Mindfulness-based approaches are growing in popularity as interventions for disordered eating and weight loss. Mindful meditation instructs the practitioner to become mindful of thoughts, feelings, and sensations and to observe them in a nonjudgmental way. Many alternative practitioners believe that mindfulness-based interventions, combined with other traditional weight loss strategies, have the potential to offer a long-term, holistic approach to wellness (Godsey, 2013). One meta-analysis found that mindfulness meditation effectively decreased binge eating and emotional eating in populations engaging in this behavior; however, evidence for its effect on weight loss was mixed (Katterman et al., 2014). Another

study that implemented meditation training found that participants in the mindfulness intervention showed significantly greater decreases in food cravings, body image concern, emotional eating, and external eating than the control group (Alberts, Thewissen, & Raes, 2012).

Lifespan Considerations

Feeding and eating disorders are often thought of as conditions limited to adolescent and teen populations, but anorexia, bulimia, BED, and other feeding/eating disorders frequently affect other populations as well. BED differs from AN and BN in terms of age at onset, gender and racial distribution, psychiatric comorbidity, and association with obesity (Smink, Hoeken, & Hoek, 2012). The *avoidant/restrictive food intake disorder* (ARFID) diagnosis addresses patients who struggle with impaired and distressing eating behaviors and symptoms and who lack the weight and body image-related concerns associated with AN and BN (Norris, Spettigue, & Katzman, 2016). Typically, patients with ARFID require the expertise of an interprofessional treatment team to provide the nutritional rehabilitation, medical management, and psychological treatment characteristic of anorexia.

Some of the considerations related to EDs at various stages of the lifespan are discussed in the following section.

Feeding and Eating Disorders in Children

Of all the EDs, ARFID is the most significant diagnosis among this age group (Ornstein et al., 2013). Note that the diagnosis of ARFID is carefully distinguished from the “picky eating” often characteristic of infants and young children. Picky or fussy eating often includes limitations in the variety of foods eaten, unwillingness to try new foods (known as food “neophobia”), and aberrant eating behaviors, including rejection of foods of a particular texture, consistency, color, or smell (Norris et al., 2016). Prevalence rates for picky eating range from 14 to 50% in preschool children and from 7 to 27% in older children. The ARFID diagnosis eliminates picky eaters by identifying only those children with clinically significant restrictive eating problems that result in persistent failure to meet the child’s nutritional and/or energy needs (APA, 2013).

Despite their high prevalence, associated morbidity and mortality, and available treatment options, EDs continue to be underdiagnosed by pediatric professionals (Campbell & Peebles, 2014). Higher rates of EDs are seen now in younger children, boys, and people of color; EDs are increasingly recognized in patients with previous histories of obesity. Furthermore, younger patients diagnosed with EDs are more likely to be boys, with a female-to-male ratio of 6:1, compared with a 10:1 ratio in adults (Campbell & Peebles, 2014).

Feeding and Eating Disorders in Adolescents and College-age Adults

According to the APA (2013), the 12-month prevalence of anorexia among young females is approximately 0.4%. For bulimia, the prior-year prevalence for young females was estimated to be 1–1.5%, with the highest prevalence occurring among young adults, because the disorder peaks in late

adolescence and young adulthood (APA, 2013). The 12-month prevalence rate for binge eating among women was 1.6% (APA, 2013).

Young females at risk for developing anorexia often have co-occurring anxiety disorders or display obsessional traits in childhood (APA, 2013). Young women who develop bulimia often have temperamental traits such as weight concerns, low self-esteem, depressive symptoms, social anxiety disorder, and overanxious disorder of childhood. Risk factors for bulimia include thin body ideal; childhood sexual or physical abuse; and childhood obesity and early pubertal maturation. BED has the same psychopathology as AN and BN, but co-occurring disorders commonly associated with BED also include bipolar disorder, depressive disorders, anxiety disorders, and substance use disorders (APA, 2013). For all eating disorders, the severity of co-occurring psychiatric disorders will predict worse long-term outcomes.

Adolescence is a critical period of development and is a time of vulnerability during which EDs can develop. Research has indicated that a number of factors influence the development of an ED, such as perceived pressure to be thin, thin-ideal internalization, and body dissatisfaction (Rohde, Stice, & Marti, 2015). Dieting and negative affectivity also accelerate the development of an ED. Although these affective risk factors are present by early adolescence, EDs tend to emerge in late adolescence and early adulthood.

Feeding and Eating Disorders in Adults

Eating disorders, especially bulimia and binge eating behaviors, that are developed in adolescence and young adulthood often persist into adulthood. The risk factors and associated behaviors remain intact with one exception: Adults who have developed obesity from an eating disorder are now more likely than ever to undergo bariatric surgery as an intervention.

In one large study of 2266 individuals electing bariatric surgery, loss of control eating was reported by 43.4% and night eating syndrome by 17.7%; 15.7% satisfied criteria for BED and 2% for BN (Mitchell et al., 2015). Factors that independently increased the odds of BED were being a college graduate, eating more times per day, taking medication for psychiatric or emotional problems, and having symptoms of alcohol use disorder, lower self-esteem, and greater depressive symptoms. Before undergoing bariatric surgery, a substantial proportion of patients reported problematic eating behaviors. Several factors associated with BED were identified, most suggesting other mental health problems, including higher levels of depressive symptoms (Mitchell et al., 2015).

Whereas patients with obesity are having some success with bariatric surgery, adults with AN have notoriously poor outcomes, and treatment evidence is limited (Schmidt et al., 2015). There has been some limited clinical success with these patients with the Maudsley Model of Anorexia Nervosa Treatment for Adults (MANTRA), in which patients receive 20 to 30 weekly therapy sessions focusing on concerns specific to AN, including a need to avoid intense emotions; personality traits such as perfectionism; pro-anorexia beliefs (believing that the illness will help manage difficult emotions and the relationships that arouse them); and the response of families to the illness.

Feeding and Eating Disorders in Pregnant Women

Pregnancy and childbirth are major life events accompanied by profound biological, social, and psychologic changes. Research has indicated that disordered eating in pregnancy persists in a substantial proportion of women who have prepregnancy eating disorders. The presence of an eating disorder in this period may negatively affect the pregnancy (e.g., weight gain), delivery (e.g., cesarean delivery, preterm delivery), or offspring (e.g., birth weight) (Knoph et al., 2013).

Pregnancy may also influence the course of eating disorders. For the majority of women with AN and BN, pregnancy appears to lead to adaptive changes in eating behaviors, with the disorders often remitting during and after pregnancy. However, for some, pregnancy may lead to maladaptive changes in eating behavior. Research has found that pregnancy poses a risk for the onset of BED in vulnerable individuals, occurring in nearly 1 in every 20 women (Knoph et al., 2013; Watson et al., 2013). Obstetricians/gynecologists and clinicians need training to detect eating disorders and devise interventions to enhance pregnancy and neonatal outcomes.

Pica, the practice of eating nonfood items during pregnancy, has been documented in health literature for many years. One recent study of women of Mexican origin in the United States associated pica with iron deficiency, not anemia as customarily reported, and found the practice to be quite common, as over half the women reported ever engaging in pica (Roy et al., 2015). Yet another study associated increased pica in urban pregnant women with higher levels of lead in the blood (Thihalolipavan, Candalla, & Ehrlich, 2012). Finally, a large meta-analysis of pica found that the prevalence was higher in Africa compared with elsewhere in the world, increased as the prevalence of anemia increased, and decreased as educational attainment increased (Fawcett, Fawcett, & Mazmanian, 2016).

Feeding and Eating Disorders in Men

In the past, it has been believed that men have eating disorders less frequently than women. According to the APA (2013), anorexia and bulimia occur less frequently among males than females, with a 1:10 male-to-female ratio. However, some studies have contradicted this statistic, reporting up to 25% of ED patients being male (Campbell & Peebles, 2014). The APA (2013) has estimated that BED occurs in males at half the rate in females (0.8% and 1.6%, respectively). However, one ED study found that BED was more common among males than previously believed (Smink et al., 2012). Recent studies have attempted to better quantify prevalence in this population and to discover factors that distinguish male ED behaviors from that of females.

Research has found that men with EDs differ from women in their weight histories. Men frequently reported being mildly to moderately obese at some point in their lives before developing an eating disorder and were particularly susceptible if they were obese in childhood (Mitchell et al., 2012). In contrast, most women with EDs typically had a normal weight history. Compensatory behaviors, such as exercise, are also used more by men than women in order to avert the potential of developing medical complications that their fathers had developed (Mitchell et al., 2012). Most women use compensatory behaviors to achieve thinness. Compared

with women, men with EDs are more often motivated to lose (or gain) weight to achieve optimal athletic performance and be eligible to compete in sports (Mitchell et al., 2012).

As is the case with women, many men with EDs have a history of sexual abuse. Research has demonstrated a strong correlation between sexual abuse and eating disorders, with an estimated 30% of eating-disordered patients having a history of sexual abuse (Mitchell et al., 2012). For men, sexual abuse has likely been underreported because of a disproportionate amount of shame and stigmatization that accompanies abuse for men versus women.

Factors predicting a male ED include childhood bullying; being gay or bisexual, which some studies have suggested may increase the likelihood of an ED by tenfold; depression and shame; excessive exercise coupled with increased diet success ("manorexia"); comorbid substance abuse, including the use of stimulants to lose weight; and media pressures resulting in male body dissatisfaction (Mitchell et al., 2012).

Feeding and Eating Disorders in Older Adults

The most common concern regarding older adults and disordered eating is the physiologic anorexia of aging. This process is characterized by a decrease in appetite and energy intake that occurs even in healthy people and is possibly caused by changes in the digestive tract, gastrointestinal hormone concentrations and activity, neurotransmitters, and cytokines (Soenen & Chapman, 2013). Unintentional weight loss in older people may be a result of protein-energy malnutrition, cachexia, the physiologic anorexia of aging, or any combination of these factors.

However, recent research has found that typical ED symptoms are also common in older adults. In a study of women age 50 and older, 62% of respondents said their weight or shape negatively impacts their life, and 64% think about their weight at least once a day (Gagne et al., 2012). Fully 13.3% of women age 50 and older exhibited ED symptoms. Binging and purging are both prevalent among women in their early 50s, but occur in women older than 75 as well. Research participants reported using unhealthy methods to lose weight and maintain thinness, including diet pills, excessive exercise, diuretics, laxatives, and vomiting. Feeding and eating disorders are detrimental to the health of individuals of all ages, but they can be particularly damaging to the bodies of older adults. The damaging effects of bulimia and anorexia exacerbate preexisting osteoporosis, cardiovascular problems, and gastroesophageal reflux disease (Gagne et al., 2012).

NURSING PROCESS

When assessing the patient with a known or suspected eating disorder, keep in mind that denial is often inherent to these conditions. Recognize that deceit and manipulation are characteristics of the disorder and not necessarily consciously chosen behaviors on the part of the patient.

Assessment

For the patient with an eating disorder, assessment combines a thorough review of both physiologic and psychosocial functioning as well as careful observations for the physiologic

manifestations associated with feeding and eating disorders. When a patient presents with a significant weight gain or loss, do not automatically assume the patient has an eating disorder. Numerous physiologic conditions can lead to muscle wasting and weight loss, including cancer, hyperthyroidism, and impaired gastrointestinal function. Likewise, weight gain may occur due to a variety of causes, including endocrine disorders and medication side effects. Before the primary care provider establishes the diagnosis of an eating disorder, other causes for weight alteration must be ruled out (Kneisl & Trigoboff, 2013).

Focused assessment of the patient's nutritional status incorporates data obtained through the patient interview, physiologic assessment findings, and review of laboratory and diagnostic test results. Assessment of nutritional status includes height, weight, BMI, mid-arm circumference (MAC), and waist-to-hip ratio. It also includes assessment of the skin, the oral mucosa and tongue, the shape of the abdomen, and the nature and presence of bowel sounds. Assess the teeth and gums for any irregularities.

On physical assessment, patients with anorexia nervosa will appear emaciated. Their skin may be dry and covered by a fine layer of hair called *lanugo*, and they also may appear jaundiced (yellow-orange in color). As a result of malnourishment, hair and nails will appear to be brittle. Undernutrition may impair the function of any body system, including the brain, musculoskeletal system, kidneys, and heart. In particular, cardiovascular manifestations may include bradycardia, hypotension, and cardiac dysrhythmias (Potter & Moller, 2014). Because the potential effects of undernutrition are numerous, these patients require a complete physical assessment.

Assessment of patients with known or suspected bulimia nervosa usually includes completion of a physical exam by the primary healthcare provider, followed by psychologic evaluation and laboratory diagnostics. Patients with BN typically maintain a body weight that meets or exceeds normal weight limits. For these patients, focused assessment of the oral cavity can be very revealing. If purging behaviors include vomiting, patients' teeth may demonstrate pitting and enamel erosion, as well as an increased incidence of dental caries. Patients who purge by vomiting may also exhibit ruptured blood vessels in the eyes, as well as a hoarse voice due to throat irritation. Laboratory tests may reveal electrolyte imbalances or dehydration due to purging (PubMed Health, 2012b). In particular, patients with BN are susceptible to metabolic acidosis. If dehydrated, they may demonstrate a variety of manifestations, including hypotension, dry mouth, poor skin turgor, complaints of light-headedness or dizziness, general weakness, decreased urine production, and concentrated urine.

Diagnosis

Nursing diagnoses that may be appropriate for inclusion in the plan of care for the patient with an eating disorder may include the following:

- *Injury, Risk for*, related to orthostatic hypotension, fluid volume deficiency, and electrolyte imbalances
- *Fluid Volume, Deficient*
- *Imbalanced Nutrition: Less Than Body Requirements*
- *Cardiac Output, Decreased*

- *Mucous Membrane, Oral, Impaired*
- *Dentition, Impaired*
- *Body Image, Disturbed*
- *Coping, Ineffective*
- *Self-Esteem, Chronic Low*
- *Anxiety.*

(NANDA-I © 2014)

Planning

Primary long-term goals of care for the patient with an eating disorder include restoring nutritional status and fluid and electrolyte balance, maintenance of body weight within an acceptable range, and development of a healthy body image. Because these patients face significant psychosocial barriers, including body image distortion and rigid behavioral patterns, intensive psychologic care is often necessary for achieving long-term outcomes. Examples of short-term patient goals that may be applicable to the nursing plan of care for the patient with an ED include the following:

- The patient will remain free from injury.
- The patient will demonstrate manifestations of fluid volume balance, including adequate urine production, vital signs that range within normal limits, and absence of symptoms such as light-headedness or dizziness.
- The patient's laboratory testing will demonstrate electrolyte levels that are within normal limits.
- The patient will remain free of purging behaviors.
- The patient will actively participate in individual and/or group therapy.
- The patient will remain free of nonsuicidal self-injurious (NSSI) behaviors, such as cutting, and will report any suicidal ideation.

SAFETY ALERT Suicide attempts and repeated attempts are common among patients with eating disorders. For a number of years, anorexia nervosa has been consistently associated with high rates of suicide among adolescents and young adults. Findings also support that suicide risk appears elevated in bulimia nervosa and is perhaps even higher than individuals with anorexia. There seems to be an association with self-injurious behaviors, with a higher risk among individuals who binge and purge. Suicide risk should be routinely assessed with all patients with eating disorders (Kostro, Lerman, & Attia, 2014; Suokas et al., 2014).

Implementation

Care of the patient who is diagnosed with an eating disorder is highly complex. Priorities of care include protecting the patient from physiologic effects of the ED. However, the ultimate goal is identification and treatment of the cause of the alterations, which is the ED itself. For these patients, the primary intervention involves intensive therapy provided by a mental health professional who is specially trained in the treatment of patients with feeding and eating disorders. While recognizing the complexity of the origin and treatment of feeding and eating disorders, the nurse can promote wellness through preventing patient injury and encouraging healthy patient behaviors and thought patterns.

Prevent Injury

Patients with feeding and eating disorders are at constant or near-constant risk for injury due to undernutrition and its consequences. The effects of purging behaviors also keep the patient at risk for injury.

Behavioral contracts that outline prohibited actions and their consequences may prove effective in the care of patients who are at risk for injurious behaviors. However, especially early in the course of treatment, behavioral contracts may have adverse effects, particularly as asking patients to promise to control compulsive behaviors is unrealistic. For these patients, many of whom are already struggling with shame, the inability to adhere to the contract could serve to heighten the sense of shame and further diminish self-esteem. For patients in the clinical setting, constant monitoring and supervision may be necessary to ensure adequate nutritional intake and prevent purging behaviors.

Additional interventions include the following:

- Teach the patient to decrease exposure to environmental stress.
- Teach the patient to decrease anxiety by eliminating caffeine and other stimulants, such as energy drinks.
- Help the patient increase social and familial connectedness through improving communication skills.
- Teach methods of self-soothing, such as watching TV, reading a book, listening to energizing music, calling a friend, or creating art.
- Encourage the patient to eliminate drugs or alcohol that can increase impulsivity (Potter & Moller, 2016).

In extreme cases, inpatient intake of nutrients and fluids may be medically ordered and administered to patients whose lives are at risk. For all patients, such issues raise ethical concerns and require the nurse to be aware of legal considerations related to forced care. Among experts in the field of feeding and eating disorders, the practice of forcing patient interventions to prevent injury (including death) is the subject of intense debate (Fox & Goss, 2012). If the patient is hospitalized for medical stabilization, the following interventions may be employed:

- Limit the patient's activity and energy expenditure, for example, no excessive exercise.
- Monitor vital signs, food and fluid intake/output, and electrolyte levels.
- Observe for signs of fluid overload, which may indicate refeeding syndrome.
- Monitor trips to the bathroom and look for food hoarding, for example, the patient has hidden food rather than eating it.
- Assess/monitor gastrointestinal and cardiac functioning, as necessary (Potter & Moller, 2016).

Promote a Therapeutic Relationship and Positive Self-Regard

Many patients with feeding and eating disorders have maintained secrecy with regard to their nutritional habits and purging behaviors. Treatment requires patients to be open

about their behaviors, as well as to discuss sensitive topics and issues that may be psychologically painful. Transitioning from secrecy to openness is a major challenge that requires great courage on the part of the patient, as well as establishment of trust between the patient and the health-care provider. With these patients, respect, consistency, and patience are keys to establishing trust, which is part of the foundation of a therapeutic relationship. Other interventions, which are equally appropriate in outpatient and inpatient settings, may include the following:

- Help the patient to identify triggers, such as troubling interpersonal relationships and turbulent internal emotional states, that promote disordered eating behaviors.
- Help the patient to reframe the feelings of purging behavior that contribute to a sense of empowerment, control, and relief from tension.
- Provide positive reinforcement when patients adhere to treatment and make efforts to meet goals.
- Help patients set short-term, realistic goals that they can easily achieve to foster opportunities for success and allow patients to see and measure their treatment progress.
- Encourage patients to reconnect with activities and experiences that they enjoy to help them begin to regain control over their own behaviors and begin to reexperience positive emotions (Potter & Moller, 2016).

Evaluation

Evaluation is a dynamic, ongoing feature of the nursing process that includes identifying the degree to which patients have achieved the goals and outcomes established in conjunction with each nursing diagnosis. While goals and outcomes for the patient with an eating disorder will vary based on patient individuality and the patient's nursing diagnoses, examples of potential outcomes relevant to the care of these patients may include the following:

- The patient remains free from injury.
- The patient's vital signs remain within normal limits.
- The patient's serum electrolytes remain within normal limits.
- The patient demonstrates production of non-concentrated urine.
- The patient denies light-headedness or dizziness.
- The patient does not demonstrate purging behaviors.
- The patient actively participates in individual and/or group therapy.

Many clinicians view recovery from eating disorders to be a cyclical rather than a linear process. Because eating disorders are complex with multifactorial influences, the care plan may need to be modified periodically if patients are not responding to planned interventions. Nurses and clinicians may need to reevaluate triggers and treatment regimens as well as help patients identify alternative methods of coping.

REVIEW Feeding and Eating Disorders

RELATE Link the Concepts and Exemplars

Linking the exemplar on feeding and eating disorders with the concept of teaching and learning:

1. In the context of caring for a patient diagnosed with an eating disorder, describe the barriers the nurse faces with regard to teaching about nutrition.
2. The nurse is caring for a 17-year-old female patient who is diagnosed with anorexia nervosa. The patient's father states, "Once she starts eating regularly, she'll get better. She's just being stubborn." To effectively teach the father about the basis of AN, how should the nurse respond?

Linking the exemplar on feeding and eating disorders with the concept of acid–base balance:

3. How does purging by way of self-induced vomiting most often affect the individual's acid–base balance? How does purging through laxative abuse most often affect acid–base balance?
4. What potential cardiac complications may arise as a result of acid–base imbalances associated with feeding and eating disorders?

REFLECT Apply Your Knowledge

Anisha Robinson is an 18-year-old college student who received a full scholarship for gymnastics. At 5' 2" and 101 pounds, Ms. Robinson is tiny, but she frequently complains about being overweight. When she is not practicing with the gymnastics team, she spends much of her time studying. Although her grades are outstanding, she worries that she will not be admitted into pharmacy school. Sometimes she is so anxious at night that she can't sleep. In order not to keep her roommate up, she'll go out and run 2–3 miles in the middle of the night. Her friends worry about her because they don't know how she can keep her strength up when she eats so little, despite the fact that she'll exercise for an hour or more after every meal. Her roommate becomes worried when they return from Thanksgiving break and she hears the gymnastics coach complaining that Ms. Robinson has gained 3 pounds over the holiday. Ms. Robinson tearfully resolves to eat less and work out more.

1. What are the priority nursing diagnoses for Ms. Robinson?
2. What nursing interventions may be appropriate for inclusion in Ms. Robinson's nursing plan of care?
3. What assessment findings may indicate that Ms. Robinson's health is deteriorating?

Exemplar 29.B Personality Disorders

Exemplar Learning Outcomes

29.B Analyze personality disorders and how they relate to self.

- Describe the pathophysiology of personality disorders.
- Describe the etiology of personality disorders.
- Compare the risk factors and prevention of personality disorders.
- Identify the clinical manifestations of personality disorders.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with personality disorders.
- Differentiate care of patients with personality disorders across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with a personality disorder.

Overview

The American Psychological Association (2013) defines **personality** as enduring characteristic patterns of thinking, feeling, and behavior that make an individual unique. These patterns begin to take shape in childhood and are set by early adulthood. Character and temperament constitute two important

aspects of a person's personality. **Character** refers to moral and ethical value judgments, whereas **temperament** refers to innate characteristics, such as nervousness or sensitivity.

The elements that make up an individual's personality are called **personality traits**. They number in the hundreds, and examples include affability, impulsiveness, and honesty.

In the field of psychology, however, special emphasis has been placed on the five-factor model: neuroticism, extraversion, openness, agreeableness, and conscientiousness (Butcher, Mineka, & Hooley, 2013). Psychologists generally use these traits to describe an individual's personality, as they are considered to be universal; however, recent research raises questions as to their universality in non-Western, pre-industrialized societies (Gurven, von Rueden, & Massenkoff, 2013).

An individual's personality determines how that individual interacts with others. When established personality patterns result in repeated conflicts with others and impair the individual's ability to function in society, that individual is said to be experiencing a **personality disorder (PD)**. PDs affect all aspects of an individual's life and are marked by overly rigid and maladaptive behaviors that make it difficult for the individual to adapt to social demands and change. PDs are independent of mental disorders and substance abuse and are generally consistent over time and across varying situations.

Pathophysiology and Etiology

PDs typically manifest themselves during adolescence and continue throughout the lifespan, although in some cases symptoms diminish with age. Symptoms include interpersonal difficulties, identity problems that result in a weak sense of self, a lack of intimate relationships, and clumsy social skills that hinder cooperation. Individuals with PDs exhibit behaviors that may include **manipulation** (controlling and taking advantage of others); **narcissism** (believing oneself superior and worthy of special treatment); and **impulsiveness** (acting without regard to potential consequences) (Kneisl & Trigoboff, 2013).

Pathophysiology

The nature of these dysfunctions is not fully understood. The American Psychiatric Association has described a number of PDs, but because clinical definitions lack precision, there is often overlap. Consequently, individuals experiencing a PD are usually diagnosed with more than one. That said, all individuals with PDs demonstrate three common behaviors. First, they manage stress by attempting to change the environment rather than themselves; second, they fail to assume responsibility for the consequences of their actions; and third, they illustrate a lack of understanding as to how their behavior affects others. In effect, individuals with PDs are **ego-syntonic**, meaning that they behave according to the beliefs, desires, and values that concur with their disorder. In other words, they see themselves and their behavior as normal and view the problems that arise with others as external to themselves, often believing they are being victimized (Kneisl & Trigoboff, 2013).

PDs are also characterized by deficits in the areas of cognition, affect, interpersonal relationships, and impulse control; individuals with PDs manifest problems and difficulties in at least two of these areas of functioning (Kneisl & Trigoboff, 2013). In addition to this impairment, developing healthy coping strategies proves to be a challenge as individuals with PDs are typically inflexible. This lack of adaptability feeds into a continual negative cycle in which the

same behaviors are consistently exhibited, sabotaging opportunities to gain new skills, and ultimately leading to social isolation.

