's educational, occupational,

and social contexts. Day-patient settings are also more conducive to the active involvement of family members (including siblings) in treatment (Espie & Eisler, 2015).

Patients with high acuity must be treated with inpatient therapy. An inpatient stay provides a structured and contained environment in which patients have access to clinical support at all times. The close proximity of medical help reduces the chance of relapse while improving the chances of recovery. Inpatient programs are now frequently affiliated with daytime programs so that patients can move back and forth to the correct level of care. The majority of inpatient programs treat only patients with anorexia, bulimia, and BED so that the symptoms can be isolated and treated as effectively as possible (Academy for Eating Disorders, 2013). Inpatient settings also allow sufficient monitoring for *refeeding syndrome*, a dangerous and potentially fatal condition that can occur when patients who are severely malnourished begin eating again.

Criteria for admission include patients at immediate risk or for whom previous treatments have failed. Further indicators for hospital admission include less than 75% ideal body weight, ongoing weight loss despite intensive management, rapid or persistent decline in oral intake, and decline in weight despite maximally intensive outpatient intervention. Other considerations include physical parameters, such as hemodynamic instability, cardiovascular risk, and electrolyte abnormalities, as well as psychiatric assessment of such factors as risk of harm to self and others (Espie & Eisler, 2015).

Complementary Health Approaches

For individuals with feeding and eating disorders, a variety of complementary health approaches can help improve recovery outcomes. However, those with feeding and eating disorders sometimes use alternative medical techniques to achieve the unhealthy goals of disordered eating. For example, some individuals use herbal dietary substances as appetite suppressants or weight loss aids. Herbal supplements can be dangerous when they interact with other products, such as laxatives and diuretics, which are frequently used by those with feeding and eating disorders. Health professionals have not determined conclusively that any complementary or alternative therapies are helpful for individuals with anorexia, bulimia, or BED, but some research indicates that some therapies may help reduce anxiety. Acupuncture, massage, yoga, and meditation have been shown to improve mood and reduce the stress associated with feeding and eating disorders (Mayo Clinic, 2016).