Etiology

Much about PDs remains unknown, and studies on PDs are hampered by several factors. For example, the lack of diagnostic uniformity makes it difficult for researchers to define samples and replicate previous studies. Another problem is that most individuals experiencing PDs do not come to the attention of mental health professionals. Many individuals with PDs fail to recognize themselves as abnormal and see no need to seek out treatment (Potter & Moller, 2016). Consequently, mental health professionals often do not encounter individuals with PD unless behaviors are severe enough to warrant intervention by family members or the court system.

What is known is that the inflexible personality and behavioral patterns that characterize PDs appear to develop gradually, often with origins in childhood (Butcher et al., 2013). PDs do not appear to be the result of any one cause. Instead, they seem to be the result of an interaction between biological and environmental factors.

Genetics

There does appear to be a genetic causal relationship with certain PDs. According to the Mayo Clinic (2013a), a family history of schizotypal PD and/or schizophrenia increases the likelihood of an individual developing schizotypal PD. Other researchers have found clinical findings regarding genetics to be highly divergent, with some studies finding high heredity and others very low. One large-scale study that sought to remove interviewer bias, long thought to be a factor in variable results, showed that Cluster B personality disorders (e.g., antisocial borderline, narcissistic, and histrionic personality disorders) were strongly heritable, in the upper range of previous findings for mental disorders (Torgersen et al., 2012). In this study, familial environment scored very low in predicting risk of developing the disorders. A study on fraternal and identical twins with antisocial personality disorder (ASPD) found genetic factors to be a greater influence than environmental factors (Kendler, Aggen, & Patrick, 2012). The American Psychiatric Association (APA, 2013) reported on increasing evidence of the link among specific genes, obsessive-compulsive personality disorder (OCPD), and the personality traits of aggressiveness, anxiety, and fear.

Neurobiology

Research points to several neurobiological factors as contributors to the development of PDs. One comprehensive literature review on borderline personality disorder supported the following findings, which can be extrapolated to other PDs: The role of a genetic vulnerability in development of a PD is largely supported; gene-environment interactions had a high likelihood in the genesis of PDs; and plasticity genes (modifiable by environment and experiences) and vulnerability genes are likely both involved in the development of PDs (Amad et al., 2014). Another neuroimaging study found that trait anxiety may cause emotional interference and disrupt cognitive processing in individuals with borderline personality disorder (Holtmann et al., 2013).

Trauma History

Early life stress, including sexual abuse, physical abuse, emotional abuse, physical neglect, and emotional neglect, has been associated with the onset and severity of psychiatric disorders in adults. One meta-analysis showed that emotional abuse and physical neglect were demonstrated to be strongly associated with the development of personality disorders (Carr et al., 2013). Another study showed a strong correlation between childhood sexual abuse and the development of borderline PD (Bohus et al., 2013). Both studies showed that the link is stronger among females, although this may reflect more self-reporting of abuse among females than males. In summary, early life stress triggers aggravate, maintain, and increase the recurrence of PDs and other psychiatric diagnoses.

Exposure to interpersonal and accidental traumatic events and/or repeated episodes of trauma that result in posttraumatic stress disorder (PTSD) are also strongly linked to the development of PDs and other psychiatric diagnoses. The link between PTSD and development of borderline PD was significantly stronger than the link between PTSD and other psychiatric comorbidities (Amstadter et al., 2012). Although PTSD is a factor in the development of borderline PD, trauma also is strongly correlated with the development of avoidant, obsessive-compulsive, and dependent personality disorders (Friborg et al., 2013).

Intrapersonal Factors

Individuals with different PDs interact with others in a variety of ways. They may project their feelings onto those around them, demonstrate problems in developing genuine intimate relationships, lack a sense of guilt, or behave childishly, depending on their personality dysfunction (Kneisl & Trigoboff, 2013).

As discussed earlier in the concept, parent–child interactions can significantly affect a person’s developing sense of self, and as a result, a child’s perception of reality may become distorted if parents are insensitive to the child’s needs. Individuals with a family background of criminality and parental separation, or a childhood marked by continually changing caregivers or care institutions, show a higher propensity for PDs. In one study, all PD dimensions were significantly related to various forms of family and school problems as well as child abuse (Hengartner et al., 2013). Poverty was uniquely associated with schizotypal PD; conflicts with parents with obsessive-compulsive PD; physical abuse with antisocial PD; and physical neglect with narcissistic PD. Sexual abuse was statistically significantly associated with schizotypal and borderline PD, but corresponding effect sizes were small (Hengartner et al., 2013).

The American Psychiatric Association (2013) also reported that individuals diagnosed with borderline PDs have a higher incidence of childhood sexual trauma. In addition, a longitudinal study of almost 800 mothers and their children showed that the incidence of borderline, narcissistic, obsessive-compulsive, and paranoid PDs increased threefold in children who were verbally abused by their mothers, independent of other factors such as sexual or physical abuse, the temperament of the child, and any coexisting psychiatric disorders (Johnson et al., 2001). Last, although mood and anxiety disorders are distinct from PDs, overlapping features

among the three types of disorders exist, which makes the correlation between childhood verbal abuse by a parent and the later development of mood and anxiety disorders and PTSD noteworthy (Stevens et al., 2013).

Sociocultural Factors

The influence of social and cultural factors in personality disorders is not fully understood, yet it is known that they contribute to personal development. For example, when certain groups are discriminated against in a society, it is difficult for the members of that group to develop a healthy self-image. In traditional cultures, such as those found in Japan, there is societal pressure to conform and adhere to group norms. In the United States, on the other hand, emphasis is placed on the personal versus the communal, leading to the prevalence of a “me-first” mentality. Thus individuals from different parts of the world have a greater propensity for certain kinds of PDs according to their sociocultural backdrop.

There is evidence that histrionic disorders are less common in Asian cultures, where individuals tend to be more reserved, than in Hispanic cultures, where individuals tend to be more expressive. In the United States, African Americans and Caucasians are less prone to develop borderline PDs than Hispanics, but they differ with respect to schizotypal PD, with African Americans showing a greater propensity than Caucasians for developing such a disorder (Butcher et al., 2013).

Risk Factors

As discussed in the concept section of this module, both genetic and environmental factors are believed to influence the development of a PD. According to the Mayo Clinic (2013a), notable risk factors include genetics, such as having relatives diagnosed with a PD or another mental illness; family life, such as an unstable home life or parental loss via death or divorce; childhood abuse, such as verbal, physical, and sexual abuse or neglect; diagnosis of other disorders, such as childhood conduct disorder; and low socioeconomic status. That said, diagnosing PDs in children can prove to be challenging because the behavioral and thinking patterns that may indicate such a disorder could actually be the consequence of a developmental phase or the experimentation that often occurs during adolescence.

Prevention

PDs can be prevented if the developing patterns of behavior, feeling, and thought are identified before they become set. This generally requires intervention during childhood and early adolescence (Evans, 2012). Consequently, prevention programs have been created to address both developmental and environmental risk factors, and to break the cycle of repeating problematic patterns by providing interventions at school and in the home. Screening programs have been implemented in schools and primary care settings to help detect risk factors and identify patterns that indicate a PD may be forming (Evans, 2012).

In terms of interventions, there are several programs in the United States focused on imparting parenting skills to address aggressive and antisocial behaviors. The Nurse-Family Partnership Program is one of them. Under this

program, registered nurses visit at-risk families with newborn children starting at the prenatal period and lasting through the child's second birthday. The nurses impart parenting skills and work with family members to change poor habits, such as smoking and unhealthy eating choices. Another is the Incredible Years Program, which uses video recordings of scenarios with parents to promote positive parent-child interactions. The program also includes a classroom management component for teachers and uses puppets to teach children social skills. A third program, New Beginnings, is designed to help children in the case of divorce by strengthening parenting skills; the program has reduced problem behaviors in children and improved parenting warmth and discipline. The parenting interventions included in these and other programs have demonstrated a positive correlation between sociable behavior and a child's self-esteem (Evans, 2012).

Barriers to these preventive measures include competing priorities, lack of infrastructure for implementation, lack of public education regarding mental health and the effectiveness of prevention, stigma, and a paucity of facilitating factors (Evans, 2012). Facilitators include leadership, flexible resources, linkage to healthcare reform or other legislation, coordination across agencies and governmental levels, and additional research.

Clinical Manifestations

The *Diagnostic and Statistical Manual*, Fifth Edition (DSM-5), specifies that individuals with PDs must exhibit dysfunctional behavior toward self and others, and they must also maintain persistent, rigid thoughts and beliefs that are incongruent with sociocultural norms (APA, 2013). Using a categorical approach, each of the 10 PDs is viewed as being a clinically distinct syndrome. However, the American Psychiatric Association also outlines criteria that are characteristic of PDs in general. These include that the individual exhibits a stable pattern of perceptions and behaviors that are out of line with cultural expectations and which occur in two or more areas: cognition, affect, impulse control, and personal relationships (APA, 2013). These patterns must not be consistent with any other psychiatric disorder or with any underlying medical illness or use or abuse of medications or substances.

The 10 personality disorders are categorized into three clusters: Cluster A includes those PDs that may be characterized by odd or eccentric behaviors; Cluster B includes the PDs characterized by dramatic, erratic, or emotional behaviors; and Cluster C includes those PDs typified by avoidant, dependent, or obsessive-compulsive behaviors (APA, 2013). The currently recognized PDs are presented in alphabetical order. For an overview of the primary PDs, see **Table 29-4** >>.

Antisocial Personality Disorder

One of the first named PDs was **antisocial personality disorder (ASPD)**, which is distinguished by the individual's propensity to manipulate or violate others' rights with a disregard for their feelings and/or the consequences (U.S. National Library of Medicine, 2012). Risk factors include having a caregiver who has antisocial PD or alcoholism and

being a victim of child abuse. An estimated 3-4% of the U.S. population has ASPD, with approximately four times as many men having the disorder than women (Potter & Moller, 2016). Because of the lack of remorse and inclination for risk-taking behavior associated with ASPD, many individuals with this PD are found in prison and substance abuse treatment centers.

To confirm diagnosis of antisocial PD, an individual must illustrate dysfunction as illustrated by egocentric behaviors, including pleasure-seeking and unlawful behaviors. In addition, impairments must exist in interpersonal functioning either via a lack of empathy and remorse for wrongdoings or the inability to form and maintain intimate relationships, which often includes deceptive or coercive behaviors. Two trait domains are associated with antisocial PD: antagonism and **disinhibition**. In addition to the other general criteria for PDs, an individual with antisocial PD must be at least 18 years of age (APA, 2013). Often individuals younger than age 18 who demonstrate behaviors typical of antisocial PD have been diagnosed with a conduct disorder, such as oppositional defiant disorder, or attention-deficit/hyperactivity disorder (ADHD) (Potter & Moller, 2016).

Avoidant Personality Disorder

Avoidant personality disorder (APD) is characterized by extreme shyness and fear of rejection. Despite the desire to connect and bond with others, their insecurities and concern for other individuals' perception of them prevent individuals with this disorder from forming relationships of substance. Approximately 2.4% of individuals in the United States have APD (APA, 2013).

Low self-esteem, poor social skills, extreme sensitivity to criticism, and unrealistic expectations related to goal achievement and interacting in groups are characteristics of individuals with APD. They also typically experience a pronounced distrust of individuals' interest in relationship building. Detachment and negative affectivity are the two trait domains associated with APD, with negative affectivity being characterized by anxiety (APA, 2013).

Borderline Personality Disorder

In 1938, psychoanalyst Adolf Stern established the label of **borderline personality disorder (BPD)**, as he believed the symptoms of BPD sat on the dividing line or "border" between psychosis and neurosis. Currently, many mental healthcare professionals take exception with Stern's use of the term *borderline* because it can reinforce already existing negative perceptions of individuals with BPD (Kling, 2014).

Impulsivity, unstable emotions, and depression are key symptoms of BPD; self-harm is also common (see **Figure 29-3** >>), with suicide occurring in 8-10% of those with this disorder (NIMH, 2013a). **Splitting**, the inclination to perceive people or situations as one extreme or the other (e.g., all good or all bad), is also commonly found among individuals with BPD; this feature contributes to their frequent extreme shifts in mood (Oltmanns & Emery, 2012). Other core characteristics include identity disturbances; frantic attempts to prevent abandonment (real or perceived); impulsive behaviors; chronic feelings of emptiness; transient paranoia; and difficulty managing anger (APA, 2013).

TABLE 29–4 Personality Disorders and Associated Characteristics

Behavioral Traits	Affective Traits	Cognitive Traits	Social Traits
Antisocial Personality Disorder			
<ul style="list-style-type: none"> ■ Impulsive; difficulty in delaying gratification ■ Dishonest ■ Irresponsible ■ Risk taking ■ Criminal behavior 	<ul style="list-style-type: none"> ■ Has no problems with self-expression yet remains detached in interactions ■ Lack of guilt and remorse for committing harmful acts ■ Callous ■ Easily agitated ■ Hostile ■ Failure to empathize 	<ul style="list-style-type: none"> ■ Egocentric ■ Grandiose ■ Despite lack of long-term planning, exhibits confidence in future success 	<ul style="list-style-type: none"> ■ Cannot form intimate relationships ■ Exploits others as form of interaction ■ Exhibits controlling and abusive behaviors ■ Aggressive
Avoidant Personality Disorder			
<ul style="list-style-type: none"> ■ Intense discomfort in social situations ■ Avoids social contact unless feels will be fully accepted 	<ul style="list-style-type: none"> ■ Timid ■ Fearful of rejection ■ Intense worry and anxiety especially with regard to forming relationships 	<ul style="list-style-type: none"> ■ Hypersensitive to others' opinions of self ■ Acceptance of others' negative evaluations 	<ul style="list-style-type: none"> ■ Wants to have intimate relationships but an extreme fear of being embarrassed, judged, or rejected by others often prevents it ■ Possesses very few close relationships that are not familial
Borderline Personality Disorder			
<ul style="list-style-type: none"> ■ Impulsive ■ Dangerous risk taking ■ Can self-mutilate and have suicidal tendencies ■ Unpredictable 	<ul style="list-style-type: none"> ■ Intense anxiety ■ Difficulty empathizing and feeling guilt ■ Psychotic episodes are common ■ Reactive moods ■ Difficulty in controlling anger ■ Consistently low mood; rarely experiences satisfaction or happiness 	<ul style="list-style-type: none"> ■ Unstable perception of self, ranging from grandiosity to self-loathing 	<ul style="list-style-type: none"> ■ Highly unstable relationships ■ Manipulative ■ Intense fear of abandonment ■ Mistrust ■ Behavior swings from all-encompassing interest in another individual to complete withdrawal
Dependent Personality Disorder			
<ul style="list-style-type: none"> ■ Passive by nature ■ Seeks out others who are dominant and who will control the relationship 	<ul style="list-style-type: none"> ■ Strives to appear friendly and helpful ■ Will subordinate personal desires and needs and instead prioritize the desires and needs of others 	<ul style="list-style-type: none"> ■ Insecure with personal decision making ■ Pervasive sense of inferiority 	<ul style="list-style-type: none"> ■ Intense fear of rejection ■ Separation from the dominant other may produce extreme anxiety and depression
Histrionic Personality Disorder			
<ul style="list-style-type: none"> ■ Flamboyant ■ Dramatic ■ Seeks to be the center of attention 	<ul style="list-style-type: none"> ■ Appears inconsiderate and incapable of empathy ■ Pervasive craving for excitement 	<ul style="list-style-type: none"> ■ Egocentric ■ Tends to prefer creative and artistic endeavors as opposed to academic achievement 	<ul style="list-style-type: none"> ■ May use sexual behaviors to manipulate others ■ May engage in high-risk sexual behaviors
Narcissistic Personality Disorder			
<ul style="list-style-type: none"> ■ Very competitive in search of power, fame, and love ■ Arrogant ■ Manipulates others to achieve own ends 	<ul style="list-style-type: none"> ■ Difficulty in expressing emotions ■ Empathy is a challenge ■ Anxiety and fear in relation to failure 	<ul style="list-style-type: none"> ■ Grandiosity ■ Believes is better than others ■ Spends much time fantasizing about being powerful, famous, loved, and beautiful 	<ul style="list-style-type: none"> ■ Balanced reciprocal relationships are rare ■ Seeks out relationships as a way to boost own self-esteem
Obsessive-Compulsive Personality Disorder			
<ul style="list-style-type: none"> ■ Perfectionist ■ Inflexible ■ Hardworking ■ High achiever ■ Compulsive; engages in repetitive or ritualistic checking 	<ul style="list-style-type: none"> ■ Difficulty in expressing emotions ■ Empathy is a challenge ■ Anxiety and fear in relation to failure 	<ul style="list-style-type: none"> ■ Extreme fear of making mistakes; may procrastinate or avoid tasks because of fear of failure 	<ul style="list-style-type: none"> ■ Tends to be controlling in relationships, which limits intimacy
Paranoid Personality Disorder			
<ul style="list-style-type: none"> ■ Suspicious and mistrusting of others ■ Rigid, fixed worldview 	<ul style="list-style-type: none"> ■ Inflexible about beliefs, perceptions, and suspicions ■ Argumentative 	<ul style="list-style-type: none"> ■ Generally intelligent and highly capable of arguing in support of personal beliefs 	<ul style="list-style-type: none"> ■ Extreme jealousy may impair intimate relationships with significant others ■ Tends to believe every action by others is driven by malevolent intent or ulterior motive

Gender plays a significant role in that 75% of diagnosed cases are in women (APA, 2013). Approximately 20% of psychiatric inpatients have BPD and 1.6% of the general population is affected; some estimates have ranged as high as 5.9% of the general population (APA, 2013). Risk factors include childhood abuse and abandonment and a strong genetic link: Individuals are five times more likely to be diagnosed with BPD if a first-degree relative also has the disorder. Anti-social personality disorder, mood disorders, and substance abuse disorders are also much more probable in families where individuals are affected with BPD (APA, 2013).

SAFETY ALERT Borderline personality disorder is often associated with self-mutilation, which can include cutting or carving into the skin (see Figure 29–3), burning, pulling out hair, and head banging, all known as nonsuicidal self-injury (NSSI). Nurses must be extremely cognizant of the signs of self-injury and demonstrate sensitivity when conducting an assessment. Patients often hide their injuries by wearing long sleeves or pants, even in warmer weather (Mayo Clinic, 2013b; NIMH, 2013b).

Figure 29–3 » Some individuals with borderline personality disorder engage in self-mutilating behavior, such as cutting.

Low self-esteem, intense self-criticism, and disassociation are associated with BPD. Interpersonal functioning is marked by the tendency to take offense easily or an intense fear of abandonment, which creates conflict-ridden and unstable relationships. The dysfunctional personality traits in BPD fall within the trait domains of negative affectivity (including emotional lability), disinhibition, and antagonism (APA, 2013). More information on borderline personality disorder can be found in **Box 29–2** ».

Borderline personality disorder carries a great deal of stigma, even among mental health professionals. Kling (2014) found that a large portion of clinicians in the mental health field hold pejorative attitudes toward those with borderline personality disorder. Often, these attitudes become manifested through the use of stigmatizing language to describe patient behavior, such as “manipulative” and “attention seeking.” In addition, Liebman and Burnette (2013) explored countertransference reactions to BPD in 560 clinicians via an online survey and found them to be markedly more negative than with any other disorder, which concurs with previous research.

Liebman and Burnette (2013) and McGrath and Dowling (2012) have recommended improved nurse training and education aimed at fostering a holistic view of BPD in order to better understand its causes and resulting behaviors. They cite CBT for nurses and BPD workshops as possible models. Kling (2014) voiced concerns on how stigmatizing language and attitudes affect the relationship between patient and clinician and how such language impacts recovery, and suggested self-governance measures that clinicians could use to improve patient interactions.

Dependent Personality Disorder

Central features of **dependent personality disorder (DPD)** include a pervasive need to be cared for, difficulty with decision making, separation anxiety, and impaired self-confidence. Individuals with DPD tend to seek out partners with dominant traits who will dictate decision making and choices (Potter & Moller, 2016). Individuals with DPD will

Box 29–2

Characteristics of Borderline Personality Disorder

Classified as a serious mental illness, borderline personality disorder impairs functioning in multiple areas because of the instability in mood, behavior, and self-image associated with the disorder. Characteristics of borderline PD include impulsive and often reckless behaviors, chronic feelings of emptiness, feelings of shame and guilt, and labile mood ranging from fear of abandonment to rage, as well as the increased risk for suicide or self-injurious behavior (SIB) (APA, 2013; Neacsiu et al., 2014). Symptoms must occur over time and not be attributed to another mental disorder or to substance use or medication side effects. In addition, individuals with borderline PD often have co-occurring mental illness. As a result, it is hardly surprising that a longitudinal study of 290 patients with borderline PD found significantly higher rates of participation in pharmacotherapy and more intensive treatment modalities (i.e., inpatient and day treatment programs associated with psychiatric hospitals) than patients with other personality disorders. The same study noted

that treatment participation rates tend to decline within the first 8 years, with the notable exception of participation rates in pharmacotherapy (Zanarini et al., 2015).

Family members of patients with borderline PD need support and resources to learn how to help their loved one as well as to take care of themselves. The National Alliance on Mental Illness (2017) recommends several strategies for family members to follow:

- Find emotional support
- Take care of yourself—eat right, exercise, and avoid alcohol and drugs
- Encourage your loved one to continue treatment
- Learn and model techniques your loved one can use as coping strategies

Nurses can help family members by encouraging them to participate in their loved one's treatment plan, find local or online support groups, and maintain their own physical and mental health.

acquiesce to the wants and needs of others, often in an attempt to build or maintain a relationship. At times, these individuals will agree to perform undesirable tasks with the goal of receiving praise or acceptance from others (Kneisl & Trigoboff, 2013). Dependent personality disorder is found in between 0.49% and 0.6% of the general population and is diagnosed more frequently in women (APA, 2013). Chronic physical illness can predispose an individual to dependent personality disorder. Individuals with this disorder may experience mild impairment in occupational and social relationships in which independence is required (Potter & Moller, 2016)

Histrionic Personality Disorder

Characteristically, individuals with **histrionic personality disorder (HPD)** are self-centered (egocentric) and dramatic. In an attempt to garner attention, they may behave erratically, even going to extremes that appear “silly.” Behind the attention-seeking behaviors is a strong sense of inadequacy and helplessness. In many cases, the individual with HPD's motivation for behaviors is rooted in a search for excitement and activity. For these patients, an apparent insincerity and inability to establish emotional commitment cause problems in the context of interpersonal relationships. The simultaneous need for love and reassurance experienced by the individual with HPD is counterbalanced by failure to demonstrate empathy and lack of consideration for significant others (Kneisl & Trigoboff, 2013). Their focus on themselves creates difficulty in establishing and maintaining relationships, and family members and caregivers may experience burnout (Potter & Moller, 2016).

Patients with HPD may demonstrate highly sexualized behaviors, appearing provocative and seductive. Seduction and sexuality serve as methods of manipulating others. For some patients with HPD, acting out may include impulsive sexual encounters and promiscuity, which lead to an increased risk for contracting and transmitting sexually transmitted infections (STIs). In addition, when needs for

attention and affection are unfulfilled, the patient with HPD may act out through demonstration of suicidal behaviors (Kneisl & Trigoboff, 2013).

Narcissistic Personality Disorder

At the heart of **narcissistic personality disorder (NPD)** is a sense of grandiosity, an inability to empathize with others, and attention-seeking behaviors. Substance-abuse disorders (especially cocaine abuse), eating disorders (particularly anorexia nervosa), and depression, dysthymia, and social withdrawal are commonly found in conjunction with NPD (APA, 2013). More men than women are diagnosed, with 50–75% of the diagnoses being made in males. It is estimated that up to 6.2% of the general population experiences the disorder (APA, 2013).

Narcissistic personality disorder is characterized by extreme reliance on other individuals' perceptions and/or an inflated sense of self, or by approval seeking and either an extremely low or high set of personal standards. A failure to identify with others and their emotions or a hypersensitivity to others creates difficulty in developing meaningful relationships. NPD aligns with the trait domain of antagonism, specifically the trait facets of grandiosity and attention seeking (APA, 2013).

Obsessive-Compulsive Personality Disorder

Obsessive-compulsive personality disorder (OCPD) is characterized by significant impairments in social functioning and relationships and an all-consuming desire to achieve perfection in all tasks. It is important to note that OCPD is not the same as obsessive-compulsive disorder (OCD), which is covered in the module on Stress and Coping. Although they share similar traits, key differences exist. The International OCD Foundation (2012) specifies that individuals with OCPD do not see anything dysfunctional about their way of thinking or acting, whereas those with OCD recognize that their thoughts are disruptive and not normal,

making them more likely to seek treatment. In addition, individuals with OCPD can demonstrate great productivity on the job, but their symptoms place strain on their interpersonal relationships; OCD generally causes disruptions in all areas. Men are twice as likely to experience OCPD as women, and approximately 2.1–7.9% of the general population is believed to have this disorder (APA, 2013).

Paranoid Personality Disorder

Individuals with **paranoid personality disorder (PPD)** tend to demonstrate an inability to trust others. Actions and intentions of others are perceived as having an underlying theme of malevolence. From the suspicious, mistrusting vantage point of the individual with PPD, others are viewed as being deceptive and disloyal. The pathologic jealousy sometimes associated with PPD can damage relationships with significant others. Tending toward being prejudicial and judgmental, individuals with PPD often maintain rigid, inflexible worldviews and will reject logic or proof that contradicts their beliefs. Hypervigilance combined with certainty that others' actions are prompted by hidden motives can lead to isolation for the patient with PPD (Kneisl & Trigoboff, 2013). Not surprisingly, the symptoms and behaviors associated with this disorder can result in family conflicts and occupational impairment (Potter & Moller, 2016). Prevalence rates for paranoid personality disorder are estimated at between 2.3% and 4.4% (APA, 2013). There is some evidence that there is increased prevalence of this disorder in first-degree relatives of individuals with schizophrenia and other psychotic disorders (APA, 2013).

Schizoid Personality Disorder

Central features of **schizoid personality disorder** include a seeming aloofness, a tendency to prefer solitary activities, absence of humor, and lack of interest in forming relationships, including those of a romantic nature. Generally disengaged and uninterested in social interaction, individuals with schizoid personality disorder may appear to be cognitively impaired and have difficulty working. Functional abilities and levels of adjustment vary among these patients; some are able to live independently and maintain marginal-to-adequate function within society, while others are institutionalized (Kneisl & Trigoboff, 2013).

Schizotypal Personality Disorder

Schizotypal personality disorder is distinguishable by extreme social anxiety and eccentric behavior. Commonly, **depersonalization** occurs, in which the individual feels apart from his body or an overall strangeness related to the physical self. Individuals with schizotypal personality disorder can also experience **derealization**, or feeling disconnected from their own body (Kneisl & Trigoboff, 2013). Schizotypal personality disorder and schizophrenia share similar criteria, but they are two different disorders, with schizophrenia being more severe. (For discussion of schizophrenia, see the module on Cognition.) For some individuals, symptoms of schizotypal personality disorder progress to a point where a diagnosis of schizophrenia is applied. Schizophrenia is commonly seen in families where another member is diagnosed with schizotypal personality disorder (Potter & Moller, 2016).

Individuals with schizotypal personality disorder experience difficulty in establishing boundaries between self and other individuals and frequently possess aims that are unrealistic or unclear. They frequently misunderstand other individuals' motives and actions, exhibit a lack of understanding of how their own behavior affects others, and experience challenges in establishing intimate relationships primarily because of anxiety and a lack of trust. The DSM-5 outlines three trait domains in schizotypal PD. The first is **psychoticism**, which is distinguished by eccentricity, cognitive and perceptual dysregulation, and unusual beliefs and experiences. The second trait domain is **detachment**, characterized by restricted affectivity and withdrawal, and the final trait domain is negative affectivity, which is defined by the trait facet of suspiciousness (APA, 2013).

» **Stay Current:** In addition to the American Psychiatric Association's website, additional information about PDs can be found at www.MayoClinic.org and the National Institute for Mental Health at www.nimh.nih.gov.

Cultural Considerations

As environmental influences play a part in the development of personality, nurses and other healthcare professionals must take care not to deem a personality trait or behavior maladaptive or dysfunctional without first considering the influence of culture. For example: Individuals who are new to the United States may present as paranoid or overly suspicious of others when in fact their behavior could simply be a result of their unfamiliarity with American customs; some cultures condition girls and women to avoid social situations; and individuals from Latin cultures are generally much more expressive and exuberant than those from Britain. Cultural competence and being aware of one's own biases is crucial in providing quality care for patients. For additional examples, see the Focus on Diversity and Culture feature.

Collaboration

The treatment of PDs requires a collaborative effort that includes the patient, the interprofessional team responsible for the patient's care, and the patient's family. The team working with the patient may include a primary medical care provider; a psychiatrist or psychologist; a licensed mental health professional; an advanced practice nurse who specializes in psychiatric mental healthcare; the registered nurse; and other professionals. The registered nurse can fill several important functions, including providing education and follow-up related to the therapeutic regimen, and instilling hope in the patient and family that achieving a more normal level of functioning is possible.

Treating PDs is a considerable challenge and can generate frustration and try the patience of healthcare workers. All those involved, including nurses, must understand that an individual's personality developed over that individual's lifetime, reflecting learned experiences, and is therefore unlikely to change drastically. The aim instead should be realistic, short-term outcomes. Eventually, patients should be encouraged to seek long-term therapy, which is considered the most effective in the treatment of PDs. Long-term therapy demands time, dedication, and buy-in from the

Clinical Manifestations and Therapies

Personality Disorders

Focus on Diversity and Culture

Mental Health and Religious Beliefs

When caring for patients with personality disorders, nurses should be aware that some patients may interpret their condition in the context of deeply held religious and spiritual beliefs. More specifically, the symptoms of delusions and hallucinations may be viewed not as mental health issues, but rather as demonic possession or the work of evil spirits (Spector, 2017; Tajima-Pozo et al., 2011).

Complicating the issue is that many religious people from a variety of cultures may believe in otherworldly beings that can cause illness and misfortune. In the Muslim faith, for example, beliefs about jinn are held by some people with and without any signs of mental illness (Guthrie, Abraham, & Nawaz, 2016). Jinn are intelligent spirits of lower rank than the angels, able to appear in human and animal forms and capable of possessing humans, and can influence humans for good or evil.

In both the distant and recent past, the medical community viewed religious and spiritual influences as more likely to be harmful than helpful in patient care. As a consequence, individuals with personality disorders who maintained a strong spiritual or religious practice often chose not to enter the mental health system, either because of shame or fear of how their beliefs would be perceived, or because of their conviction that only religious and spiritual healing could help them (Pargament & Lomax, 2013). Today, the role of religion is viewed much differently. Partly because of a greater awareness of the need for cultural competence in mental healthcare, professional caregivers are more willing to integrate religious and spiritual elements into treatment (Pargament & Lomax, 2013). Many clinicians have realized that for some patients, religion instills hope, purpose, and meaning in their lives and also influences treatment compliance and outcomes (Grover, Davuluri, & Chakrabarti, 2014; Potter & Moller, 2016). Some therapists have begun to incorporate religious contexts and accommodations into CBT and other therapies with good results (Pargament & Lomax, 2013).

patient (Potter & Moller, 2016). Nurses should also be especially cognizant of establishing and maintaining firm, consistent boundaries with patients.

Diagnostic Tests

There is no one test mental health professionals use to diagnose PDs. Instead, PDs are typically diagnosed through an interview with the patient that covers issues such as symptoms, family history, and thoughts of violence, suicide, or self-injury. Although a single interview may be sufficient for an experienced clinician to make a diagnosis, it is more often necessary for the clinician to conduct more than one interview spaced over time to arrive at a definitive diagnosis (APA, 2013). A physical exam and laboratory tests (such as a toxicology screen) also help rule out other factors that could be the cause of abnormal behavior, such as drug and alcohol abuse (NIMH, 2013c; Mayo Clinic, 2013b).

Although mental health professionals refer to the specific diagnostic criteria for each PD found in the most recent version of the DSM, identifying the specific PD that a patient is experiencing can be complicated because of the frequent overlap of symptoms across disorders. The subjectivity of the patient's descriptions and the care provider's interpretation

of those descriptions also pose a challenge (Mayo Clinic, 2013a). In this respect, there are a number of psychologic tests that can help mental health professionals arrive at a more definitive diagnosis, including personality inventories in a true/false or yes/no format, such as the Personality Diagnostic Questionnaire commonly used to identify NPD, and open-ended projective tests, such as the Thematic Apperception Test frequently used to identify personality traits (D'Agostino et al., 2012; Hopwood et al., 2012).

If the disorder becomes so pronounced that an individual is unable to provide self-care or is in imminent jeopardy of causing harm to self or others, especially with dangerous self-injurious behaviors or suicidal ideation, then the individual should be hospitalized. Different inpatient options exist, such as day hospitalization or residential treatment (Mayo Clinic, 2013b).

Pharmacologic Therapy

Individuals with PDs often are prescribed medications to control their symptoms. Obsessive-compulsive, aggressive, and self-destructive behaviors may be held in check with the use of SSRIs, such as fluoxetine (Prozac). Symptoms associated with avoidant and borderline disorders may be minimized with antidepressants, just as acute psychosis may be ameliorated with antipsychotic drugs. Medications, however, should be used to complement a comprehensive treatment plan that includes therapy (ideally long-term) that incorporates various approaches (Potter & Moller, 2016).

Psychotherapy

Long-term psychotherapy is the most highly recommended treatment for individuals with PDs. There are various different types of psychotherapy, some more suitable to certain types of PDs than others. Medical professionals usually draw from and combine elements of the different types of psychotherapy to meet a particular patient's needs (NIMH, 2013c). All of the therapies described here are generally available as both outpatient and inpatient services.

Cognitive–Behavioral Therapy

CBT combines cognitive aspects to change thoughts and beliefs with behavioral aspects to alter problematic action patterns. It focuses on skill training and problem solving. Typically, the therapist serves as a guide to assist the patient in recognizing harmful ways of thinking and erroneous beliefs and works with the individual to purge them by analyzing and reinterpreting both past and current experiences, thus helping the patient adopt positive behaviors and interactions with others.

If trauma has occurred, exposure therapy can be used. This is a behavioral therapy in which patients, guided by the therapist, repeatedly approach trauma-related thoughts, feelings, and situations that they have been avoiding because of the distress they cause. Repeated exposure to these thoughts, feelings, and situations helps reduce the power they have to cause distress (U.S. Department of Veterans Affairs, 2015). These therapies aim to reduce symptoms by offering patients the chance to develop concrete coping strategies in conjunction with the therapist. CBT can also help individuals with mood disorders recognize when their mood is about to shift, thus giving them the foresight to

apply coping strategies to deal with these changes (APA, 2013; NIMH, 2013c).

Dialectical Behavioral Therapy

A combination of cognitive and behavior therapy, DBT originally was developed to treat individuals with suicidal thoughts. *Dialectical* refers to striking a balance between two extremes; the therapist displays understanding and validates the patient's behaviors and feelings while at the same time imposing limits and making the patient responsible for changing unhealthy patterns. It has proven effective in treating borderline personality disorder, showing lower dropout rates than other therapies and decreasing the frequency of suicide attempts. Through DBT, patients learn to accept things as they are and apply techniques to control strong emotions that might otherwise overwhelm them. Mindfulness is one such technique, where patients learn to become aware of and explore emotions without reacting to them. DBT also teaches patients emotional regulation and distress tolerance. This type of therapy usually relies on individual sessions to teach new skills and strategies, and then group sessions to apply them. Traditional and cognitive approaches are also used in conjunction with DBT to help patients foster better relationships with others (APA, 2013; NIMH, 2013c; Oltmanns & Emery, 2012).

Schema-Focused Therapy

Schema-focused therapy (SFT) combines aspects of CBT with other forms of psychotherapy to change a patient's self-perception. This is often applied to personality disorders, where the individual typically has a poor self-image. SFT aims to help patients view themselves differently so they can create new and more effective ways of interacting with their environment and others (NIMH, 2013c). Research has shown that SFT is an extremely effective treatment option for individuals with BPD, sometimes leading to recovery (Jacob & Arntz, 2013).

Group Therapy

Group therapy is also important to the treatment of certain PDs. For example, it can be helpful in strengthening empathic skills for individuals with ASPD in that it allows for feedback about the perceptions of the other group members (Potter & Moller, 2016). Another example of group therapy is the Systems Training for Emotional Predictability and Problem Solving (STEPPS), consisting of 20 two-hour sessions led by a social worker. According to the NIMH (2013c), the STEPPS program, when combined with other approaches, such as pharmacologic treatments and psychotherapy, has alleviated depression and improved the quality of life of individuals with borderline personality disorder.

Family-Focused Therapy

Family-focused therapy is often useful for the family members of patients with PD to participate in FFT so as to cope with the stress of living with a loved one with a personality disorder and avoid behaviors that might worsen the patient's condition. FFT educates family members about their loved one's disorder, giving them the necessary knowledge to improve interactions and play an active role in supporting the patient. For example, the patient's family can

develop a course of action in case warning signs of a relapse appear. In addition, family therapy programs such as Family Connections address the needs and concerns of the patient's family members. DBT family therapy helps family members understand and support relatives with PD by teaching them skills and strategies and having them participate in the patient's treatment sessions (NIMH, 2013c).

Complementary Health Approaches

Although there is not a specific form of integrative therapy that is recommended for patients with PDs, complementary health approaches may provide some relief from certain symptoms, such as anxiety and depression. For instance, yoga, meditation, breathing exercises, and chamomile tea can help individuals with anxiety to relax, while vitamin B₁₂ and omega-3 fatty acids can ease depression (National Center for Complementary and Integrative Health, 2016a). Studies indicate that omega-3 fatty acids may also serve to prevent psychosis from fully emerging in young individuals who show signs of developing such a disorder (National Center for Complementary and Integrative Health, 2016b).

Lifespan Considerations

Personality traits are enduring patterns of perceiving, relating to, and thinking about the environment that are exhibited in many social and personal contexts (APA, 2013). The essential diagnostic feature of a personality disorder is the enduring, inflexible pattern of inner experience and behavior and its effects on at least two of the following areas: cognition, affectivity, interpersonal functioning, or impulse control (APA, 2013). Characteristics of personality disorders at different ages during the lifespan are discussed below.

Personality Disorders in Childhood

Many times, traits of a PD that appear in childhood do not persist into adult life. However, a PD may be diagnosed in children or preadolescents in relatively unusual cases where the child's particular maladaptive personality traits appear to be pervasive, persistent, and unlikely to be limited to a specific development stage or another mental disorder (APA, 2013). For a PD to be diagnosed in childhood, the features must have been present for at least 1 year.

The exception is antisocial personality disorder, which cannot be diagnosed in someone under age 18. Often younger patients with similar behaviors are diagnosed with more age-appropriate disruptive, impulse-control, or conduct disorders prior to age 18 (APA, 2013). Research in this area has been focusing on the genetic, cognitive, emotional, biological, environmental, and personality characteristics of callous and unemotional traits displayed early in life by children with conduct disorders (Frick et al., 2014). Research has also been conducted to determine whether borderline personality-related characteristics observed in children are associated with increased risk for the development of borderline personality disorder. The research found that BPD-related characteristics measured at age 12 years were highly heritable; were more common in children who had exhibited poor cognitive function, impulsivity, and more behavioral

and emotional problems at age 5 years of age; and co-occurred with symptoms of conduct disorder, depression, anxiety, and psychosis (Belsky et al., 2012).

The avoidant behavior characteristics of Cluster C (avoidant and dependent personality disorders) often start in infancy or childhood, with display of shyness, isolation, and fear of strangers and new situations (APA, 2013). Although these behaviors are not uncommon in young children, they do tend to dissipate as most children age.

Personality Disorders in Adolescence and Early Adulthood

The features of a personality disorder become recognizable typically during adolescence or early adulthood. Cluster A disorders, such as paranoid, schizoid, and schizotypal PDs, may present in childhood and adolescence. These individuals will display characteristics such as solitariness, poor peer relationships, social anxiety, underachievement in school, hypersensitivity, peculiar thoughts and language, and idiosyncratic fantasies (APA, 2013).

Individuals diagnosed with Cluster B disorders, such as BPD, often overuse health- and mental-health-related resources. Individuals with BPD frequently display chronically unstable behaviors in early adulthood, with a serious lack of affective and impulse control. Impairment from the disorder and the risk for suicide are highest during the young-adult years (APA, 2013).

Individuals who will be later diagnosed with a Cluster C disorder (avoidant or dependent) will become increasingly shy during adolescence and early adulthood and avoid developing the social relationships characteristic of that developmental age (APA, 2013). However, clinicians caution against diagnosing children with dependent and avoidant disorders when the behaviors may actually be developmentally appropriate.

Personality Disorders in Pregnant Women

Little is known about the relationship of personality disorders and pregnancy. However, there has been some limited research on the relationship between hyperemesis gravidarum (HG), intractable nausea and vomiting during pregnancy, and psychiatric disorders, particularly anxiety and personality disorders. One study discovered that rates of major depression, generalized anxiety disorder, avoidant personality disorder, and obsessive-compulsive personality disorder were significantly higher in women with HG, with the onset of the disorder primarily occurring prior to pregnancy (Uguz et al., 2012).

Personality Disorders in Older Adults

Although by definition personality disorders have an onset no later than early adulthood, individuals with PDs may escape clinical attention until they are middle-aged or in later life. Often, loss of a significant support person or a stabilizing social situation, such as a job, exacerbates display of the disorder, and associated symptoms cause the individual to seek treatment (APA, 2013). A trained clinician should always evaluate personality changes in middle adulthood or

later life to assess for medical conditions or previously undiagnosed substance use issues (APA, 2013).

Some types of personality disorders, such as antisocial and borderline PDs, become less evident or remit with age, particularly as an individual enters his or her 40s (APA, 2013). The risk of suicide also gradually wanes with age.

NURSING PROCESS

Just as the care of patients with personality disorders will be specific to each patient and the manifestations of the disorder, certain features of the nursing assessment will vary as well. Nurses working with patients with personality disorders should remember that some of the symptoms (e.g., labile affect and impairments in social skills) make it difficult to develop the nurse–patient relationship, especially when the patient denies the presence of symptoms or problems.

Assessment

Assessment data serves as the basis for application of the nursing process. However, assessment of the patient with a personality disorder may be complicated by a number of factors, including lack of insight or self-awareness; denial of the existence or manifestations of a disorder; inability to trust; and ineffective communication skills.

Within the realm of psychosocial assessment, the primary goals of assessment include identification of behaviors, beliefs, or thought patterns that disrupt the patient's social, professional, and personal life. When the patient lacks insight about the existence or effects of a PD, pertinent information may be gleaned from reports by family members or others who are closely associated with the patient. However, because maintenance of patient confidentiality is essential, the nurse must avoid overstepping the patient's personal and legal boundaries during data collection.

Data collection should include assessing work history; history of behavior problems, including violence directed at self or others; history of suicidal ideation; methods of resolving conflicts; alcohol and drug use; and nature of relationships with family members, coworkers, and friends. The nurse should ask questions that encourage the patient to describe aspects of self:

- When was the last time you were upset? What upset you? How did you handle it?
- How do others describe you?
- How would you describe yourself?
- What do you like about yourself? What would you like to change?
- How do you usually relate to others?

Assess for signs of self-directed violence, such as cutting (see Figure 29–3); assess for evidence of alcohol or drug use.

Diagnosis

Selection of nursing diagnoses depends on patient-specific needs and strengths, as well as on functional capability. For example, high-functioning patients who have insight into the nature and effects of their PD may be well suited for patient teaching, whereas patients who demonstrate significant

functional impairment and lack of insight may not benefit from teaching. General examples of nursing diagnoses that may be appropriate for inclusion in the plan of care for the patient with a PD may include the following:

- *Injury, Risk for*
- *Self-Directed Violence, Risk for*
- *Other-Directed Violence, Risk for*
- *Self-Mutilation*
- *Coping, Ineffective*
- *Anxiety*
- *Social Isolation*
- *Social Interaction, Impaired*
- *Role Performance, Ineffective*
- *Disturbed Personal Identity*
- *Interrupted Family Processes.*

(NANDA-I © 2014)

Planning

Patient goals are measurable, patient-specific outcomes that allow for evaluation of the efficacy of nursing interventions. Goals of care should be realistic and tailored to the patient. Examples of patient goals that may be applicable to the nursing plan of care for the patient with a PD include the following:

- The patient will remain free from injury.
- The patient will refrain from violent behaviors.
- The patient will report a reduction in anxiety.
- The patient will verbalize emotions to staff.
- The patient will adhere to established rules and guidelines.
- The patient will actively participate in one-on-one and/or group therapy sessions.

Implementation

As with assessment and planning, implementation of the nursing plan of care will vary based on the manifestations and effects of the patient's PD. In general, nursing interventions for patients diagnosed with a PD will include preventing injury and maintaining physical safety of the patient, as well as protecting the safety of individuals with whom the patient interacts. In addition, promotion of comfort—both physical and psychosocial—is a priority of care. Psychosocial aspects of comfort promotion include building a therapeutic relationship with the patient and effectively managing conflicts. In a respectful, professional manner, the nurse establishes clear boundaries and limits for the patient. For patients who are amenable to socialization, the nurse identifies patient-specific interventions that will afford the patient the opportunity to learn and practice social skills.

Promote Safety

With all patients, priorities of care include injury prevention and safety promotion. For patients with PDs, some of whom are prone to self-destructive and impulsive behavior, the emphasis on injury prevention is heightened. Behavioral contracts that outline prohibited actions and the consequences of

those actions may be used to establish clear guidelines and expectations with regard to any form of behavior, including that related to injuring self or others. Basic precautions for patients in hospital settings include:

- Ensuring that the patient's environment is free from items that may be used to harm self or others
- Providing close supervision and monitoring
- Encouraging patients to seek assistance from members of the healthcare team when they need to process their feelings, including when they perceive that their stress levels are rising
- Encouraging patients to participate actively in therapy and groups.

In the community setting, clinicians also need to monitor patients for safety. Some considerations include the following points on medication safety and self-monitoring of mood and environment.

- Provide medication teaching regarding dosage and intervals, anticipated side effects, potential adverse reactions, and when to contact the healthcare provider for follow-up care.
- With adolescents and young adult patients, make sure that the patient and the family or support persons know that SSRIs carry an FDA black box warning regarding increased suicidality for that age group and are aware of the warning signs of increased suicidal ideation.
- Ensure that patients who engage in nonsuicidal self-injury (NSSI) know to contact their healthcare providers if they experience an increase in the occurrence or severity of these behaviors.
- Make sure that patients live in a safe environment where they will not be exposed to violence or financially or emotionally exploited. Patients who receive disability payments for their mental health disorders are often isolated and can be preyed on by coercive family or individuals in the community.

Promote the Therapeutic Relationship

The ineffective social skills and impaired perceptions that often accompany PDs can create unique challenges in the establishment of a therapeutic nurse–patient relationship. Moreover, for patients who struggle with trust issues, unplanned admission to a hospital or treatment center can exacerbate their anxiety and sense of mistrust. Consistency with patient care—including demonstration of respect for the patient at all times—is one of the first steps to building trust.

- Avoid stigmatizing the patient because of his illness. Individuals with PDs have a neurobiological imbalance in the brain, not a defective personality. Also, consider that many patients also have medical conditions and have experienced stress, trauma, severe childhood abuse, prolonged substance abuse, and exposure to toxins, and have genetically inherited traits.
- Balance flexibility with firmness. Patients may be unwilling to accept responsibility and unable to remember agreements, and they may be untrustworthy, difficult to understand, inconsistent with discipline, poor at keeping

appointments, and unpredictable emotionally. However, missed appointments, lying, and dangerous behaviors cannot be accepted. Precise oral and written communication is the best way to avoid misunderstandings.

- Focus on the strengths of the individual and his family system. Clinicians will have more success and reduce stress and stigmatization if they match interventions with patient strengths.

Establish Boundaries

Boundaries are limits that define what is acceptable to an individual in every facet of life, including the physical, mental, emotional, sexual, relational, spiritual, and professional realms. A breach of boundaries occurs when those limitations are ignored or exceeded. In many ways, definition of boundaries occurs during childhood, beginning in infancy, through experiencing interactions with others.

In the context of the nurse–patient relationship, establishing and maintaining healthy boundaries establishes a sense of safety and predictability for the patient. As the result of past experiences, including a history of abuse and a sense of shame that may accompany the stigmatization often associated with mental illness, the patient with a PD may have unhealthy, unclear, or nonexistent boundaries. The nurse can help the patient to understand and set healthy boundaries through interventions such as teaching, as well as through role playing with the patient. In helping the patient establish healthy boundaries, the nurse can use role play to simulate situations in which the patient is faced with potential boundary violations, assess the patient’s coping skills, and teach the patient about healthy responses to attempted boundary violation (Potter & Moller, 2016).

Regardless of the patient’s behaviors, the nurse is responsible for maintaining healthy professional boundaries. Provision 2 of the American Nurses Association’s (ANA) Code of Ethics (2015) requires the nurse to establish and maintain boundaries, and to effectively set limits with patients. Establishing professional boundaries includes choosing which of the nurse’s personal information is appropriate for sharing with the patient. Especially because of the intimate nature of the nurse–patient relationship, the patient also may ask personal questions—for example, whether or not the nurse is married or has children. Sharing some degree of background information in an appropriate, professional manner can strengthen the nurse–patient relationship; however, the oversharing of personal information is detrimental and non-therapeutic. Through sharing details of personal problems and struggles with the patient, the nurse can create an unnecessary—and unethical—burden for the patient, who is the one seeking care. Boundary violations occur when meeting the nurse’s needs takes precedence over meeting the patient’s needs. For further illustration of maintaining professional boundaries in nursing, see **Table 29–5** ».

» **Stay Current:** The National Council of State Boards of Nursing offers additional guidance and strategies regarding professional boundaries at <https://www.ncsbn.org/professionalboundaries.htm>

Evaluation

Evaluation is a dynamic, ongoing feature of the nursing process that includes identifying the degree to which patients have achieved the goals and outcomes established in relationship to each nursing diagnosis. While goals and outcomes for the patient with a PD will vary based on

TABLE 29–5 Maintaining Professional Boundaries in Nursing

Boundaries Maintained	Boundaries Breached
Keeping one’s personal life private and focusing on the patient’s needs	Sharing details of personal life, issues, and/or problems with a patient
Sharing limited details about basic background information when asked, such as marital status, number of children, educational background, and professional nursing background	Discussing the state of one’s marriage (e.g., marital separation or currently in the process of divorce); sharing about one’s children’s behavioral problems or medical challenges; discussing personal, emotional, or legal problems or setbacks
Maintaining all patient-related information as confidential, and discussing only relevant aspects of the patient’s condition and care with the necessary health-care team members in the workplace	Revealing patient-related information to anyone who is not involved in planning or administering care to the patient
Limiting discussion of patients and their care to within the clinical setting	Discussing patients and their care in the hospital cafeteria, hallways, or other nonclinical areas; sharing any patient-related information through any format, including via social media
Interacting with the patient only during scheduled duty hours for professional intents and purposes	Visiting the patient during off-duty hours, in or away from the clinical setting; communicating with the patient by any means for purposes other than those directly related to the patient’s plan of healthcare
Demonstrating respect for one’s institution or organization, work policies, and other members of the healthcare team, and declining to discuss workplace-related conflicts or criticisms	Venting to the patient about issues or concerns regarding one’s employer, work policies, or other members of the healthcare team
Facilitating referrals for patients with financial needs to appropriate organizations or assisting the patient in connecting with official agencies who can provide assistance	Giving patients personal items or financial assistance
Identification and referral to appropriate healthcare team members for resolution of the patient’s personal conflicts	Choosing to side with a patient during conflict between patients and their spouses, family members, or significant others

Sources: Based on Potter, M. L. & Moller, M. D. (Eds.). (2016). *Psychiatric-mental health nursing: From suffering to hope*. Upper Saddle River, NJ: Remshardt, M. A. (2012). Do you know your professional boundaries? *Nursing Made Incredibly Easy*, 10(1), 5–6.

patient individuality and the nursing diagnoses included in the nursing plan of care, examples of achieved outcomes relevant to the evaluation of patient care may include the following:

- The patient remains free from injury.
- The patient does not demonstrate violent behaviors toward self or others.
- The patient verbalizes understanding of the concept of boundaries.
- The patient verbalizes understanding of the principles of respecting boundaries related to self and others.
- The patient actively participates in individual and/or group therapy.

Given that many of the personality disorders discussed in this section are resistive to treatment and the therapies are challenging and lengthy even for motivated patients, treatment failures do occur. In these cases, the clinician should reevaluate the plan of care. This includes conducting a strengths-based assessment of the patient and his or her supports: Has the patient's financial situation changed, necessitating more community services? Has a lifelong support died or disappeared from a patient's life, affecting his or her ability to cope? Are additional community services available that were not in place when the patient's last plan of care was constructed? Is the patient enthusiastic about the new plan of care, and is he or she capable of participating in the interventions proposed?

Nursing Care Plan

A Patient with Borderline Personality Disorder

Kathryn Harrison is a 20-year-old female patient transported to the emergency department (ED) by law enforcement. Officer Rick Natami, the attending police officer, reported that Ms. Harrison broke a window with her fist while arguing with her boyfriend. Subsequently, Ms. Harrison told her boyfriend she was going to kill herself. At that point, Ms. Harrison's boyfriend called 911. In addition to law enforcement, emergency medical personnel also responded to the call. Officer Natami reported that Ms. Harrison was combative at the scene and would not allow the paramedics to assess her injuries, nor would she permit them to transport her to the ED by ambulance. Her boyfriend had handed her a dish towel to wrap her hand, and while there is blood visible on the towel, the bleeding does not appear to be copious. As a result, because of her injuries and her threat to commit suicide, Officer Natami handcuffed and transported Ms. Harrison in his squad car for physical and psychiatric evaluation.

Upon arrival to the ED, Ms. Harrison is cursing at Officer Natami, as well as anyone with whom she makes eye contact, including her attending nurse. When the ED physician asks if he can assess Ms. Harrison's injuries, she replies, "Yeah, if you tell the cop to take these handcuffs off me and make him leave! You're cool, but he's a total jerk!" The ED physician tells Ms. Harrison he will ask the police officer to remove the handcuffs and stand outside the examination room, but only if she agrees to remain calm and noncombative. Ms. Harrison agrees, and the officer removes her handcuffs and steps outside the room. Because Ms. Harrison has previously been treated at the facility, her electronic medical record (EMR) is accessible. Based on her EMR, her past medical history includes borderline personality disorder and previous treatment for self-inflicted superficial leg lacerations. Before the ED physician evaluates Ms. Harrison's lacerations, he quietly asks the nurse to order a psychiatric consultation for the patient.

ASSESSMENT	DIAGNOSES	PLANNING
Following closure of her lacerations, Ms. Harrison agrees to allow the nurse to assess her vital signs and auscultate her heart and lungs. Vital signs include temperature 97.3°F oral, pulse 90 bpm, respirations 20/min, and BP 133/71 mmHg. Ms. Harrison's heart tones are normal; however, the nurse hears faint, bibasilar wheezes in her lungs. When the nurse asks if Ms. Harrison has had any recent respiratory problems, she replies, "I have no idea. I don't have health insurance and nobody cares anyway. I'm just a piece of garbage." Ms. Harrison begins to cry and states, "I don't know why I get so mad. I'm such an idiot! My boyfriend should dump me, just like everybody else does." The nurse verbally reassures Ms. Harrison that she is safe and will receive the best possible care. Ms. Harrison replies, "I'm sorry I called you names earlier—you're the nicest nurse I've ever met. The nurses on the psych floor are mean. They're only going to make me take a bunch of pills. I wish I could stay here, with you."	<ul style="list-style-type: none"> ■ <i>Injury, Risk for</i> ■ <i>Self-Directed Violence, Risk for</i> ■ <i>Other-Directed Violence, Risk for</i> ■ <i>Skin Integrity, Impaired</i> ■ <i>Self-Mutilation, Risk for</i> ■ <i>Coping, Ineffective</i> ■ <i>Suicide, Risk for</i> <p>(NANDA-I © 2014)</p>	<ul style="list-style-type: none"> ■ The patient will sustain no further physical injury. ■ The patient will not injure others. ■ The patient's wound will be closed and protected from further injury or contamination. ■ The patient will express her emotions to members of the healthcare team in a nondestructive manner. ■ The patient contracts for safety by agreeing to notify staff if she experiences any thoughts of nonsuicidal self-injury (NSSI) or suicide.

(continued on next page)

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Maintain or delegate a team member to maintain constant observation of the patient to assess for and prevent injurious behavior.
- Outline behavioral guidelines for the patient, including the requirement that she cannot injure herself or attempt to injure others.
- Follow institutional guidelines for the application of physical restraints as needed.
- Seek to establish rapport with the patient through demonstrating respect and establishing therapeutic communication patterns.
- Enforce firm boundaries with the patient to prevent staff splitting.
- Encourage the patient to verbalize her emotions and use active listening techniques.
- Educate the patient about dressing changes and basic principles of wound care.

EVALUATION

Following evaluation by the on-call psychiatrist, Ms. Harrison was admitted to the psychiatric unit and hospitalized for 3 days. During her stay, she was argumentative with several of the staff nurses and patient care technicians, but she appeared to favor one of the nurses, Jim. When Jim was on duty, she first insisted that he be assigned to care for her but later refused to allow him to be her nurse, stating, "He's a jerk, just like my boyfriend." In meetings with the clinical psychologist, Ms. Harrison reported a history of physical abuse during childhood, including sexual abuse by an uncle, as well as several physically abusive dating relationships. When asked

about abuse in her current relationship, Ms. Harrison denied any abuse and reported that her boyfriend was "the only person who ever cared" about her. The psychologist referred Ms. Harrison to a counselor who specialized in dialectical behavior therapy (DBT), but Ms. Harrison declined and stated, "I don't want to keep talking about stuff that happened when I was a kid. I just need to stop getting so mad at my boyfriend." She sustained no further injury during her hospitalization and was not physically abusive toward staff. Upon discharge, Ms. Harrison agreed to return to the ED in 7 days for suture removal.

CRITICAL THINKING

1. What other nursing interventions might be appropriate for inclusion in the plan of care for Ms. Harrison?
2. Describe two instances in which Ms. Harrison demonstrated splitting. How should the nurse address patients who demonstrate splitting behaviors?
3. Why did the psychologist recommend dialectical behavior therapy (DBT) for Ms. Harrison? How is DBT believed to be beneficial to patients diagnosed with BPD?

REVIEW Personality Disorders

RELATE Link the Concepts and Exemplars

Linking the exemplar on personality disorders with the concept of stress and coping:

1. In relationship to personality disorders (PDs), describe three behaviors that reflect impaired coping.
2. How does manipulation, which is a behavior associated with several PDs, affect the nurse's morale and stress level? Explain how the nurse can effectively cope with manipulation in the course of a therapeutic relationship.

Linking the exemplar on personality disorders with the concept of safety:

3. Which PDs are associated with a high risk for injury? How does impulsiveness increase the risk for injury?
4. A patient who is diagnosed with schizotypal personality disorder tells her nurse she hears voices that are ordering her to cut her wrists. How should the nurse respond? To protect the patient from injury, what actions should the nurse take?

REFLECT Apply Your Knowledge

Steffan Richter, a 32-year-old man, recently was diagnosed with avoidant personality disorder. The psychiatrist who made the diagnosis recommended that Mr. Richter begin psychotherapy, but Mr. Richter declined after learning that group therapy may be indicated at some point during treatment. To Mr. Richter, psychotherapy would be almost unbearable, but talking about his issues in a group setting would be impossible.

Since graduating from college 10 years ago, Mr. Richter has worked as a mailroom clerk. Having earned a bachelor's degree in accounting, Mr. Richter is qualified to apply for other, higher-paying positions within the company. However, he chooses to maintain his current position, as his present job responsibilities greatly limit his need to interact with other individuals. Several years earlier, he was offered a supervisory position; however, he declined the offer. The promotion would have increased his salary significantly, but the job responsibilities included a great deal of interaction with the mailroom team and administrators.

During lunchtime, the mailroom shuts down operations so all employees can eat their meals together in the staff lounge. Because he finds the lunchtime social interaction in the staff lounge to be forced, unpleasant, and overwhelming, Mr. Richter remains in the quiet mailroom and reads a book during his break. Company policy restricts employees from eating in any areas other than the staff lounge, and employees are forbidden to leave the building during their work shift. Therefore, Mr. Richter never eats lunch during the week.

Because Mr. Richter is extremely shy and quiet, several of his coworkers refer to him as “the invisible man.” He is also very underweight, and some of his coworkers tease him about his size. Although he finds his nickname and the teasing to be cruel and humiliating, Mr. Richter does not share his feelings; instead, he resolves to stay as far away as possible from the group. Several of his coworkers have invited him to join the group for social activities outside of work; however, he declines their invitations, as he knows his coworkers will only further demean and embarrass him. To avoid being humiliated or

rejected, Mr. Richter does not build friendships at or away from his workplace.

1. How are the effects of avoidant personality disorder impacting Mr. Richter’s occupational and professional advancement?
2. In what ways does avoidant personality disorder impact Mr. Richter socially, both in and out of his workplace?
3. How does avoidant personality disorder affect Mr. Richter’s nutritional habits?

Module 30

Spirituality

Module Outline and Learning Outcomes

The Concept of Spirituality

Components of Spirituality

30.1 Analyze the components of spirituality.

Spirituality Throughout the Lifespan

30.2 Summarize the development of spirituality across the lifespan.

Concepts Related to Spirituality

30.3 Outline the relationship between spirituality and other concepts.

Health Promotion and Nursing Assessment

30.4 Explain the promotion of healthy spirituality and the techniques used to determine spiritual needs.

Spiritual Practices Affecting Nursing Care

30.5 Outline spiritual beliefs that can affect nursing care.

Independent Interventions and Collaborative Therapies

30.6 Summarize independent interventions and collaborative therapies used by healthcare teams for patients with spiritual needs.

Spirituality Exemplars

Exemplar 30.A Spiritual Distress

30.A Analyze spiritual distress as it relates to patient health.

Exemplar 30.B Religion

30.B Analyze religion as it relates to spirituality.

>> The Concept of Spirituality

Concept Key Terms

Religion, 2024
Spiritual development, 2025

Spiritual distress, 2024
Spiritual well-being, 2024

Spirituality, 2023

Spirituality is a word derived from the Latin word *spīrare*, which means “to blow” or “to breathe”; it has come to connote that which gives life or essence to being human. A definition of spirituality developed at an interprofessional, international consensus conference, recognized it as

a dynamic and intrinsic aspect of humanity through which persons seek ultimate meaning, purpose, and transcendence, and experience relationship to self, family, others, community, society, nature, and the significant or sacred. Spirituality is expressed through beliefs, values, traditions, and practices (Puchalski et al., 2014, p. 646).

Components of Spirituality

Because spirituality is a reflection of an inner experience that is expressed individually, it includes as many representations as there are human beings.

Spirituality, according to one classic source, can be described by measuring it, so to speak, on a “spirit titer” (Jourard, 1971). One’s spirit titer is influenced by numerous factors, such as life experiences, coping skills, social supports, and individual

belief systems. Individuals experience multiple changes and losses over their lifespan; if their spirit titer is low, they may become dispirited or depressed. If they have a high spirit titer, they will lean toward being inspired and becoming an inspiration to others in spite of hardships they experience (**Figure 30–1** >>). Nurses can aid healing when they assist patients in attaining and maintaining a high spirit titer.

Since 1989, more than 40 nurse scholars have conducted conceptual analyses of spirituality or closely related concepts to identify their constituent facets and characteristics. These analyses and definitions typically offered in the nursing literature consistently identify several core facets (e.g., Stephenson & Berry, 2014; Weathers, McArthur, & Coffey, 2016). Whether describing the spirituality of children or persons facing the end of life, these core facets include:

- Meaning (having purpose, making sense of life, having explanatory beliefs)
- Connecting (relating to others, nature, Ultimate Other, Higher Power, or God)
- Transcendence (appreciating a dimension that is beyond the self)

Figure 30-1 >> Each individual's spirit titer is influenced by their life experiences, coping skills, social support, and belief system.

Understanding how spirituality influences a patient's decision making and response to a health challenge, as well as how spirituality can be affected by illness, is crucial for nurses. Key components and expressions of spirituality include spiritual well-being, spiritual distress, spiritual needs, religion, and morality and ethics.

Spiritual Well-Being

Spiritual well-being, *wellness*, or *health* was defined by NANDA-I as a "pattern of experiencing and integrating meaning and purpose in life through connectedness with self, others, art, music, literature, nature, and/or a power greater than oneself that is sufficient for well-being and can be strengthened" (Carpenito-Moyet, 2013, p. 838). It is characterized by trusting relationships, inner strength, meaningfulness, and "motivation and commitment directed toward ultimate values of love, meaning, hope, beauty, and truth" (p. 838). According to one pioneer in the field, spiritual well-being is manifested by a feeling of being "generally alive, purposeful, and fulfilled" (Ellison, 1983, p. 332).

Spiritual Distress

Spiritual distress refers to a challenge to or feeling of dissatisfaction with one's spiritual well-being or with the belief system that provides strength, hope, and meaning to life. Some factors that may be associated with or contribute to an individual's spiritual distress include physiologic problems, treatment-related concerns, and situational concerns (e.g., death or illness of a significant other, inability to practice

one's spiritual rituals, or feelings of embarrassment when practicing them) (Carpenito-Moyet, 2013).

Spiritual Needs

Just as every individual has a spiritual dimension, all patients have needs that reflect their spirituality. These needs are often accentuated by an illness or other health crisis. Patients who have well-defined spiritual beliefs may find that their beliefs are challenged by their health situation or may hold to their beliefs more firmly and appreciatively. Patients who have no defined beliefs may suddenly come face to face with challenging questions such as "Why me?" and others related to the meaning and purpose of life. Nurses need to be sensitive to indications of the patient's spiritual needs and respond appropriately. Examples of spiritual needs are listed in **Box 30-1** >>.

Religion

Although nurses may use the term *spirituality*, patients may equate it with religion. A **religion** is a system of beliefs that offer explanations and practices that allow one to cope with life's questions and challenges (Taylor, 2012). Thus, religions, whether institutionalized or not, provide means for gaining awareness of and expression of spirituality. Religious beliefs begin to answer questions about what is the nature of humankind and, how it came to be, what its purpose is, what is suffering, and what happens after death. Religious practices allow for the study and integration of these beliefs, and means and support for worshipping and

Box 30-1

Examples of Spiritual Needs

Needs Related to the Self

- Need for meaning and purpose
- Need to express creativity
- Need for hope
- Need to transcend life challenges
- Need for personal dignity
- Need for gratitude
- Need for vision
- Need to prepare for and accept death.

Needs Related to Others

- Need to forgive others
- Need to cope with loss of loved ones.

Needs Related to the Ultimate Other

- Need to be certain there is a God or Ultimate Power in the universe
- Need to believe that God is loving and personally present
- Need to worship.

Needs Among and Within Groups

- Need to contribute or improve one's community
- Need to be respected and valued
- Need to know what and when to give and take.

Source: From Taylor, E. J. (2002). *Spiritual care: Nursing theory, research, and practice*. Upper Saddle River, NJ: Prentice Hall. Reprinted by permission of Pearson Education, Inc., Upper Saddle River, New Jersey.

connecting with what is divine. Given this, it is natural that many religious practices are related to such life events as birth, transition from childhood to adulthood, marriage, illness, and death. Religious rules of conduct, typically influenced concurrently by culture, may also apply to matters of daily life such as dress, food, social interaction, childrearing, menstruation, and sexual relationships (Taylor, 2012).

Spirituality generally involves a belief in a relationship with some higher power, creative force, divine being, or infinite source of energy. For example, an individual may believe in God, Allah, the Great Spirit, or a Higher Power. Monotheism is the belief in the existence of one god, whereas polytheism is the belief in more than one god. An agnostic is an individual who doubts the existence of God or a supreme being or who believes that the existence of God has not been proved. An atheist is an individual who does not believe in any god.

Those who live in the United States of America are fairly religious. Surveys of U.S. Americans (The Association of Religion Data Archives, n.d.) revealed the following:

- 77% reported religion was an *important* part of their life
- 48% identified themselves as Protestant, 25% as Roman Catholic, 17% as “None,” 8% as other (e.g., Buddhist, Muslim, Hindu), and 2% as Jewish (see **Figure 30-2** »).
- 63% agreed that they had “no doubt that God exists,” whereas 12% did so but with some doubt; 12% believed in “a Higher Power or cosmic force”
- 57% prayed at least once a day, 28% read sacred texts about weekly or more frequently, and 23% attended religious services at least once every week.

The frequency of religious practices does vary over the lifespan with an increase correlating directly with age. Indeed, various surveys suggest that older adults (especially those facing death), African Americans, and women tend to report more religiosity (e.g., Krause, 2011).

SAFETY ALERT Thinking about spirituality only as religion will cause an unethical stance toward nonreligious patients that is insensitive and domineering. Conversely, conceptualizing spirituality without religion will contribute to nursing care that is insensitive of patient religiosity and overlook this salient influence on religious patients’ illness experiences (Pesut, 2016).

Morality and Ethics

Ethics guides the determination of what is “right” and “wrong” and deals with “oughts” and “shoulds” (Fowler, 2015). Morality refers to the rules a society has created for promoting ethical conduct, or right and virtuous behavior (see the module on Ethics). Considering that spirituality by definition recognizes individual needs for meaning and concern about supreme values, it certainly can be related to morality and ethics. Applying values and assigning meaning to things in life is inherent in ethical and moral decision making. The acts of valuing and finding meaning are acts involving and reflecting spirituality. When one asks ethical questions (e.g., “What is right in this situation? What ought I to do?”), one is also inevitably raising spiritual questions (e.g., “What is the source of truth for me?”).

Spirituality Throughout the Lifespan

Just as individuals develop physically, cognitively, and morally, they also develop spiritually. The most influential description of **spiritual development** was offered by Fowler (1981). Although Fowler used the term “faith” development, he recognized faith as a universal human phenomenon that leads individuals to need and find meaning and an understanding of themselves in relation to their world. Fowler arrived at these seven stages of faith development after analyzing in-depth interviews with more than 400 individuals who ranged in age from 3 to 84 years.

- **Undifferentiated faith** (infancy to 3 years): During this time, neonates and toddlers are acquiring the fundamental spiritual qualities of trust and mutuality, as well as courage, hope, and love. The transition to the next stage of faith begins when the child’s language and thought start to converge, allowing for the use of symbolism. Sadly, these spiritual qualities can also be undermined, rather than developed, as may occur in situations of child abuse.
- **Intuitive-Projective faith** (3 to 7 years): This is the “fantasy-filled, imitative phase in which the child can be powerfully and permanently influenced by examples, moods, actions and stories of the visible faith” (Fowler, 1981, p. 133). During this stage, children relate intuitively to the ultimate conditions of existence through stories and images, the fusion of facts and feelings. Magical thinking and reality overlap during this stage. For example, children at this age view Santa Claus as real and may view God as a big, smiling (or frowning) granddaddy in the sky (depending on the stories the important adults in the child’s life tell).
- **Mythic-Literal faith** is found among school-age children (up to 12 years) but can linger even into adulthood. During this stage of faith, children are attempting to sort out what is fantasy from what is fact, by demanding

proofs or demonstrations of reality. Stories become a critically important means for children this age to find meaning and to give organization to experiences. It is a task of these children to learn not only the stories but also the beliefs and practices of their community. They accept stories and beliefs literally rather than with abstract meanings. In this stage, for example, a Latter Day Saints child will begin learning the stories of the Bible and Book of Mormon, accepting them at face value; these stories will provide the child with a way of making sense of the community and the world of which he or she is a part.

- **Synthetic-Conventional faith** emerges when the individual begins to reflect on incongruities observed between stories. This stage of faith usually applies to adolescents and teens, but it can also characterize some adults. The synthetic-conventional stage accompanies the individual's experience of the world that is now beyond the family unit (e.g., school, media), and must provide a helpful understanding of this extended environment. While faith "must synthesize values and information; it must provide a basis for identity and outlook" (Fowler, 1981, p. 172). At this stage, individuals generally conform to the beliefs of those around them, because they have yet not reflected or studied these beliefs objectively. Thus, beliefs and values of teens are often held tacitly. For example, an adolescent or teen raised by observant Jews will likely continue to observe the Jewish practices of parents and accept parents' beliefs.
- **Individuative-Reflective faith** is typically observed among young adults, but may continue into later adulthood. This stage of faith is characterized by the development of a self-identity and worldview that is differentiated from those of others. The individual forms independent commitments, lifestyle, beliefs, and attitudes. The child who obediently attended Mom's Roman Catholic mass every Sunday will now examine independently what religious practices and beliefs to accept. Another characteristic of this stage of development is the demythologizing of symbols into conceptual meanings. To illustrate, the young adult who was taught as a child not to place anything on top of holy scriptures because of their sacredness, now understands that this is not religious edict, but rather an authority's attempt to teach respect for an object that informs the reader about what is sacred.
- **Conjunctive faith** usually is found among adults past midlife. At this stage, adults find new appreciation for their past, value their inner voices, and become aware of deep-seated myths, prejudices, and images that are indwelling because of their social background. An individual with conjunctive faith "strives to unify opposites in mind and experience" and allows "vulnerability to the strange truths of those who are 'other'" (Fowler, 1981, p. 198). For example, instead of trying to dissuade or avoid another with differing spiritual beliefs, a person in this stage of faith would embrace persons of other faith traditions, recognizing that in their faith may be new understanding. Also, an adult whose faith is conjunctive may practice prayer in a way that allows listening to the deeper self, instead of petitionary praying.
- **Universalizing** of faith is infrequently reached. Those in this stage of faith have a "sense of an ultimate environment

[that] is inclusive of all being. They have become incarnators and actualizers of the spirit of an inclusive and fulfilled human community" (Fowler, 1981, p. 200). These persons work to unshackle social, political, economic, or ideologic burdens in society. They fully love life, yet simultaneously hold it loosely. Fowler identified Martin Luther King, Mahatma Gandhi, and Mother Teresa as examples of those having developed this level of faith.

From this descriptive theory, it is evident that the spirituality of children, adolescents, adults, and older adults will differ, although spiritual maturity can be stunted and change little for some. For example, the spirituality of adolescence may continue into adulthood, or the spirituality of mid-adulthood may not change as a person ages. Indeed, it is the crisis of illness, disability, or facing death that often causes individuals to revisit their spirituality and jumpstart continued development.

Another approach to theorizing how individuals develop spiritually is offered by psychologists influenced by theories about object relations and attachment (Hall et al., 2009; Harris et al., 2015). That is, it is proposed that how an individual has related to his mother or other significant caregivers during infancy and early childhood establishes a pattern for how he will relate to others, including a divinity or spiritual community, as an adult. Whereas there is evidence that individuals' ways of relating to God and others—with secure versus insecure attachment (e.g., avoiding or resisting)—corresponds with how they related to their parent figure(s), there is also evidence that compensatory attachments can also occur. For example, a person whose parent abused them as an infant can compensate by viewing God as the ideal parent.

Research by Hall and colleagues (2009, 2015) integrates these notions of correspondence and compensation. They proposed that explicit aspects of spirituality that can be chosen and controlled (e.g., religious beliefs and practices) can mediate implicit spirituality, which is based on the unconscious emotional information processing all persons have and which is influenced by early life experiences. For example, a patient who had an insecure attachment with a parent who was often absent, and coped with it by avoiding that parent, may experience the divine (e.g., God) as absent and avoid intimacy with God. Spiritual beliefs may, however, encourage the patient to use practices that allow this human-divine abyss to be approximated.

Spiritual Development of Children

Given the development of spirituality in children parallels their cognitive and psychosocial development, nursing care that supports spiritual well-being will consider what is age appropriate. Nurses can help ill or injured children to make sense of their health challenge by asking simple questions (e.g., "How are you like [name child's hero/heroine]?"), by actively listening, by offering opportunities to practice religious rituals the ways their parents do, and by providing materials for nonverbal expression (e.g., painting, play, music) (Petersen, 2014). For infants especially, it is imperative that nurses support parent-child bonding so that trust and a secure attachment can be encouraged. Secure attachment can be encouraged not only by allowing parents to be present with their child, but also by modeling or otherwise teaching parents about how to be fully and empathically present to their child.

Spiritual Development of Adolescents

Adolescents are, by nature, in the process of learning to differentiate themselves from their parents, form their own unique identity, and think independently and critically. Their spirituality will reflect this development. Adolescents are risk takers, seek to conform to others, and often make decisions that are focused in the present rather than on future possibilities or consequences (Magaldi-Dopman & Park-Taylor, 2013). Thus, adolescents may be inclined toward a spirituality or religiosity that “scratches these itches” (e.g., hyper-sensationalized worship experiences, cults, critically evaluating parental religiosity, choosing non-institutionalized expressions of spirituality). Yet evidence also indicates that adolescent religiosity generally corresponds with parental religiosity, especially if there is a warm, stable home environment and healthy parent-child relationship (Taylor et al., 2015). Nursing care for adolescents that supports spiritual well-being will recognize these characteristics. An example of a proven intervention for enhancing the spiritual well-being of adolescents with cancer is that of producing a music video. Working with a music therapist, adolescents can compose their lyrics, choose music, and select images or cast members and direct and produce their own videos (Robb et al., 2014).

Spiritual Development of Adults

Adulthood is a season of the lifespan when individuals typically form their own nuclear family and build a career and roles in their community. Meaning and connectedness are often related to these natural strivings. Thus, when the plan is ruined (e.g., by a significant loss or change such as divorce, chronic illness or disability, deadly accident, unemployment, or natural disaster), and the individual's sense of the world as safe and good is shattered, the person begins to reconstruct meaningfulness (Marris, 2016). Whereas some patients will “get stuck” asking existential questions and “Why me?”, others will find illness to be a sacred journey and suffering to prompt spiritual transformation (Linders & Lancaster, 2013). As Fowler (1981) observed, some adults maintain the spirituality of their adolescence and young adulthood, while others grow spiritually.

Spiritual Development of Older Adults

There is evidence that spirituality increases among older adults, especially among women, starting as early as the late 50s (Krause, 2011; Wink & Dillon, 2003). Many older adults frequently use and highly value religious coping strategies such as prayer. Older adults may be especially concerned about living a purposeful life, about maintaining loving relationships to avoid social isolation, and about leaving a legacy and preparing for a peaceful death. Nursing care for older adults can support meaning-making activities. Some examples of meaning-making activities include conducting a life review or reminiscence therapy that allows the patient to weave together the strands of lived life; encouraging the patient to become dedicated to some social, political, religious, or artistic cause; and supporting the patient to leave a legacy or do an altruistic deed. As appropriate, nurses may also support older adults to reframe the “losses” of aging as “liberations.” For example,

older adults possess great wisdom and are in a season of life that promotes spiritual growth.

Patients with dementia present special circumstances for spiritual caregiving. Nurses can help those with early stages of dementia to focus on the positives, the “haves” rather than the losses. Allowing older adults with dementia to tell their stories helps them to maintain some identity in the face of a disease that threatens the very sense of self. It also gives the nurse a window into the patient's world. Patients with dementia can also worship and express their hope and creativity through various art forms (e.g., movement, painting, music). These patients are often able to experience the compassion of others when they feel their caring touch or hear their soothing voice.

SAFETY ALERT Fowler (1981) observed that it is easy for individuals to have a disparaging view of those who are in a spiritual developmental phase from which they have just emerged. It is important for nurses to not view another as spiritually immature. Rather, it is helpful to remember that all persons are journeying as best they can through life (Brown, 2015).

Case Study » Part 1

Tom Denton, a young adult male Jehovah's Witness, is brought into the emergency department (ED) with a gastrointestinal (GI) bleed. He is vomiting blood, hypotensive, pale, and diaphoretic, and his pulse is weak and thready. He is alert enough to hear Sharon Hynes, the ED physician, order a type and cross for four units of blood. Mr. Denton interrupts and states that he does not want the blood transfusion because of personal religious beliefs. Dr. Hynes orders volume-expanding agents to be used instead. Mr. Denton's wife Melissa arrives not long before he loses consciousness, and they discuss the use of the volume expanders versus blood transfusions. She agrees with his decision and tells him she loves him. He tells her he loves her also.

Clinical Reasoning Questions Level I

1. What are the primary concerns for Mr. and Mrs. Denton?
2. How are the staff and others likely to react to the couple's decision? Why?
3. How do the principles of autonomy affect this scenario?

Clinical Reasoning Questions Level II

4. Jehovah's Witnesses who receive a blood product against their will refer to that as “medical rape.” In what ways might they experience rape trauma syndrome symptoms?
 5. If Dr. Hynes had written a PRN order for blood “just in case Mr. or Mrs. Denton change their mind,” what would be your role as a nurse advocate?
 6. If Melissa had disagreed with Tom regarding this matter, how could an RN facilitate open and helpful communication between them?
-

Concepts Related to Spirituality

In today's busy healthcare environment, it can be easy for nurses and other healthcare providers to overlook a patient's spirituality. However, nurses understand that spiritual assessment can inform interventions that foster hope and incorporate a patient's spirituality as a resource for motivating patient change and improving patient outcomes (Neuman & Fawcett, 2002). As such, spirituality can be related to all aspects of a

Concepts Related to Spirituality

CONCEPT	RELATIONSHIP TO SPIRITUALITY	NURSING IMPLICATIONS
Comfort	Spiritual/religious beliefs may dictate how to interpret and address pain and discomfort.	Assess how patients ascribe meaning to pain and suffering. Consider alternative therapies to manage discomfort if the patient wants to avoid opioids or other medications.
Culture and Diversity	Religion, an expression of spirituality, is integral to culture.	Be aware and sensitive to the diverse religious beliefs and practices of patients. If you don't know, assess (e.g., Please tell me about any religious beliefs or practices that should affect your healthcare).
Legal Issues	Western cultures, such as those in North America, have federal laws protecting personal religious liberties.	Clarify, advocate, and seek legal support if necessary, when a patient or colleague's religious liberties are threatened.
Nutrition	Spiritual/religious beliefs often prescribe a diet (e.g., vegetarianism, abstinence from alcohol). Some religious holidays are observed with fasting from all or certain specified foods.	Assess what diet the patient prefers.
Sexuality	Practices related to sexuality, such as family planning/birth control, may be influenced by spirituality.	When appropriate, assess the influence of spirituality on sexuality and associated practices. Provide care that is congruent with patients' spiritual/religious beliefs and practices.
Stress and Coping	People can use positive and negative religious coping strategies. Negative religious coping is associated with poor adjustment and outcomes.	Observe for expressions of negative religious coping (e.g., "God is punishing me" or "God/my church isn't there for me anymore"); make an appropriate referral (e.g., chaplain) if it is observed.

patient's health, mental health, and safety. For example, religious practices may include certain dietary restrictions or practices. These can affect prescribed diets, especially when the patient is a member of a family with limited funds for purchasing and organizing family meals. Spirituality may affect sexuality and reproduction if the patient adheres to sexual practices outlined by a religion. Spiritual practices and coping mechanisms can reduce stress and promote healthy coping, but there are some practices that may negatively impact a patient's ability to cope with stress.

The Concepts Related to Spirituality feature links some, but not all, of the concepts integral to spirituality. They are presented in alphabetical order.

Health Promotion and Nursing Assessment

Given that spirituality is an expression of the innate human yearning for meaningfulness, connection, and self-transcendence, it is no wonder that humans in their diversity have developed diverse ways for promoting their spiritual well-being or health. Whether individuals consider themselves as religious or spiritual, most prefer to have satisfactory responses to life's big questions, prefer to be at peace within and without, and want to be awed by something greater and more ultimate.

Until recently, spiritual practices tended to be religion and culture specific (Fowler et al., 2011). For example, Roman

Catholics primarily sought to promote their spiritual health by following the dictates of their church (e.g., regularly attending Mass, confession) and by praying in certain ways (e.g., with rosary, a string of beads that can be touched while saying a petitionary, memorized prayer). Likewise, Sikhs may have sought to become a baptized Khalsa (e.g., live a virtuous life dedicated to God, be prayerful, never cut any body hair, wear specific emblems). In fact, prior to modernization and the Enlightenment, most spiritual health promotion practices would have been religious.

In the world of internet, airplanes, and books, however, ideas are easily transmitted and spiritual practices are readily shared across cultures and continents. Concurrently, spirituality is no longer only within the domain of religion (Wuthnow, 1998). Today, many individuals have a "hyphenated" religiosity or a combination of self-selected spiritual practices that they find personally satisfying (Taylor, 2012). For example, an individual born and raised in a Seventh-day Adventist family may, as an adult, choose to worship weekly in an interfaith congregational church, read about and practice Buddhist meditation, and attend a monthly Baha'i fellowship meeting.

Although spiritual practices rooted in a religious tradition (at least originally) continue to be practiced in or out of a religion, many individuals also recognize secular (or non-religious) approaches to spiritual health. Examples include spending time in nature, experiencing art and beauty, and gaining self-awareness through reflection and conversation.

Hodge (2015) and Taylor (2015) recommend a two-tiered approach to assessing patient spirituality. This approach typically involves the nurse first conducting an initial screening and a slightly more thorough spiritual history assessment. Next, an expert, typically the chaplain, will conduct a more in-depth interview, referred to as the spiritual assessment.

Screening

When a patient enters the healthcare system, a nurse can screen for the presence of any spiritual distress likely to interfere with healing. Fitchett and colleagues (King, Fitchett, & Berry, 2013) developed a screening protocol that is easily implemented. The protocol involves first asking the yes/no question, “Is spirituality or religion (S/R) important to you as you cope with illness?” If a patient responds with “yes,” then the clinician can ask, “How much strength/comfort do you get now?” If spirituality or religiosity is important to the patient, but he is currently not receiving adequate strength or comfort from it, then the nurse can assume that spiritual distress is present and make a referral. If, however, the patient responds that S/R is unimportant, then the nurse can ask, “Has there ever been a time when S/R was important?” If the patient indicates that S/R has been important in the past, it is appropriate for the nurse to ask if the patient would like to visit with a chaplain. If S/R was never important or the patient receives adequate strength/comfort, then the nurse can infer there is no immediate spiritual crisis requiring support. When Fitchett’s team studied the efficacy of this protocol, they found that the screening process was effective 92% of the time in correctly identifying patients with spiritual crisis.

Another approach to spiritual screening is to select a couple of general questions about the impact of spiritual or religious beliefs and practices on health and healthcare (e.g., “What spiritual beliefs or practices are important to you now while you live with illness?” and “How would you like your healthcare team to support you spiritually?”). Only patients who manifest some type of unhealthy spiritual need or who are at risk for spiritual distress need be subjected to a more thorough spiritual history or referred to a chaplain for an in-depth spiritual assessment.

SAFETY ALERT Because nurses are generalists in spiritual care (whereas chaplains, clergy, and others are spiritual care specialists), the role of the nurse in conducting spiritual assessment should be limited to that which is relevant to providing healthcare. It is inappropriate, unnecessary, and harmful to the patient–nurse relationship for a nurse to conduct a spiritual assessment because of personal curiosity or desire to proselytize.

Spiritual History and Observation

Data about a patient’s spiritual beliefs are obtained from the patient’s general history (religious preferences or orientation); through a nursing history; and by clinical observations of the patient’s behavior, verbalizations, mood, and interactions with others. Nurses should never assume that a patient accepts all of the beliefs or follows all of the practices of the patient’s stated religion.

When a more thorough assessment is needed (e.g., the patient is being admitted to the healthcare system and a

more general assessment is appropriate, or the screening protocol reveals spiritual need), the nurse can assess further by conducting a spiritual history. Although the nurse will continually be assessing, the spiritual history is best taken at the end of the assessment process or following the psychosocial assessment, after the nurse has developed a relationship with the patient and/or the patient’s support person. A nurse who has demonstrated sensitivity and personal warmth, earning some rapport, will be more successful during a spiritual assessment.

The most common spiritual history tool may be Puchalski’s (2014) mnemonic **FICA**. This tool prompts the clinician to inquire about these four aspects of spirituality:

Faith or beliefs (“What spiritual beliefs are most important to you?”)

Implications or influence (“How is your faith affecting the way you cope now?”)

Community (“Is there a group of like-minded believers with whom you regularly meet?”)

Address (“How would you like your healthcare team to support you spiritually?”)

Many other questions, however, can be asked. For patients who are not religious, it will be important to select language that is not religious. Examples of questions to ask may include:

- What are your spiritual or religious beliefs or practices that would be important for your healthcare providers to know about?
- How is being sick or in the hospital challenging your spiritual or religious beliefs or practices?
- How is your faith helpful to you? In what ways is it important to you right now?
- What are your hopes and your sources of strength right now? What comforts you during hard times?
- In what ways can I boost your spirit?
- Would you like a visit from your spiritual counselor or the hospital chaplain?

Nurses can also observe for cues about patients’ spiritual and religious preferences, strengths, concerns, or distress. These may be revealed by one or more of the following:

- **Environment.** Does the patient have a Bible, Torah, Quran, other prayer book, devotional literature, religious medals, rosary, cross, Star of David, or religious get-well cards in the room? Does a church send altar flowers or Sunday bulletins? Is there a religious service that is televised or streamed over the internet that the patient would like to watch?
- **Behavior.** Does the patient appear to pray before meals or at other times or read religious literature? Does the patient have nightmares and sleep disturbances or express anger at religious representatives or at a deity?
- **Verbalization.** Does the patient mention God or a higher power, prayer, faith, a church, a synagogue, a temple, a spiritual or religious leader, or religious topics? Does the patient ask about a visit from the clergy? Does the patient express fear of death, concern with the meaning of life,

inner conflict about religious beliefs, concern about a relationship with a deity, questions about the meaning of existence or the meaning of suffering, or questions about the moral or ethical implications of therapy?

- **Affect and attitude.** Does the patient appear lonely, depressed, angry, anxious, agitated, apathetic, or preoccupied?
- **Interpersonal relationships.** Who visits? How does the patient respond to visitors? Does a minister or other spiritual mentor come? How does the patient relate to other patients and nursing personnel?

To provide holistic care, it is important for the nurse to understand the spiritual needs and beliefs of the patient. Understanding and support of a patient's spiritual beliefs and practices builds trust in the nurse-patient relationship, makes the patient feel more comfortable in strange environments, and individualizes the nursing plan of care to meet each individual's unique needs.

Case Study » Part 2

Mr. Denton has slipped into a coma. Mrs. Denton is crying and begging her husband not to leave her. The staff members continue to treat the patient with the volume expanders, but there is no significant improvement. Dr. Hynes speaks to Mrs. Denton and asks whether she has changed her mind.

Clinical Reasoning Questions Level I

1. What would be an empathic and spiritually supportive comment an RN could offer to Mrs. Denton?
2. Who could be called to help Mrs. Denton during this time?
3. What resources are available to help Mrs. Denton?

Clinical Reasoning Questions Level II

4. How should the nurse assess the needs of Mr. and Mrs. Denton at this time?
5. Does Dr. Hynes have the right to ask Mrs. Denton this question? Why or why not?
6. What would be a healing environment for a patient in a coma?

Spiritual Practices Affecting Nursing Care

Patients frequently identify religious practices such as prayer as important strategies for coping with illness (Taylor, 2012). The most common practices affecting the nursing care of patients include practices associated with diet, healing, dress, birth, and death.

Beliefs Affecting Diet

Many religions have proscriptions regarding diet. There may be rules about which foods and beverages are allowed and which are prohibited. For example, Orthodox Jews are not to eat shellfish or pork, and Muslims are not to drink alcoholic beverages or eat pork. Members of the Church of Jesus Christ of Latter-Day Saints (Mormons), Seventh-day Adventists, and Hindus are not to drink coffee or alcoholic beverages. Older Catholics may choose not to eat meat on Fridays because it was prohibited in years past, and abstinence from meat is still required on some days during Lent. Many Buddhists and Hindus are generally vegetarian, not wanting to

take life to support life. Religious law may also dictate how food is prepared; for example, orthodox Jewish patients will request kosher food and Muslims will request halal. For these diets, food (especially meat) is to be obtained and prepared according to rules of the respective religious tradition.

Some solemn religious observances are marked by fasting, which is the abstinence from any or specified food for a specified period of time. Fasting in some religions may also require restricting beverages; others allow drinking of water or other sustaining beverages (e.g., fruit juice) on fast days. For example, Christians who are adherents of an Eastern Orthodox tradition observe numerous feast and holy days during the year. Each holy day has its rules regarding foods to eat; an oil-free and alcohol-free vegan diet will often meet these rules of fasting. During the month of Ramadan, devout Muslims eat no food and avoid beverages during daylight hours before breaking their fast after sunset. Members of Jewish synagogues fast on Yom Kippur, and devout Catholics may fast on the Lenten holy days of Ash Wednesday and Good Friday. Most religions lift the fasting requirements for seriously ill believers for whom fasting may be a detriment to health (e.g., patients with diabetes). Some religions may exempt nursing mothers or menstruating women from fasting requirements.

Healthcare providers should assess and incorporate patients' dietary and fasting beliefs prior to providing meals or prescribing diet plans.

Beliefs Related to Healing

Some patients attribute illness to a spiritual etiology. The most common attributions with spiritual or religious overtones may be those that construe benefit and punishment (Fowler et al., 2011). Examples of construed benefit include: "My illness is making me stronger inside," "This sickness is a wake-up call to get my life in order!" or "This health challenge is really making me draw closer to God and making me appreciate life more." Indeed, many religious traditions view illness and suffering as a test of faith and an opportunity for spiritual growth (Taylor, 2012).

Source: GoldenKB/iStock/Getty Images.

Figure 30-3 » Conservative and Orthodox Jewish men may wear a yarmulke at all times, even in the hospital. Reform Jews may wear yarmulkes only while praying and on religious occasions, such as this family celebrating Hanukkah.

Conversely, a health challenge can be thought of as a punishment, a reflection of a spiritual weakness, or as the result of an evil force. Illustrative patient statements could include: “If I hadn’t been so wild and sinful as a youth (or so unfaithful as an adult), I wouldn’t have this diagnosis now,” or “Satan caused my sickness—and God allowed it.” Although less than a quarter of patients likely make such negative attributions, they are detrimental to psychologic and spiritual well-being (Taylor, 2011). Patients who make such observations warrant further assessment and referral to a specialist. Indeed, clarifying that illness as punishment is not a belief congruent with the patient’s religion (as is often the case) can bring enormous relief and spiritual healing.

Many religions offer healing rituals that symbolize the patient’s choice to place their illness outcomes in the care of the divine (Taylor, 2011). Patients belonging to many Protestant denominations may request their local church minister and/or leaders to administer an “anointing.” Similarly, Roman Catholics will appreciate a priest offering the Anointing of the Sick, as this is not just a ritual for the end of life. Healing rituals may involve reading scriptural passages offering hope and prayers for healing, usually with blessed oil being placed on the recipient’s head. The family of a Hindu patient may visit the local temple and ask the priest for puja, a ritual involving a mantra said with the patient’s name, lighting candles, burning incense, and offering fruit or flowers to an image of a deity. The family may be given a symbol (e.g., piece of sacred cloth) to give to the patient, who can wear it or place it above their bed. A more superstitious Jewish patient may tie a red string around the bedpost or place a psalm on the headboard. Orthodox and Roman Catholic patients, as well as many Protestants, will likely be eager to receive communion and confession from a priest or lay clergy. Patients who profess spirituality may adopt beliefs and rituals from a combination of sources, such as chanting, energy work, lighting candles, or burning sage. Despite the diversity of healing rituals and traditions patients may use, all reflect the human yearning for healing and blessing.

Beliefs Related to Dress

Many religions have laws or traditions that dictate dress. For example, Orthodox and Conservative Jewish men believe that it is important to have their heads covered at all times and therefore wear yarmulkes (**Figure 30-3** ▶). Orthodox Jewish women cover their hair with a wig or scarf as a sign of respect to God (Orthodox-Jews.com, 2014). Mormons may wear temple undergarments in compliance with their religious dictates (Taylor, 2012). Some religions require women to dress in a conservative manner, which may include wearing sleeves and modestly cut tops, and skirts that cover the knees. Many Muslim women also cover most of their body in accordance with their particular ethnic or national background; conservative Muslim men and women ensure that the area between their navel and knees is always covered (Mujallad & Taylor, 2016). Hindu women accustomed to wearing saris prefer to cover all of the body except their arms and feet (**Figure 30-4** ▶).

Women who wish to comply with religious dress codes may find wearing hospital gowns uneasy and uncomfortable.

Source: Charlie Westerman/Photodisc/Getty Images.

Figure 30-4 ▶ Many Hindu women cover all of their body except for their face, arms, and feet.

Patients may be especially disconcerted when undergoing diagnostic tests or treatments, such as mammography, that require body parts to be bared. Similarly, a Khalsid Sikh who has vowed to never cut body hair will be distraught if a nurse tries to do so in preparation for surgery or intravenous line insertion (Taylor, 2012).

Beliefs Related to Birth

Many religions have specific ritual ceremonies for a newborn that consecrate the infant to God (Taylor, 2012). For example, when a Muslim child is born, the father or other relative or cleric recites the Islamic call to prayer into the infant’s ear. Hindus observe ceremonies for both the newborn and mother that involve symbolisms of purity and well wishes. A Jehovah’s Witness will request that placental or umbilical cord blood be disposed of rather than extracted. Many Christians will christen or baptize their infant. Christian parents of seriously ill newborns may want baptism performed by the nurse or primary care provider if a chaplain or clergy person is not present. Religious dictates about circumcision vary. Whereas Hindus do not practice it, Muslims and Jews circumcise male infants. Christian traditions vary but generally leave the decision to parents (Taylor, 2012).

When nurses are aware of the religious needs of families and their infants, they can support families in fulfilling their religious obligations if necessary. This is especially important when the newborn infant is seriously ill or in danger of dying, because some individuals believe that if religious obligations are not fulfilled the infant will not be accepted into the community of the faithful after death.

Beliefs Related to Death

Spiritual and religious beliefs play a significant role in the believer's approach to death just as they do in other major life events (Taylor, 2012). Many believe that the individual who dies transcends this life for a better place or state of being. Some religions have special rituals surrounding dying and death that must be observed by the faithful. Observance of these rituals provides comfort to the dying individual and his or her loved ones. Some rituals are carried out while the individual is still alive and can include special prayers, singing or chants, and reading of sacred scriptures (e.g., Buddhists). Roman Catholic priests perform the sacrament of Anointing of the Sick (previously referred to as the Last Rites or Extreme Unction) when patients are very ill or near death. Muslims who are dying want their body or head turned toward Mecca and are encouraged to say the prayer recognizing their loyalty to Allah (God).

Bereavement rituals likewise vary across faith traditions (Taylor, 2012). For example, Jews have a tradition of burial within 24 hours following death, except on the Sabbath, and they sit Shiva (gather to pay respects). Tibetan Buddhists read the *Tibetan Book of the Dead* within 7 days of the death to release the soul of the deceased. Hindus cremate and Muslims bury the body within 24 hours ideally. Postmortem rituals and practices such as bathing and preparing the body for interment (e.g., especially for Jews and Muslims), saying specified prayers, and beliefs regarding methods for body disposal and what happens in an afterlife likewise vary by religion and culture. Religious symbols or objects should be treated with respect and kept with the body.

The nurse can help to support family members of the deceased by providing an environment conducive to the performance of their traditional death rituals. This will be possible if during the terminal illness, the patient and family are queried about observances or rituals surrounding the time of death.

Case Study » Part 3

Mr. Denton's minister arrives, and Mrs. Denton and the minister discuss the situation. They agree that the situation has been handled according to Mr. Denton's beliefs. Mr. Denton dies, and Mrs. Denton states, "He died as he believed; God's will has been done." Members of the ED staff are overheard saying things like "He was too young to die" and "If only they had allowed the blood transfusion."

Clinical Reasoning Questions Level I

1. What should the nurse do to help Mrs. Denton at this time?
2. How can an RN support community-based spiritual caregivers such as ministers?
3. What should the staff members do to help deal with their own feelings?

Clinical Reasoning Questions Level II

4. If the patient in the case study had been 10 years old and the parents had made the decision to treat with volume expanders only, with the same results, what would have been the staff's responsibility?
5. What ethical and legal issues would be involved in the decision-making process in this situation?
6. What end-of-life care would be appropriate before and after Mr. Denton's death?

Independent Interventions and Collaborative Therapies

When facilitating interventions or providing nursing therapeutics to nurture patient spiritual well-being, nurses should avoid unethically imposing personal spiritual beliefs on patients, whose circumstances inherently leave them vulnerable. Observing guidelines for ethical conduct in spiritual caregiving is essential. The following guidelines for nurses were offered by Winslow and Wehtje-Winslow (2007):

- First seek a basic understanding of patients' spiritual needs, resources, and preferences (i.e., assess).
- Follow the patient's expressed wishes regarding spiritual care.
- Do not prescribe or urge patients to adopt certain spiritual beliefs or practices, and do not pressure them to relinquish any of their beliefs or practices.
- Strive to understand personal spirituality and how it influences caregiving.
- Provide spiritual care in a way that is consonant with personal beliefs.

Although some patients are eager for nurses' overt offers of "spiritual care," others may be uncertain or opposed to such offers (Taylor, 2012). Patients often confuse religiosity with spirituality; this may contribute to their uncertainty about receiving spiritual care from nurses. Observing and using the patient's language for spirituality (e.g., "being at peace" or "faith") and exhibiting large measures of sensitivity and respect will help nurses to converse therapeutically with patients to provide spiritual care.

Before sharing personal beliefs or practices, a nurse must consider questions such as the following:

- For what purpose am I sharing my beliefs or practices? By doing so, am I meeting my needs or my patient's?
- Is my spiritual care reflecting a spiritual assessment?
- Am I preying on a vulnerable patient?
- Am I offering my beliefs or practices in a manner that allows my patient to comfortably refuse?
- Does my spiritual care hurt or contribute to a therapeutic relationship with the patient? (Taylor, 2012).

Prior to discussing ways nurses can support and nurture patient spirituality, it is also important to recognize how the spirituality of the nurse can impact the nurse-patient relationship (Taylor, 2012). How a nurse believes can affect the way that nurse provides care (Taylor, Gober, & Pfeiffer, 2014). For example, a nurse who believes God answers prayers for healing will likely be eager to pray for a patient (Minton, Isaacson, & Banik, 2016). The converse is also likely to be true. Therefore, it is important for the nurse to reflect on how his personal spirituality can ethically and effectively influence professional responsibilities. Also, the extent to which a nurse provides spiritual self-care may contribute to the extent with which that nurse is personally able to provide spiritual nurture (Taylor, 2012). See **Box 30-2** » for suggestions for engaging in spiritual self-care.

Box 30–2

Spiritual Self-Care for Nurses

- Learn and practice mindfulness. That is, be tuned in mentally, emotionally, and physically to what you are experiencing in the present moment; do so without judgment about whether it is right or wrong. It will boost compassion for others and for yourself.
 - Classes, books, magazines, and internet sites offer much information about how to develop mindfulness.
 - Reflect on how mindful you are by taking the quiz at the Greater Good Science Center (http://greatergood.berkeley.edu/quizzes/take_quiz/4/).
- Recognize your own woundedness (e.g., fears, longings, obstructed goals). Know that it is this woundedness that allows you to be present to another's spiritual wounds. Although you do not need to have had the same experiences as your patients, you do need to be able to understand their emotions if you are to be compassionate—spiritually caring.
- Be as compassionate to yourself as you are to patients.
 - Helpful self-talk when you are hurting may include nonjudgmental, tender statements recognizing the pain as well as comforting comments (e.g., “This is hard; it is good to let myself admit this and feel it” and “My dear self, you are not alone; you are loved”).
 - Reflect on how kind you are to yourself by taking a 26-question Self-Compassion Scale available at <http://self-compassion.org/test-how-self-compassionate-you-are/>
- Experience self-compassion, the sacred source (a.k.a. God's love), when you are fully present to your woundedness. This may be felt as a softening of your “heart” when you are still.
- Remember there is a compassionate core in every person: “Call it the Buddha nature of love and compassion, the divinely bestowed image of God, the ever-present Beloved Lover, or simply the steady ember of our truest Self, a compassionate connection resides within every human heart—no matter how damaged or hardened that heart may become” (Rogers, 2015, p. 85).
- Notice the opening of your heart with compassion toward others when you realize that their woundedness essentially mirrors yours (e.g., you also have fears, longings, and obstructed goals).
- When you find yourself irritated or lacking compassion for a patient or colleague, appreciate that that person is functioning as a mirror and can teach you what needs compassion within yourself.

Engaging Community-based Spiritual Care Experts and Resources

If a patient is a member of a spiritual community, its leaders, members, and resources may provide support in various ways. For example, many religious traditions have systems in place for providing social support services to members in need (Taylor, 2012). These services may include respite care for caregivers, financial support, weekly visitations, or organizing meals and help with household duties.

Some religious traditions use lay leaders instead of trained clergy or may not have enough trained clergy to meet the needs of their congregants. Whether trained or untrained in pastoral counseling, a religious congregation or community will typically have someone whose role is to visit the sick (Taylor, 2012). Usually, it is the chaplain or family's prerogative to contact this religious leader.

Although not a prevalent resource, many large congregations (especially Christian) will have a faith community nurse (FCN) who is employed either by the congregation or by a local healthcare system. FCNs, or parish nurses, provide individual and community-oriented care for the congregation (e.g., home visits to the sick or elderly, health education or screening during church events) (Balint & George, 2015; Ziebarth, 2014). FCNs typically have received additional training in spiritual care. Their care is thought to help reduce hospital readmissions and lower healthcare costs (Yeaworth & Sailors, 2014; Ziebarth & Campbell, 2016).

Whether or not an FCN is present within a congregation, the faith community has often been found to be an excellent place for health promotion and disease screening, especially within African American Christian congregations. A number of health researchers have observed positive outcomes from health-related programs such as cancer or HIV screening, or

lifestyle education for individuals with heart disease or diabetes (e.g., Brewer et al., 2016; Morris, 2015; Sattin et al., 2016). These typically integrate some aspect of the religion's beliefs into the program (e.g., reminding participants that their bodies are God's “temple”).

Spiritual Therapies for Home or Hospital

There are several therapies that a nurse can recommend or facilitate that can promote spiritual well-being for a patient. Some of these are listed in **Table 30–1** ».

SAFETY ALERT Nurses must recognize the limitations of their spiritual care abilities. Whereas some nurses may have knowledge and experience with a therapy, others may not. Nurses who do not have knowledge with a particular therapy may make tentative suggestions or call another nurse or expert to assist or follow up. Information from a trustworthy book or website may also be used.

Collaborating with Chaplains

Chaplains who are board certified are trained and credentialed in a religious tradition, as well as trained in counseling so that they can provide expert spiritual care regardless of a patient's spiritual or religious background. Chaplains provide assistance with religious rituals and support for patients and families with emotional, ethical, or spiritual concerns (Massey et al., 2015). Although a Swiss study of hospitalized patients found that the offer of a chaplain visit to a patient was half as likely to result in the acceptance of the offer if the offer was made by a nurse rather than a chaplain (Martinuz et al., 2013), nurses should still make such offers.

Research findings indicate that patients who are visited by a chaplain are more likely to be satisfied with the care

TABLE 30–1 Spiritual Therapies for Home or Hospital

Spiritual Therapy	Evidence/Rationale	Practice Suggestions
Altruism (Huber & MacDonald, 2012; Kahana et al., 2013; Marsh et al., 2015)	Oxytocin promotes altruism and altruism contributes to prosociality; it also is observed to predict life satisfaction and emotional and spiritual well-being.	<ul style="list-style-type: none"> ■ Do a “random act of kindness” without expecting a reward, preferably one that involves some interaction with the recipient of the kindness ■ Savor the feeling of happiness the action provides (thereby creating a feedback loop) ■ Patients with limited abilities can phone or write to encourage others; smile at, listen empathically to, or pray for others; create inexpensive gifts to meet others’ needs; and so forth
Awe (Piff et al., 2015; Van Cappelen & Saroglou, 2012)	Awe is “an emotional response to perceptually vast stimuli that transcend current frames of reference” (Piff et al.), and something that leaves one “feeling small.” Awe is associated with greater prosociality, generosity, and ethical decision making. Awe may activate spiritual/religious feelings.	<ul style="list-style-type: none"> ■ Provide virtual or real experiences in nature (e.g., video about galaxies, trip to local gorgeous place, sit under the night sky, National Geographic series) ■ Provide awe-inspiring music or other form of art, or stories that create a sense of awe (e.g., about a heroic act) ■ Remember that even gazing at the clouds out a hospital window or studying the dew on a blade of grass can stir awe ■ Recognize and cherish the feeling of awe for at least 15 seconds
Expressive artwork (Iliya, 2016; Robb et al., 2014; Yount, Rachlin, & Siegal, 2013)	Creating art is a means for self-expression and meaning making. It has been used in acute and community care settings with children, adolescents, individuals with mental health and disabilities, older adults, and individuals who have experienced trauma or displacement. Creative acts appear to lower cortisol (stress).	<ul style="list-style-type: none"> ■ Expressive artwork can be completed individually or in a group setting ■ Depending on patient preferences, setting, and available resources, a type of art can be selected (e.g., digital media, drama, poetry, visual art) ■ An art, music, or play therapist, or recreation director may facilitate, or a nurse can simply provide materials and support ■ After the artwork is completed, it can be verbally discussed or performed—or kept private. If a patient wants to share, the nurse can ask the patient about what the artwork means or symbolizes for her ■ Reactions to the artwork are best if neutral and observational in nature
Dignity therapy (Chochinov et al., 2005; Fitchett et al., 2015)	Developed by psychiatrist Chochinov and evaluated in numerous settings and found to be effective for improving spiritual and emotional outcomes for patients at the end of life primarily. Encourages patients to tell their life story and construct meaning, and leave a legacy.	<ul style="list-style-type: none"> ■ Listen deeply to patient’s life stories, recognizing that they are attempts to make sense of one’s life ■ Life stories can be recorded, transcribed, and compiled with photographs or other life mementos ■ Prompts can address what individuals view as important aspects or times in their lives, how they wish to be remembered, salient roles they have played in life, achievements, what they still want to say to others, what life lessons they wish to pass on ■ Whereas such extensive life storytelling is likely beyond the time resources of a nurse, a nurse can adapt the process or facilitate others (e.g., trained volunteers) to do this work
Gratitude (Emmons, 2013)	Affirming goodness and appreciating that this goodness comes from outside of yourself creates gratitude. It is associated with prosociality, emotional well-being, and other positive outcomes.	<ul style="list-style-type: none"> ■ Intentionally look for opportunities to verbally express thanks to others (e.g., write a letter of gratitude) ■ Journal or make lists of graces for which one is thankful (e.g., journal five events at the end of each day that created meaning or gratitude) ■ Breathe deeply in a sense of grace and breathe out gratitude ■ Savor for 15 seconds the feeling accompanying acknowledgement of the grace and gratitude
Mindfulness, meditation (Boccia, Piccardi, & Guariglia, 2015; Buttle, 2015; Marchand, 2012)	<p>Of Buddhist origin yet pervading Western societies, mindfulness meditation techniques have been adapted for Christian prayer and as a nonreligious lifestyle strategy for improving health and overall well-being.</p> <p>Numerous studies document various physical, psychologic, and spiritual benefits for those who practice mindfulness regularly.</p>	<p>Mindfulness techniques vary, but key elements include:</p> <ul style="list-style-type: none"> ■ Focused attention on the present moment, the body’s experience ■ Awareness, depth, and steadiness of breathing ■ Put judgmental and intrusive thoughts “on hold” ■ Mindfulness can be taught individually or in groups by a mindfulness expert; manualized training to nurses can prepare them to support patients to meditate
Writing a prayer or spiritual expression (Bennett & Elliott, 2013; Toussaint et al., 2014)	Writing about negative life events is known to improve emotional and physical well-being. Writing about negatives in the form of a prayer or as a spiritual expression may contribute to similar positive outcomes.	<ul style="list-style-type: none"> ■ Encourage the patient to express feelings as well as facts; authenticity of expression may be an indicator of depth of the relationship with the divine ■ Writing can be put in a diary, laptop, or scratchpad; ensuring privacy for the written work is paramount ■ When writing a prayer (e.g., questions about suffering) to God, one can do so with the dominant hand; next, write with the nondominant hand any spontaneous thoughts that occur in response. These may be divinely inspired.

they receive at the hospital and be more likely to perceive that their emotional and spiritual needs were met (Marin et al., 2015; Sharma et al., 2016). Smith and colleagues (2013) explored how young persons with cancer who do not receive spiritual support from a chaplain were more likely to have worse quality of life, fatigue, and physical, emotional, social, and school/work function than those who did

receive spiritual services ($N = 525$, age 15–39). Although chaplains are increasingly generating evidence that their work produces positive outcomes, they often are not called until death is imminent (Choi, Curlin, & Cox, 2015). Nurses can be instrumental in making referrals to chaplains and collaborating with them to support patients' spiritual well-being at any stage of illness.

REVIEW The Concept of Spirituality

RELATE Link the Concepts

Linking the concept of spirituality with the concept of development:

1. How might a nurse address the spiritual needs of an 8-year-old child who has leukemia?
2. How might a nurse address the spiritual needs of a teenager with cystic fibrosis?

Linking the concept of spirituality with the concept of culture and diversity:

3. What could a nurse say to a Muslim patient who wants to fast during the day because it is the month of Ramadan, even though his physician has ordered a clear liquid diet?
4. How would you preoperatively prepare a Khalsid Sikh man for surgery requiring shaving of body hair when this man has vowed to never cut his hair?

REFLECT Apply Your Knowledge

Yasmeen is a 32-year-old woman who is 7 months pregnant. She presents to the emergency department complaining of moderate

vaginal bleeding and significant tenderness around her abdomen. She wears a long dress and scarf over her hair. While her husband, Khaled, is parking their car, Jonathan, her RN, quickly wheels her into a room and asks her to lie on a gurney. He pulls her gown up while simultaneously trying to protect her pelvic area from view by covering it with a blanket. He quickly works to expose her belly and apply a fetal monitor. Yasmeen appears very uncomfortable, but Jonathan assumes she is anxious because she could lose her baby. Just as the monitor begins to indicate signs of fetal distress, Khaled enters the room and insists that Jonathan leave immediately and get a female RN and MD for Yasmeen. He also quickly moves to cover Yasmeen's exposed belly and pull the falling scarf back over her hair.

1. The other female RNs in the ED are busy with a trauma patient, and time is of essence to care for Yasmeen and the fetus. What should Jonathan do?
2. Jonathan knows that the only ED physicians in house now are male. What should he say to Khaled?
3. If no female staff are available to help patient who refuses a male healthcare provider, what measures can be taken to promote modesty? How could you help a female patient who is disturbed by wearing a hospital gown that exposes her arms and legs?
4. If Yasmeen and Khaled's infant dies, what words or actions might comfort them?

Exemplar 30.A Spiritual Distress

Exemplar Learning Outcomes

30.A Analyze spiritual distress as it relates to patient health.

- Describe spiritual distress as the etiology.
- Apply the nursing process in providing culturally competent care to an individual with spiritual distress.

Overview

Spiritual beliefs and practices, whether religious or not, can be a strongly sustaining influence for critically or chronically ill patients and their families. As discussed earlier in this module, spiritual distress may be characterized by expressions of a deficit in meaning, purpose, hope, forgiveness, intimacy with the divine, and anger or a lack of interest about previously spiritually nurturing persons or

Exemplar Key Term

Presencing, 2036

resources (Carpenito-Moyet, 2013). For example, "I'll never forgive myself/them!" "What good is it now to keep on living?" or "I'm never going to pray again, because what good did it do me?" No list of spiritual distress characteristics can be complete, however, considering the complexity and variability of individuals and their spiritual dimensions. By addressing spiritual distress (or the potential for spiritual distress), nurses are providing care that is truly healing and holistic.

Addressing Spiritual Distress

Spiritual distress may affect other areas of functioning and indicate other diagnoses. In these instances, spiritual distress may be the etiology. Examples of nursing diagnoses related to spiritual distress include the following:

- *Fear* related to apprehension about the soul's future after death and unpreparedness for death
- *Chronic or Situational Low Self-Esteem* related to failure to live within the precepts of one's faith
- *Disturbed Sleep Pattern* related to spiritual distress
- *Ineffective Coping* related to feelings of abandonment by God and loss of religious faith
- *Decisional Conflict* related to conflict between treatment plan and religious beliefs.

(NANDA-I © 2014)

NURSING PROCESS

Patients in spiritual distress require the nurse's thoughtful interventions to be performed in a timely manner. Although the nurse may not be able to provide the spiritual guidance patients require, the nurse can use sensitivity and therapeutic communication to help patients explore their feelings and work through their distress and help them talk with an individual who can provide the necessary spiritual guidance such as a religious leader, spiritual guide, or elder in their community.

Assessment

As part of the assessment of the patient, ask questions to determine the patient's spiritual beliefs and practices and how they affect or are affected by the patient's health condition. Asking open-ended questions such as "What was going on in your thoughts when you learned about the possible problems that can happen with your treatment?" serve to build the nurse-patient relationship as well as eliciting information the nurse will need to formulate the plan of care. Patient statements such as "Why is God doing this to me?" "I don't care anymore," and "I wish I were dead" indicate that the patient is in spiritual distress. A quality improvement project related screening for spiritual distress to patient satisfaction with and trust in their overall care for patients on an inpatient oncology unit (Blanchard, 2012). The findings concluded that nurses are interested in the spiritual well-being of their patients and assess for spiritual distress. When nurses were more likely to use referrals to chaplains after a brief spiritual screening protocol, patients reported improved patient outcomes and fewer harmful effects of spiritual distress.

Diagnosis

Carpenito-Moyet (2013) recognized three diagnoses related to spirituality: *Spiritual Distress*, *Readiness for Enhanced Spiritual Well-Being* (which recognizes that some individuals respond to adversity with an increased sensitivity to spirituality or spiritual maturation), and *Risk for Spiritual Distress* (which may be appropriate for a patient who currently shows no

indication of this disruption of spirit yet may if a nurse fails to intervene).

Planning

In the planning phase, the nurse identifies interventions to help the patient achieve the overall goal of maintaining or restoring spiritual well-being so that the patient may realize spiritual strength, serenity, and satisfaction. Outcomes of care may include the following:

- The patient will fulfill religious obligations.
- The patient will find meaning in existence and the present situation.
- The patient will feel a sense of hope.
- The patient will have access to spiritual resources as needed.

Implementation

Spiritual care can include anything that supports spiritual well-being; it can be, for example, any of the following diverse actions:

- Recognize and validate the inner resources of an individual, such as coping methods, humor, motivation, self-determination, positive attitude, and optimism.
- Assist the patient to leave a legacy by storytelling and/or recording life stories for family and friends, and encouraging creative expression through art, music, and writing.
- Foster ways for patients to keep in touch with nature and maintain a sense of wonder.
- Facilitate a reunion with an estranged child.
- Provide a story about how someone in similar circumstances maintained hope and grew spiritually.
- Recognize that the seasons, the emergence of flowers in spring, the phases of the moon, and the migrations of birds provide examples of orderliness in the universe, even in the midst of chaos and loss.

Whereas there are spiritually nurturing activities and therapeutics that a nurse can introduce to a patient, what is likely most important is that the nurse is present to the patient in ways that communicate, "I hear you; I am with you; you are important; I will not judge you."

Provide Presence

Presencing refers to "just" being there or with a patient. Du Plessis (2016) observed that presencing can be the entering wedge for nurses wanting to provide spiritual care. That is, an inexperienced nurse who is uncomfortable with the intimate nature of spiritual care may be able to offer presencing. In a classic article about presencing, Pettigrew (1990) identified four distinguishing features: giving of self in the present moment, being available with all of the self, listening with full awareness of the privilege of doing so, and being there in a way that is meaningful to another individual.

To be fully present to a patient, a nurse must be purposefully attentive (Fahlberg & Roush, 2015). To be comfortable being

fully present to another person, however, one must be comfortable being fully present to oneself (du Plessis, 2016). Strategies for increasing the ability to be present to a patient include:

- Slow down. Calm yourself.
- Make sure that in your “heart” you are willing to be present. Taking deep, slow breaths to center yourself. Nurses who listen attentively to patients yet fail to give of self (i.e., inwardly “make room”) diminish their effectiveness.
- Sit down; keep your eye level at the same level as the patient’s.
- Allow silence.
- Smile or exude positive energy while remaining respectful of the patient’s emotional state (e.g., convey quiet, inner courage if the patient is experiencing sorrow or despair). Follow the patient’s nonverbal cues.
- Focus. With whatever brief or long amount of time you have available, use it maximally by focusing completely on the patient. Be physically, emotionally, and mentally present.
- Empathize with the patient; actively and deeply listen (Fahlberg & Roush, 2015; Penque & Kearney, 2015; Taylor, 2007).
- Self-disclosure (e.g., telling the patient about how you overcame a similar situation) is never appropriate unless the patient requests it and it is shared with therapeutic intent rather than for self-serving reasons. (Ask, “Whose needs are being met here?”)

Presencing is often the best and sometimes the only intervention to support a patient who suffers under circumstances that medical interventions cannot address. When a patient is helpless, powerless, and vulnerable, a nurse’s presencing can be most beneficial. Rather than worrying about saying or doing “the right thing,” nurses should focus on being fully present (Taylor, 2007).

Refer Patients for Spiritual Counseling

In some cases spiritual care is best referred to other members of the healthcare team. Referrals can be made for hospitalized patients and their families through the hospital

chaplain’s office if one is available. Nurses in home and community health settings can identify spiritual resources by checking directories of community service agencies, telephone directories, or religious directories that describe available spiritual counselors and the services provided through the religious community. Many religious counselors will provide assistance to members of their faith who are not members of their specific religious community. For example, a priest may attend a patient in the hospital or at home even though the individual is not a member of the priest’s parish. The patient’s permission is needed before seeking an outside counselor in order to protect the patient’s right to confidentiality.

Referrals may be necessary when the nurse makes a diagnosis of spiritual distress. A nurse and religious counselor can work together to meet the patient’s needs. One situation the nurse may encounter is patient refusal of necessary medical intervention because of religious tenets. In this case, the nurse encourages the patient, primary care provider, and spiritual adviser to discuss the conflict and consider alternative methods of therapy. The nurse’s major roles are to provide information the patient needs to make an informed decision and to support and advocate for the patient’s decision.

Evaluation

Using the measurable desired outcomes developed during the planning stage, the nurse collects data needed to judge whether patient goals and outcomes have been achieved. Appropriate outcomes for the patient who needs to maintain or be restored to spiritual health include the following:

- The patient identifies purposeful activities or ways of thinking.
- The patient articulates a sense of hopefulness about the future.
- The patient articulates how to access spiritual resources.
- The patient finds meaning and existence in the present situation.

Nursing Care Plan

A Patient with Spiritual Distress

ASSESSMENT

Ms. Sally Horton is a 60-year-old hospitalized homemaker who is recovering from a right radical mastectomy. Her primary care provider told her yesterday that because of metastases of the cancer, her prognosis is poor. This morning her nurse finds her tearful, stating that she slept poorly and has no appetite. She asks the nurse, “Why has God done this to me? Perhaps it’s because I have sinned in my life. I’ve not gone to church or spoken to a minister in several years. Is there a chapel in the hospital where I could go and pray? I’m terribly afraid of dying and what awaits me.”

DIAGNOSES

- *Spiritual Distress* related to feelings of guilt and alienation from God as evidenced by questioning why “God has done this”; inquiries about praying in a chapel; insomnia; no appetite

(NANDA-I © 2014)

PLANNING

- The patient will interact with a spiritual leader from her faith.
- The patient will read about spiritual practices that provide her comfort.
- The patient will start a gratitude journal.
- The patient will connect with others to share thoughts, feelings, and beliefs.

(continued on next page)

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Create an accepting, nonjudgmental atmosphere.
- Assist her to express and reflect on her anger.
- Encourage the use of spiritual resources, if desired by the patient.
- Encourage verbalization of feelings, perceptions, and fears. Allow time for grieving.
- Referral to spiritual care expert of patient's choice to discuss self-forgiveness and perception that God may be punishing her.

EVALUATION

Ms. Horton has been visited on several occasions by her minister. She reads scripture each day and has found consolation in reading the book of Psalms. She states, "God is merciful and will help me bear my suffering."

CRITICAL THINKING

1. What spiritual resources might you recommend for this patient?
2. If Ms. Horton's husband believes that her disease is a result of sins committed throughout life, how could you help this patient?
3. If your religious beliefs would help this patient obtain spiritual well-being, what actions could you take to help this patient?

REVIEW Spiritual Distress

RELATE Link the Concepts and Exemplars

Linking the exemplar of spiritual distress with the concept of oxygenation:

1. Describe the risk for spiritual distress faced by the parents of a child who has just died from sudden infant death syndrome.
2. What caring interventions would you offer to the child's parents?

Linking the exemplar of spiritual distress with the concept of development:

3. What signals or words might indicate that an 8-year-old child from a Protestant Christian family is in spiritual distress? What caring interventions would be appropriate for a child this age?
4. How might a teenager communicate spiritual distress? What interventions would be appropriate for a teenager that would not be appropriate for a younger child?

REFLECT Apply Your Knowledge

Terry Mears is a 32-year-old man who received several pints of blood following an automobile crash 10 years ago. Five years ago he was diagnosed with AIDS, and he is now in the hospital with pneumonia and severe diarrhea. He is very ill and very discouraged. While you are caring for Mr. Mears, he comments, "I might as well die right now because I'm not going to get well. My folks were Methodist, but I guess I'm being punished because I'm not very religious."

1. Mr. Mears stated that he was "not very religious." Does that mean that he is not spiritual? Explain.
2. What data suggest that Mr. Mears may be experiencing spiritual distress?
3. How might illness affect one's spiritual beliefs? Religious beliefs?
4. How might a spiritual assessment be of benefit to both you and Mr. Mears?

Exemplar 30.B Religion

Exemplar Learning Outcomes

30.B Analyze religion as it relates to spirituality.

- List characteristics shared by all religions.
- Outline the components of religion.
- Compare the aspects of religion that affect medical care.

- Apply the nursing process in providing culturally competent care to a religious patient.

Exemplar Key Terms

Denomination, 2040
Holy day, 2039

Overview

Religion is an organized, communal approach to human spirituality. In its simplest terms, a religion provides its members with the constructs of beliefs, moral values, and

spiritual practices that guide its members' expressions of their spirituality. Although religion is typically practiced in a community setting, such as a church, synagogue, or mosque, most religious individuals also practice their religion outside

of this setting in various ways, and individuals who are separated from their religious community will often continue their observations of holy days and rituals in private.

Although there are many differences among religions, there are also many similarities. Characteristics common among all religions include:

- **Belief in god(s) or higher power.** Adherents of some religions, including Hinduism, Buddhism, and modern paganism, worship multiple gods.
- **Belief that the god or higher power has influence over humanity.**
- **Direct communication.** Members believe they communicate with the higher power, usually in the form of prayer that is expressive and receptive. Dreams, meditations, corporate worship, and rituals may also be means for human–divine communication and interaction.
- **Community.** Members typically worship collectively on a regular basis in a communal setting, such as a church, synagogue, gurdwara, temple, or mosque. Some religions use ritual rites of passage to admit new members (e.g., doctrinal or confirmation classes and baptism for most Christians).
- **Ethical or moral codes.** Probably the single best-known example of a religious moral code is the Ten Commandments.

Many societies have taboos or laws that prevent individuals or communities from expressing or practicing religion. Some countries have state religions (e.g., Islam in many Middle East countries, Eastern Orthodox traditions in Russia); these countries may or may not be welcoming to other religions. The U.S. Constitution mandates that religion be separate from government, yet how this doctrine of the separation of church and state is applied in society continues to be debated and interpreted.

Components of Religion

Religions also have similarities and differences about how to think about health, illness, suffering, and death. The very brief descriptions included later in this exemplar are mere snapshots intended to raise awareness of some important areas of health and healthcare that can be affected by an individual's religion. When appropriate, nurses should assess how patients' spiritual or religious beliefs and practices affect their approach to healthcare. These beliefs and practices often pertain to how patients relate to sacred time, scripture, symbols, and to the divine through prayer and other practices.

Holy Days

A **holy day** is a day set aside for special religious observance; all world religions observe certain holy days. For example, Christians (Catholics, Orthodox, and Protestants) observe Easter and Christmas, Jews observe Yom Kippur and Passover, Buddhists observe the birthday of the Buddha, Muslims observe the month-long holy period of Ramadan, and Hindus observe Mahashivratri, a celebration of Lord Shiva. Many religions require fasting, extended prayer, and reflection or ritual observances on sacred (or high holy) days. Believers who are seriously ill are often exempted from such requirements. Because many religions follow

calendars other than the Gregorian calendar, a multifaith calendar can be used to identify the holy days of the various religious groups (Taylor, 2012).

The concept of the Sabbath is common to Christianity and Judaism, in response to the biblical commandment “Remember the Sabbath day to keep it holy.” Most Christians view Sunday as “the Lord’s day,” whereas Jews and sabbatarian Christians (e.g., Seventh-day Adventists) observe their Sabbath on Saturday. Muslims (particularly men) traditionally gather on Friday at noon to worship and learn about their faith. Patients who are devout in their religious practices may want to avoid any special treatments or other intrusions on their day of rest and reflection.

Sacred Writings

Each religion has sacred and authoritative scriptures that provide guidance for its adherents' beliefs and behaviors. In addition, sacred writings frequently tell instructive stories of the religion's leaders, kings, and heroes. In most religions, these scriptures are thought to be the word of God or the Supreme Being as written down by prophets or other human representatives. Christians rely on the Bible, Jews on the Torah and Talmud, and Muslims on the Quran; Hindus have several holy texts, or Vedas; and Buddhists value the teachings of the Tripitakas. Scriptures generally set forth religious law in the form of admonitions and rules for living. This religious law may be interpreted in various ways by subgroups of a religion, and this may affect a patient's willingness to accept treatment suggestions.

Individuals often gain strength and hope from reading religious writings when they are ill or in crisis. Examples of scriptural stories that may give comfort to patients are Job's suffering, found in both the Jewish and Christian scriptures, and Jesus's healing of individuals who were physically or mentally ill, as outlined in the New Testament of the Bible.

Sacred Symbols

Sacred symbols include jewelry, medals, amulets, clothing, or body ornamentation (e.g., tattoos) that may be worn as a symbol of faith, for spiritual protection, or as a source of comfort and strength. Some individuals may wear religious medals at all times, and they may wish to wear them when they are undergoing diagnostic studies, medical treatment, or surgery. Individuals who are Roman Catholic may carry a rosary for prayer (see **Figure 30-5** >>>); an individual who is Muslim may carry a mala, or string of prayer beads.

Individuals may have religious icons, altars, statues, totems, or other religious objects in their home, car, or place of work as a personal reminder of their faith or as part of a personal place of worship or meditation. Hospitalized patients or long-term care residents may wish to have their spiritual icons or objects with them as a source of comfort.

Prayer and Meditation

Prayer is “human communication with divine and spiritual entities” (Gill, 1987, p. 489). Some argue that because prayer requires a belief in a divine or spiritual entity, not all individuals pray, while others consider prayer a universal phenomenon that does not require such belief. Ulanov and Ulanov (1983), for example, proposed that everyone prays: “People pray whether or not they call it prayer. We pray

Figure 30-5 » Patients may bring objects to the hospital to use in prayer or other religious rituals. Caregivers should respect such objects, because they usually have great significance for patients.

every time we ask for help, understanding, or strength, in or out of religion . . . who and what we are speak out of us. . . . To pray is to listen to and hear this self who is speaking” (p. 1). Prayer continues to be prevalent in American society. In a 2014 Pew Research Center survey, only 23% of those surveyed reported they seldom or never pray. The remaining respondents report praying daily (55%) or weekly or monthly (21%) (Pew Research Center, 2015).

Prayer experiences vary. Categories of prayer that still influence how researchers think about prayer have been identified by Poloma and Gallup (1991):

- **Ritual** (e.g., the Lord’s Prayer, memorized prayers that can be repeated)
- **Petitionary** (e.g., “God, cure me!” or intercessory prayers when one is requesting something of the divine)
- **Colloquial** (i.e., conversational prayers)
- **Meditational** (e.g., moments of silence focused on nothing, a meaningful phrase, or a certain aspect of the divine).

Although meditational and colloquial prayer experiences have been found to be associated with spiritual well-being and good quality of life in healthy adults, ritual and petitionary prayer experiences may be most comforting and appropriate for those who are ill.

Some religions have prescribed prayers that are printed in a prayer book, such as the Anglican/Episcopal *Book of Common Prayer* or the Catholic missal. Some religious prayers are attributed to the source of faith; for example, the Lord’s Prayer for Christians is attributed to Jesus, and the first sutra for Muslims is attributed to Mohammed.

Some religions require daily prayers or dictate specific times for prayer, meditation, or worship: the five daily prayers, or Salat, of the Muslims are performed while facing east toward Mecca at dawn, noon, midafternoon, sunset, and evening (see **Figure 30-6** »). Other examples include the daily Kaddish of the Jews and the seven canonical prayers of the Roman Catholics. Individuals who are ill may want to continue or increase their prayer practices (Taylor, 2012). They may need uninterrupted quiet time during which they have their prayer books, rosaries, malas, or other icons available to them. Nurses can help patients by ensuring a quiet time for them to pray or meditate.

Aspects of Religion That Affect Medical Care

There are many categories (broad forms or types) of religions. Within each category are any number of **denominations**, subgroups with somewhat distinctive practices and beliefs. Even within a specific denomination, there may be further sects or denominations within the larger group. For example, there are Serbian, Greek, Russian, and other denominations of Eastern Orthodox Christians. There are Sunni, Shia, and Sufi Muslims as well as different types of Buddhists, Lutherans, Baptists, Jews, and so forth. Because of the great diversity of religious beliefs and practices even within one religious tradition or denomination, it is important to assess how patients interpret and apply their religion to their present health challenge (Taylor, 2012). Likewise, a patient who belonged to a particular religion as a child may have since modified her practices to suit her evolving beliefs.

The following sampling reviews some of the unique and salient religious beliefs and practices pertinent to healthcare. Although this information can help the nurse to be aware and supportive of each patient’s religiosity, the nurse must always ask patients about their preferences.

Buddhism

Buddhism originated in Asia and spread throughout that continent, and many Asians are influenced by its teachings. Practicing Buddhists generally prefer Eastern medicine, believing that most illnesses can be cured through the mind and the use of herbs. This does not mean that Buddhists will refuse Western medicine. However, a Buddhist patient or patient of Asian origin may use traditional therapies in addition to those prescribed by a healthcare provider. Buddhists may be vegetarian, maintain an altar to Buddha, and practice a form of meditation.

Hinduism

Hinduism is a religion practiced by individuals from India and other parts of southern Asia. Typically, Hindus embrace Western medicine, but they will also employ alternative therapies from their culture such as yoga and various

Source: John Gillis/AP Images.

Figure 30-6 >> Muslim students at Johns Hopkins University at their weekly prayer meeting.

Ayurvedic remedies. Hindus generally do not eat beef or much meat, and may prefer not to use medications that are derived from animals. Many will have food preferences and will want to achieve balance between foods thought to generate heat versus coolness within the body. Because Hindus greatly value cleanliness, nurses may need to offer support for specific cleansing rituals at the start of the day or before a meal. Hindus generally believe that they have more than one life, and as a result may choose not to participate in organ donation. As with many other religions, Hinduism has ceremonial rites that are practiced at the time of dying and immediately after death.

Islam

Islam is the second largest religion in the world, and those who practice Islam are called Muslims. Because many Muslims view events in their lives as a direct result of God's will, they may view illness or death as the will of God and therefore believe that healing can take place only through God's will. Cleanliness and modesty are of great importance in Islam. Respect modesty, avoid nakedness. Be scrupulous about keeping all but hands, face, and feet covered for the conservative Muslim woman. If possible, provide a nurse of the same gender to care for the patient. If not possible, allow a colleague or family member of the patient's gender to be present, leave a window or door ajar (if the patient is not exposed physically), and touch the patient only as necessary to conduct procedures (e.g., do not extend a handshake or caring touch). A male family member may request to remain present when a woman or girl is being examined or treated, as the role of protector is taken seriously. Practicing Muslims follow dietary practices that avoid overeating, alcohol, and pork and pork-based products. During the month of Ramadan, Muslims fast during daylight hours, although exceptions may be made for those who are weak or ill. Muslims are obligated to pray five times a day, so nurses working with Muslim patients should take these prayer times into consideration. These

prayers occur at dawn, midday, late afternoon, after sunset, and late evening. Prior to prayer, ablutions (cleansing rituals) are performed; if the patient cannot use water, sand may be substituted. Prayers are made while facing the direction of Mecca, the Muslim holy city in Saudi Arabia.

Judaism

Typically, Jewish individuals participate actively in their medical care and seek treatment from modern Western doctors. Many Jews keep to a kosher diet to varying degrees (e.g., avoid pork and shellfish, do not mix dairy and meat). Sabbath observance varies (e.g., Orthodox Jews avoid traveling in vehicles, writing, turning on electric appliances and lights); some may refrain from healthcare activities, whereas others will want to not interrupt them. Traditionally Jews pray three times a day in a group; however, a nurse can pray with a Jew using "God" or "Lord" to address the divine. Because there are prescribed Jewish rituals for individuals who are near death and for the time of and after death, Jewish families will often request the presence of a rabbi, a Jewish spiritual leader, when they know a loved one is near death. Jewish burial customs require the dead to be buried as soon as possible, preferably within 24 hours.

Christianity

Although all Christians believe that Jesus was the Son of God and most accept a trinitarian God of Father, Son, and Holy Spirit, there are myriad Christian traditions. After Jesus was crucified, resurrected, and returned to His Father in heaven, the early Christian fellowship evolved into the western European branch of Roman Catholicism and the eastern branch of Orthodox Christianity, making those two denominations the earliest Christians. Then, in medieval times, a movement to reform the Roman Catholic church arose, leading to many subsequent Protestant denominations (e.g., Episcopalians, Methodists, Baptists, Lutherans, Presbyterians, and Anabaptists [e.g., Mennonites]) (see **Figure 30-7** >>>). In the 19th century in the United States, several churches emerged that are typically considered Protestant (e.g., Latter-Day Saints, Jehovah's Witnesses, Seventh-day Adventists, and Christian Scientists).

Like those of most world faiths, Christians in the United States (Catholics, Orthodox, and Protestants) believe their body is a "temple" of God and life is a grace. They generally embrace Western medicine, although they may differ in their views about birth control, abortion, same-sex marriage, and end-of-life care. A few of the unique religious practices not mentioned already in this module follow:

- Anabaptists denomination members may not have insurance coverage and rely on their religious community for support; however, they may refuse expensive healthcare, believing it is poor stewardship.
- Although most Christians will appreciate receiving the Eucharist or Holy Communion, Anglicans, Episcopalians, and Roman Catholics may be especially dutiful about receiving it. Communion is a ritual of ingesting bread and wine (or grape juice) led by clergy or lay leaders to commemorate the death of Jesus. The Lenten season (the 40 days from Ash Wednesday to Easter) may involve some degree of abstention from food.

Figure 30–7 >> There are more than 300,000 Protestant churches in the United States. Surveys show that 90% of them serve fewer than 350 people while the other 10% are megachurches with anywhere from 3000 to 30,000 worshippers each week. Half of all those who attend a Protestant church attend a megachurch (National Congregations Study, 2015).

- Christian Scientists typically oppose Western medical interventions, relying instead on lay and professional Christian Science practitioners. Faith and a positive attitude are paramount.
- Jehovah's Witnesses refuse most blood products. Alternative treatments such as blood conservation strategies, autologous techniques, hematopoietic agents, non-blood volume expanders, and so on can be discussed with the patient, who may want contact with the local Jehovah's Witness hospital liaison committee.
- Latter-Day Saints (LDS or Mormons) avoid alcohol, coffee, tea, and smoking. They may wear temple undergarments, which should be treated with respect.
- Seventh-Day Adventists likely will avoid unnecessary treatments on Sabbath, which begins at Friday sundown and ends at Saturday sundown. Adventists prefer restful, spirit-nurturing, family activities on Sabbaths. They are often vegetarian and abstain from caffeinated beverages, and do not smoke or drink alcohol.
- Roman Catholic doctrine posits that life begins at conception and should not be tampered with; therefore, abortion, euthanasia, and birth control are sinful. Confession of one's sins to a priest and accepting absolution from the priest is an important healing sacrament. Nurses working with a very sick or dying member of the Roman Catholic faith will want to make sure that the family has the opportunity to call for a priest to administer the sacrament of the Anointing of the Sick. Be aware that some patients may think that an offer of this sacrament means they are dying; in fact, it may be administered to anyone who is seriously ill or about to undergo a major operation.
- Orthodox Christians are urged to remain in contact with their local priest, rather than a hospital chaplain. Fasts from certain foods are often observed (i.e., most Wednesdays, Fridays, and Lent); these are relaxed for those who are ill, depending on their circumstances.

NURSING PROCESS

The nursing process can be applied to spiritual or religious care.

Assessment

As discussed in the Concept section of this module, assessment of the patient's spiritual or religious beliefs and practices occurs as part of the nursing history. The longer the patient's hospitalization or institutionalization, the more important this assessment becomes. In addition, any patient with an illness or injury that may result in a threat to life should be assessed for religious practices and spiritual needs. Depending on the patient's circumstances, nurses likely will need to inquire about religious practices related to:

- Diet (e.g., "What dietary preferences do you have? Are there specific foods or drinks you avoid, or certain diets for certain days that you try to keep?")
- Prayers, devotions, or worship desires (e.g., "What do you like to do to keep hopeful or find comfort?" or "How can we support you with any spiritual practices you like to do regularly? For example, do you like to pray, meditate, or read to be inspired or comforted?")
- Sacred objects (e.g., "Are there any personal items [sacred or religious objects or books or things] that we should make sure do not get lost here?")
- Prohibitions regarding medical procedures or treatments (if any).

Note the nonreligious language of the illustrative assessment questions.

Diagnosis

Any number of health challenges can threaten an individual's ability to practice his religion. NANDA International has three nursing diagnoses that reflect patient religious

issues: *Impaired Religiosity*, *Risk for Impaired Religiosity*, and *Readiness for Enhanced Religiosity* (Carpenito-Moyet, 2013).

The religious patient and family may observe a number of religious practices at home, and these may be an essential part of each day in the life of the family. *Interrupted Family Processes* and *Readiness for Enhanced Family Coping* may also be appropriate diagnoses if these normal daily practices are disturbed by hospitalization. Because the individual's sense of self may be closely tied to his religious practices, *Risk for Compromised Human Dignity* and *Risk for Powerlessness* may also be appropriate diagnoses.

Impaired religiosity is the impaired ability to exercise reliance on religious beliefs and/or participate in rituals of a particular faith tradition. Illness or injury that disrupts religious practice can impair the patient's religiosity and result in emotional distress. An example of impaired religiosity might be the situation of the Roman Catholic patient who attends daily Mass but is on enforced bedrest or requires an extended hospitalization, or the Muslim patient who says evening prayers daily at the local mosque and is in the same situation.

In certain situations, a medical condition may require a decision that is in conflict with a patient's or family's religious practice. For example, a pregnant patient who believes that life begins at conception discovers at 20–22 weeks' gestation that she will not be able to carry the fetus to term and attempting to do so will most likely result in her death. How will she decide what to do? If she had been trying for years to get pregnant without success, how would that influence her decision? How would her decision be affected if she had two small children at home? In such a situation in which a medical condition presents a complication that is at odds with a patient's faith, the nursing diagnosis of *Risk for Impaired Religiosity* may be appropriate.

The relationship between the individual and her religion and religious practices is complex. Sometimes events that might threaten one individual's faith strengthen the faith of another. *Readiness for enhanced religiosity* is defined as the ability to increase reliance on religious beliefs and/or participate in rituals of a particular faith tradition.

Planning

When planning care, the nurse attempts to preserve the patient's and family's ability to observe their religious practices to every extent possible. This may include the following goals of care:

- The patient will be able to participate in religious observances as the patient desires.
- The patient will be able to participate in prayer at prescribed times without interruption.
- The patient will receive meals in keeping with religious dietary restrictions or requirements.
- The patient will have access to religious resources, including ministers, prayer partners, sacred texts, and sacred objects.

Implementation

Providing care related to the patient's religious needs must be done with great tact and sensitivity. The nurse's own religious beliefs may influence the approach to implementing care, but the nurse should never preach or proselytize his or

her own beliefs and practices; rather, the nurse should focus on supporting the needs of the patient.

Support Religious Practices

Nurses need to consider specific religious practices that will affect nursing care, such as the patient's beliefs about birth, death, dress, diet, prayer, sacred symbols, sacred writings, and holy days. See **Box 30–3** for ways in which the nurse can help patients to continue their usual spiritual practices.

Assist Patients with Prayer

Prayer involves a sense of love and connection, as well as a reaching out. It offers a means for someone to talk to a greater power, a mechanism for expressing care, and a sense of serenity and connection with something greater. Evidence indicates that prayer boosts emotional and spiritual well-being (Jors & Bussing, 2015). From a national survey of Americans, Schafer (2013) found that when people knew that others were praying for them, they were more optimistic. Thus, this study suggests that telling patients that you are praying for them is a type of social support with positive impact.

Box 30–3

Supporting Religious Practices

- Create a trusting relationship with the patient so that any religious concerns or practices can be openly discussed and addressed.
- If unsure of the patient's religious needs, ask how nurses can assist in having these needs met. Avoid relying on personal assumptions when caring for patients.
- Do not discuss personal spiritual beliefs with a patient unless the patient requests it. Be sure to assess whether such self-disclosure contributes to a therapeutic nurse–patient relationship.
- Inform patients and family caregivers about spiritual support available at your institution (e.g., chapel or meditation room, chaplain services).
- Allow time and privacy for, and provide comfort measures prior to, private worship, prayer, meditation, reading, or other spiritual activities.
- Respect and ensure safety of the patient's religious articles (e.g., icons, amulets, clothing, jewelry).
- If desired by the patient, facilitate clergy or spiritual care specialist visitation. Collaborate with the chaplain (if available).
- Prepare the patient's environment for spiritual rituals or clergy visitations as needed (e.g., have a chair near the bedside for clergy, create private space).
- Make arrangements with the dietitian so that dietary needs can be met. If the institution cannot accommodate the patient's needs, ask the family to bring food. (Most religions have some recommendations about diet, such as espousing vegetarianism or rejecting alcohol.)
- Acquaint yourself with the religions, spiritual practices, and cultures of the area in which you are working.
- Facilitating/supporting a patient's religious practice does not require that you share the same beliefs or must participate in it yourself.
- Ask another nurse to assist if a particular religious practice makes you uncomfortable.
- All spiritual interventions must be done within agency guidelines.

Box 30–4

When a Patient Asks for Prayer

- When a patient asks the nurse to pray, determine prayer preferences before starting (e.g., “How would you like to pray?”). Patients may prefer praying silently, while others may want the nurse to lead the prayer or to listen to the patient’s prayer.
- Assess how the patient approaches the addressee of prayer. For example, a Baptist may pray to Jesus, whereas a Jew would pray to God or Lord. Use terms such as “God” or “Sacred Source” until you know your patient’s preference.
- Before praying, assess what the patient would like you to pray (e.g., “For what would you like me to pray?”). The answer may provide greater insight into the patient’s fears and concerns.
- You may personalize the prayer by presenting your patient’s name and personal concerns to the Divine.
- If the prayer is colloquial, prayer can be used to summarize a conversation. This lets the patient know you have heard what was said. It may also help the patient to view circumstances more objectively.
- Prayer may be the springboard to further discussion or catharsis. Stay with the patient after a prayer until there has been time for conversation.
- Be mindful of one difference between magic and prayer. Magic invokes a greater power for personal gain. Prayer allows the greater power to do the greater good (“Thy will be done”).
- Praying with a patient may not involve verbalization. You may feel it will be more comfortable or appropriate if you remain quiet and fully present, praying silently.
- Facilitate the patient’s prayer practices. Schedule time when the patient will be undisturbed, palliate distressing symptoms that interfere with praying, help with articles that accompany prayers (e.g., rosaries, prayer garments, books of prayers), and so on.
- In times of distress, a patient or loved one may not be able to construct a prayer spontaneously. You may want to model or teach a centering prayer that is very brief (e.g., “Lord, have mercy/healing”). Nurses can discuss with care recipients what prayer would benefit them most and encourage them to use it while alone. These prayers may be more beneficial when they are framed in a positive sense. To illustrate, “Jesus loves me” or “The Lord has mercy.”
- Encourage patients to think (privately or with you or a chaplain) about what prayer means to them. Offer questions such as these: What prompts you to pray? What do you expect from your praying? Are these expectations appropriate? How content are you with your prayer experiences? Is there a yearning for something more in your prayer experience?

Sources: Based on Taylor, E. J. (2012). *Religion: A clinical guide for nurses*. New York, NY: Springer; Hubbart, B., Corey, D., & Kautz, D. D. (n.d.). *Nurse, please pray with me*. Retrieved from <http://mjournal.com/journal-of-nursing/nurse-please-pray-with-me>; Taylor, E. J. (in press). Spiritual and religious support for persons living with cancer. In L. M. Gorman, & N. J. Bush (Eds.), *Psychosocial nursing care along the cancer continuum* (3rd ed.). Pittsburgh, PA: Oncology Nursing Society.

Illness can interfere with some patients’ ability to pray (Taylor, 2012). Feelings such as anxiety, fear, guilt, grief, despair, and isolation can produce barriers to relationships in general and to the relationship the individual has with the Divine. In these instances, patients may ask the nurse to pray with them. Praying with patients should be done only when there is mutual agreement between the patients and those praying with them. Nurses who are unaccustomed to praying aloud or in public may find it helpful to have a formal prayer or a scriptural passage readily available. Because prayer can evoke deep feelings, the nurse may need to spend time with the patient following a prayer to enable the patient to express these feelings.

Patients may choose to participate in private prayer or may want group prayer with family, friends, or clergy. In these situations the nurse’s major responsibility is to ensure a quiet environment and privacy. Nursing care may need to be adjusted to accommodate periods for prayer. Patients’ preferences for prayer also reflect their personalities. That is, introverts may prefer being alone to pray, and their

prayers will reflect their capacity for introspection. In contrast, extroverts’ prayers may revolve around their relationships with others and be expressed in creative, verbal ways. Similarly, a prayer of a feeling-type patient may be emotion filled, whereas the prayer of a thinking-type patient may be based on ideas and logic. The nurse should support prayer according to the patient’s preferences (see **Box 30–4** >>).

Evaluation

Expected outcomes of nursing care with regard to the patient’s religious needs include the following:

- The patient has been provided the opportunity to practice religious rituals, including prayers.
- The nursing and dietary staff made appropriate considerations regarding dietary restrictions.
- The patient successfully maintained connection with his or her religious practices and community of faith.

REVIEW Religion

RELATE Link the Concepts and Exemplars

Linking the exemplar of religion with the concept of stress and coping:

1. How might the patient’s inability to perform customary religious rituals during times of illness result in anxiety?
2. How does helping the patient meet his or her religious needs, thus reducing anxiety, help the patient to recover more quickly?

Linking the exemplar of religion with the concept of development:

3. How might religious beliefs change as a patient ages?
4. In assisting the patient to meet his or her needs related to religion, how might the nurse’s interventions differ based on the developmental stage of the patient?

REFLECT Apply Your Knowledge

Olivia Rossi is an 80-year-old woman who attends Catholic Mass at her church every day. She enjoys shopping at the Italian market that is within walking distance of her home. A couple of years ago she was diagnosed with Parkinson disease. At first she did well, thanks to medication and therapy, but in the past few months her symptoms have become worse, and she is afraid to continue to live on her own. After going to visit several assisted living centers, she and her adult children chose one that is very nice, with a very well-qualified staff, but is a 15-minute drive from the nearest Catholic church. After a few weeks, the nurse working on Mrs. Rossi's floor notices

that Mrs. Rossi has become depressed. The nurse approaches Mrs. Rossi and begins to talk with her about the changes she's experienced since moving to the center. Mrs. Rossi expresses her sadness at not being able to attend Mass and says that she misses her church community.

1. What are the priority nursing diagnoses for Mrs. Rossi?
2. What caring interventions could the nurse implement to help Mrs. Rossi?
3. What are the possible outcomes if Mrs. Rossi does not receive any nursing interventions?

Module 31

Stress and Coping

Module Outline and Learning Outcomes

The Concept of Stress and Coping

Stress and Homeostasis

31.1 Contrast stress and homeostasis.

Stressors and the Coping Process

31.2 Explain types of stressors and the psychodynamics of coping.

Manifestations of Stress

31.3 Outline the manifestations and indicators of stress.

Concepts Related to Stress and Coping

31.4 Outline the relationship between stress and coping and other concepts.

Alterations from Normal Coping Responses

31.5 Differentiate alterations in coping.

Health Promotion

31.6 Explain the promotion of healthy coping and the prevention of stress-related illness.

Nursing Assessment

31.7 Differentiate among common assessment procedures and tests used to examine levels of stress and coping mechanisms.

Independent Interventions

31.8 Analyze independent interventions nurses can implement for patients with alterations in stress and coping.

Collaborative Therapies

31.9 Summarize collaborative therapies used by interprofessional teams for patients with stress-related illness and alterations in coping.

Lifespan Considerations

31.10 Differentiate considerations related to the care of patients with stress throughout the lifespan.

Stress and Coping Exemplars

Exemplar 31.A Anxiety Disorders

31.A Analyze anxiety disorders as they relate to stress and coping.

Exemplar 31.B Crisis

31.B Analyze crisis as it relates to stress and coping.

Exemplar 31.C Obsessive-Compulsive Disorder

31.C Analyze obsessive-compulsive disorder (OCD) as it relates to stress and coping.

Although everyone experiences stress, what triggers stress in one individual may not cause stress in another. These triggers are known as stressors. A **stressor** is an external influence that threatens to disrupt the equilibrium necessary to maintain homeostasis. **Homeostasis** is classically described as the body's ability to maintain a stable, balanced internal environment despite the constant challenges posed by external influences (Cannon, 1929). When healthy and functioning properly, the body adapts to these external influences, or stressors, and promotes maintenance or restoration of homeostasis. Homeostasis is demonstrated by the body's ability to maintain fluid and electrolyte balance, oxygenation, and thermoregulation (the control of heat production and heat loss to maintain a steady body temperature). In particular, physiologic maintenance of the body's delicate acid–base balance provides a classic example of homeostasis in action (Cannon, 1932).

Stressors may be physical, mental, or emotional; they also may be positive or negative, depending on several variables, including the individual's perception of the experience. However, by definition, all stressors share one commonality: They have the capacity to cause stress.

Stress and Homeostasis

The term *stress* has appeared in the literature since approximately the 14th century, at which time it was applied in reference to hardship, adversity, or some form of affliction (Lumsden, 1981). However, the present-day understanding of the concept of stress was initially developed through the research and publications of Dr. Hans Selye (1907–1982). Selye was an endocrinologist and a pioneer in the study of stress and the stress response. Selye (1956) defined **stress** as the body's general, nonspecific response to the demands placed on it by a stressor. Selye further asserted that not all stress is bad; in some cases, stress can help an individual achieve desired goals or exceed self-imposed limitations (Cherry, 1978; Selye, 1956, 1976). Good stress, which Selye called **eustress**, is associated with accomplishment and victory. The opposite of eustress is **distress**, which is stress that is associated with inadequacy, insecurity, and loss (Cherry, 1978; Selye, 1956).

In further refining Cannon's conceptualization of homeostasis from a more holistic standpoint, Sterling and Eyer (1988) originated the term **allostasis**, which refers to the changes necessary to achieve the characteristic stability of homeostasis. During homeostasis, the body maintains vital functions such as heart and respiratory rates and oxygen and glucose levels within an ideal range. In contrast, current literature describes allostasis as the process the body uses to maintain a pathophysiologic deviation from the normal homeostatic operating level in the presence of stressors (Ramsay & Woods, 2014). This deviation from normal homeostasis allows the body to function as optimally as possible in the presence of major stressors. The process of allostasis includes the psychosocial and physiologic changes that occur in response to stress, many of which are triggered by activation of the sympathetic nervous system. In addition to other functions, the sympathetic nervous system triggers the body's "fight-or-flight" response, which is necessary for survival. Activation of the

sympathetic nervous system causes release of hormones such as epinephrine, which increases the heart rate and blood pressure to help deliver oxygen to tissues and organs. Epinephrine also causes bronchial dilation, which allows for increased oxygen uptake. This increase in oxygen uptake and delivery is intended to meet the increased metabolic demands associated with facing (fight) or escaping (flight) the stressor.

Formally referred to as the **stress response**, physiologic changes triggered by stress include activation of the neural, neuroendocrine, and endocrine systems as well as activation of target organs (Everly & Lating, 2013). The two primary stress mediators are glucocorticoids (e.g., cortisol) and catecholamines (e.g., epinephrine). These hormonal **stress mediators** are intended to promote adaptation (e.g., by triggering an increase in heart rate and blood pressure) when faced with physical danger.

Under ideal conditions, the stress response permits the body to compensate for the impact of stressors and ensure survival by either maintaining or regaining homeostasis. However, repeated activation of the stress response takes a toll on the individual. The physical cost of adaptation to physiologic or psychosocial stressors is referred to as the **allostatic load**. In addition to hormonal changes, the allostatic load also includes behavioral responses to stress. These can be favorable, as in participating in yoga or exercise, or unfavorable—for example, smoking or drinking alcohol. Chronic, prolonged overexposure to stress mediators, as well as inefficiency of the stress response and unhealthy behavioral responses to stress, can lead to illness (Robertson et al., 2015).

How an individual responds to stress varies and depends on both the individual and the stressor. **Coping** is a dynamic process through which an individual applies cognitive and behavioral measures to handle internal and external demands that the individual perceives as exceeding his available resources (Lazarus & Folkman, 1984). Individuals cope by integrating environmental and cognitive measures to mitigate or diminish the stress response (Everly & Lating, 2013). For example, a nursing student who is studying for final exams might cope with stress through environmental measures such as taking a walk or meeting a friend for coffee. Cognitively, the nursing student might alter her appraisal of the upcoming examination, choosing not to see it as an insurmountable barrier, but rather as a challenge for which she can prepare and that she can successfully master.

When an individual is unable to adapt to stress sufficiently to maintain homeostasis, functional impairment may occur. For example, a young child may become irritable and not be able to sit in the circle during morning carpet time at preschool, and may strike out at a classmate. An adult who fears the consequences of exposure to germs may compulsively wash his hands or clean the house, disrupting his ability to participate in normal activities. Individuals who experience impairment of functioning related to stress and coping may develop one of several stress or anxiety disorders. This module provides a discussion of stress and coping as well as a more detailed picture of specific related conditions, including anxiety disorders, phobias, and obsessive-compulsive disorder.

Stressors and the Coping Process

When patients in distress present to clinics, emergency departments, or mental health centers, nurses assist by assessing the source of the stress and the patient's response and by helping the patient cope with the stressor. To be able to respond appropriately, nurses must have a working knowledge of types of stressors; how human beings respond to or cope with stress; and theoretical models of stress and coping that provide insight into how nurses can support patients during types of stress.

Not everyone will agree as to what constitutes a stressor. For example, one individual may view bungee jumping as a terrifying, life-threatening event that should be avoided, but another individual views this activity to be an exhilarating form of stress release. Identification of a stressor depends on the individual's personal perception of the event or circumstance. However, certain stressors naturally evoke the physiologic stress response in all individuals, without regard to personal perception.

Types of Stressors

Stressors may be categorized using a variety of methods. From a broad standpoint, stressors often are categorized as being either biogenic or psychosocial (Everly & Lating, 2013).

Biogenic stressors directly trigger the stress response without any necessary cognitive process on the part of the individual; that is, the individual does not need to recognize the experience or circumstance as being stressful. Common examples of biogenic stressors include caffeine, amphetamines, and extreme temperatures (Everly & Lating, 2013). **Psychosocial stressors** may be either real or imagined. Rather than directly triggering the stress response, psychosocial stressors can facilitate its activation, depending on how the individual perceives the stressor (**cognitive appraisal**, discussed later in this module) (Everly & Lating, 2013). For example, an individual who has a fear of heights may respond to cleaning the gutters on her house differently than an individual who is not afraid of heights.

Just as the severity (or perceived severity) of a stressor impacts the magnitude of the stress response, so does the length of time to which the individual is exposed to the stressor. This is true regardless of whether the stressor is biogenic or psychosocial in nature—both can be equally powerful. In fact, anticipation of a stressor can produce the same physiologic response that occurs when faced with the stressor in reality (Matta, 2012). For example, anticipating or imagining a potential physical attack can evoke the release of the same stress hormones as those released during an actual physical fight.

From the standpoint of duration of exposure, stressors may be classified into four categories:

1. Acute and time limited
2. Sequential events following an initial stressor
3. Chronic intermittent
4. Chronic permanent

See **Table 31-1** for examples of each classification.

To understand the reciprocal and dynamic relationship between the individual and the environment, it is necessary to consider sources of stress and types of stressors. The

TABLE 31-1 Classifications and Examples of Stressors

Classification of Stressors	Examples
1. Acute and time limited	Ankle sprain Nursing licensure exam
2. Sequential events following an initial stressor	Losing a job and subsequently filing for bankruptcy
3. Chronic intermittent	Strained relationship with in-laws Shared caregiving for an elderly parent
4. Chronic permanent	Paralysis Disability (e.g., blindness, deafness)

degree of a stressor's impact ranges from the benign (non-threatening) hassles of daily living to traumatic events within an individual, family, and society. Examples of traumatic events include rape, life-threatening illness or injury, and natural disasters such as hurricanes. **Box 31-1** lists some common stressors. Additional stressors related to lifespan and development are discussed in the section on Lifespan Considerations.

Daily Hassles

The individual day-to-day tensions that people face are commonly referred to in stress and coping research as **daily hassles**. Examples of daily hassles include making it through a work day or having to care for a small child after a poor night's sleep. Research indicates that hassles are more strongly correlated with somatic health and symptoms than more eventful stressors (DeLongis et al., 1982). A person's physical, emotional, and spiritual health affects whether or not the individual views a hassle as a minor inconvenience or a major strain. Alterations of health in any of these areas may overwhelm an individual's ability to cope with a specific stimulus or event, no matter how mild.

Box 31-1 Types of Stressors

Daily Hassles

- Roles of living
- Caring for children
- Pets
- Work responsibility
- Paying bills
- Traffic
- Neighbors

Internal Stressors

- Cognition (thoughts)
- Spirituality
- Emotions

Environmental Stressors

- Major cataclysmic changes affecting a large number of people (natural disasters, war, floods, hurricanes)
- Major changes affecting one or a few people (divorce, bereavement)

Internal Stressors

The **internal environment** includes the physical, spiritual, cognitive, emotional, and psychologic well-being of an individual and depends on the satisfaction of basic human needs. According to Lazarus and Folkman (1984), the drive to fulfill human needs internally sparks the stimulus to produce energy to seek gratification. When these internal needs are not met, individuals find it harder to cope with changes to their circumstances, including dealing with daily hassles, developmental stressors, or external stressors.

Dossey and Keegan (2016) address the spiritual dimension of the human condition as part of the individual’s internal environment. The authors define *spirituality* as the essence of who we are and how we relate to the world. They incorporate elements of spirituality that include individual values, our place or fit in the world, and a sense of peace. Recent research has identified interconnectedness with the self, individuals, and the world around us as important components of spirituality. (See the module on Spirituality.)

Environmental Stressors

External environmental stressors include triggers outside of the individual that demand change or disrupt homeostasis. Positive stressors, such as graduation from college, generally produce eustress. Negative stressors, such as the inability to find employment, tend to cause distress. Stressors also may be simultaneously positive and negative, as with the combination of pending college graduation and imminent lack of employment. An event is a stressor if it creates a change in the individual or the individual’s circumstances. **Table 31-2 »** outlines specific individual and environmental factors that affect an individual’s response to a stressor.

The Coping Process

As stated earlier, **coping** is the process by which individuals can control or modify their responses to stressors. Successful coping allows individuals to maintain or return to homeostasis within a reasonable amount of time. Individuals who are unable to cope successfully may experience a range of symptoms requiring intervention from nurses and other healthcare professionals.

TABLE 31-2 Factors Affecting an Individual’s Stress Response

Individual Factors	Environmental Factors
Genetic predisposition	Family support and connectedness
Past experience coping with stressors	Community support
Ability to meet own basic human needs	Financial resources
Cultural beliefs and customs	Community resources
Holistic health and well-being	Access to healthcare and education
Personal worldview and appraisal	Family appraisal
Coping mechanisms and history of coping successes	Social support

Cognitive Appraisal

Cognitive appraisal is a key factor in the patient’s ability to cope with stressors. As the individual experiences exposure to a stressor, he appraises the stressor; that is, the individual mentally sorts, assesses, categorizes, evaluates, and frames the significance of an event or stressor with respect to his own well-being. The **primary appraisal** is the “first impression,” occurring immediately on exposure to a stressor. Based on the transactional model, which is described in detail later in this module, there are three ways in which an individual categorizes a stimulus or demand: (1) irrelevant, (2) benign-positive, or (3) stressful. Irrelevant stressors are appraised as having no meaningful effect on the individual or his circumstance and are disregarded. Benign-positive stressors are demands for change that are perceived as preserving or enhancing well-being, such as taking a driver’s education class. Stressors or stimuli categorized as stressful include those viewed as harmful, threatening, or disturbing, such as the death of a family member or a threat to life or safety.

During the **secondary appraisal**, the individual attempts to predict the impact, intensity, and duration of the coping behavior necessary to respond to the stressor. At this time, the individual selects a coping response.

In some cases, the intensity of an individual’s stress response may appear to be incongruent with the stressor. For example, for some individuals, the loss of a family pet may be devastating and elicit an extreme stress response, whereas other individuals may demonstrate a response that is mild in intensity when faced with a similar loss. Likewise, some students may view earning a grade of “C” on an examination as being successful, because it is a passing grade; for others, earning anything less than an “A” is distressing. Keeping in mind that each individual is unique, **Maslow’s hierarchy of needs** offers a model that is useful for understanding the significance of stressors within the context of human needs.

Maslow’s Hierarchy of Needs

When Abraham Maslow introduced his hierarchy of needs in 1943, he proposed the existence of levels of human needs that could be organized into five categories: physiological, safety, love and belonging, self-esteem, and self-actualization (see **Figure 31-1 »**), listed in order of importance. Although Maslow later expanded his model to include self-transcendence as a sixth level of need (Koltko-Rivera, 2006; Maslow, 1968, 1987), the five-stage model is widely used to assist nurses and other professionals in identifying and prioritizing patient needs and interventions. According to Maslow, unmet lower-order needs will dominate the individual and prohibit higher-order needs from emerging. For example, for an individual who is experiencing extreme hunger or starvation, the quest for food becomes life’s focus. As each category of needs is met, the individual’s focus shifts to meeting higher-order needs: Once hunger is satiated, the need for safety and protection emerges and becomes the individual’s primary goal. The satisfaction of both physiologic and safety needs allows for the emergence of needs related to love and belonging. This process continues as the individual is able to meet each stage of needs (Maslow, 1987).

Figure 31-1 » Maslow's hierarchy of needs.

It is important to note that individual traits and variations lead to flexibility with regard to the sequencing of Maslow's hierarchy of needs. As a result, the prioritization of needs may vary, depending on the individual (Maslow, 1987). As an example, for an individual who demonstrates an extremely powerful drive to achieve professional success, esteem needs (e.g., respect from others, empowerment, competence) may supersede needs related to love and belonging. Likewise, mental illness may lead to the exclusion of certain categories of needs (Maslow, 1987). For example, antisocial personality disorder is characterized by a lack of concern for the safety needs of self or others.

Effective Coping

Effective coping is a learned process, not an inherent personality trait. It includes all efforts mobilized by the individual to manage stressors. Coping involves constant change by the individual and includes spiritual, emotional, cognitive, and behavioral efforts to manage the demand. Lazarus and Folkman's (1984) transactional model describes coping as a means to manage or alter the problem causing the distress. The appraisal process allows the individual to inform the coping response by incorporating the person's own spiritual, cognitive, affective, and inherent vulnerability. In essence, every person responds to a stressor according to his or her unique worldview and condition.

Two forms of coping are (1) **problem-focused coping**, which is aimed at managing or altering the stressor, event, or circumstance; and (2) **emotion-focused coping**, which is directed at regulating the emotional response to the distress. Emotion-focused coping is used most when the stressor is perceived to be beyond the individual's control. In problem-focused coping, generally the perception is that the stressor can be changed (Lazarus & Folkman, 1984). Additional subcategories of coping include **avoidance coping** (using both behaviors and cognitive processes to avoid the stressor) and **approach coping** (confronting and trying to change the stressor by taking direct action). Finally, there is also **meaning-focused coping**, which involves re-evaluation to reduce the appraisal of a threat (Carver & Connor-Smith, 2010).

It is crucial for nurses to understand that any form of coping is an individual process influenced by the number of stressors; their source, type, intensity, and duration; and the individual's support, experience, and vulnerability. Nurses need to be aware of their own coping styles and maintain a nonjudgmental attitude about the coping mechanisms of individuals experiencing stressors. **Table 31-3** » depicts various forms and examples of coping with stressors.

Healthcare professionals and researchers have clearly established the strong and complex relationship among stress, coping, and physical and psychologic illness (Cohen et al., 2012). Lazarus and Folkman (1984) note that it is the reaction to the demand, not the stimulus itself, that causes stress. The nursing transactional model allows the nurse to consider individual patient preferences, resources, culture, and environment in the assessment of the patient's abilities to respond to stress and to assist the patient in returning to homeostasis.

Reappraisal and Adaptation

Following attempts to cope with the stressor, the individual engages in a **reappraisal** process. During this time, the individual evaluates which coping mechanisms were successful and which were not. Ideally, the person begins another attempt to respond to the stressor and return to homeostasis. In terms of its effects on the body, stress is not viewed as "good" or "bad," but merely according to how much, what kinds, and under what conditions is it harmful or helpful (Lazarus & Folkman, 1984). **Adaptation** refers to the use of physiologic and psychologic processes to come to terms with the implications and outcomes of stressors (Biesecker

TABLE 31-3 Examples of Types of Coping

Types	Emotion-focused Coping (Defensive)	Problem-focused Coping	Avoidance	Approach	Meaning
Cognitive	Minimizing the event: "Oh, it's not that bad!"	Information gathering: "What are my odds of surviving?"	Denial of a situation or limiting information about stressful situations: "This is a bad dream!"	Confronting the situation	Identifying positive changes associated with stressful events; for example, personal illness that leads to increased family bonding
Behavioral	Performing physical activity to avoid thinking about a stressful situation	Adhering to a health-care plan	Refusing to get a mammogram when a history of breast cancer runs in the family	Seeking means to exercise control	Attempting to fit into the environment: "I'll make the best of the situation."
Affective	Hoping for a miracle	Keeping feelings from interfering	Dealing with feelings later	Using feelings to motivate change	Seeking control of environment; regulating the emotional response to stress

et al., 2013). Adaptation and the development of health alterations are influenced by personal variables, with cognitive appraisal of the stressor, genetic predisposition to illness, and behavioral responses to stress being among the most significant factors (Herman, 2013).

Theoretical Models of Stress and Coping

Several theories and models exist to explain the phenomenon of stress. This section outlines stimulus-based and response-based stress models before presenting the transactional model in more detail.

Stimulus-based Stress Models

Stimulus-based stress models view “stress” as being synonymous with “stressor.” These models define stress as being a life event that requires change or adaptation on the part of the individual who is experiencing the life event. Exposure to such life events leads to physiologic and psychologic “wear and tear” and can increase the individual’s susceptibility to illness (Holmes & Rahe, 1967; Lyon, 2012). In their classic work, Holmes and Rahe (1967) proposed the Social Readjustment Rating Scale (SRRS), which quantified the impact of 43 significant life events—with none of the events classified as being either positive or negative—by assigning a numerical value to each individual experience. Examples of life events identified by Holmes and Rahe include death of a spouse or child, marriage, divorce, change of residence, and loss of a job. Variations of the SRRS questionnaire are still in use today. In 1997, a 77-item version of the SRRS was created (Miller & Rahe, 1997). In 2002, a shortened version was designed (Rahe & Tolles, 2002).

When considering the validity of the SRRS and similar scales, note that perception of a life event will vary among individuals, particularly with regard to cognitive appraisal of the event as being a stressor. Likewise, the impact of significant events must be considered from the standpoint of the individual’s simultaneous exposure to routine stressors.

According to Lazarus and Folkman (1984), in comparison to experiencing significant life events, exposure to life’s daily hassles was more likely to lead to stress-related alterations.

Response-based Stress Models

In **response-based stress models**, stress is considered to be a response to a stressor. According to Selye (1956, 1976), stress is “the nonspecific response of the body to any kind of demand made upon it” (1976, p. 1). Selye’s model described the stress response as a three-stage chain of events called the **general adaptation syndrome (GAS)** or *stress response*. Selye used the term *stressor* to distinguish between the stimulus and the response. Within the context of GAS, stressors are any stimuli that evoke the stress response. Selye (1974) also proposed that not every instance of disruption of homeostasis qualifies as an occurrence of stress. For example, a close-flying insect that stimulates an individual to blink excessively may disturb the body’s equilibrium, but this event does not necessarily trigger the GAS.

The stress response may be global (generalized) or local. A global response typically provokes physiologic changes that include hormone production and release and alterations in organs and structures. A local stress response, during which one organ or body system reacts to stress, may produce **local adaptation syndrome (LAS)**. For example, local inflammation in response to a scrape or minor laceration is an example of LAS. However, according to Selye (1976), both GAS and LAS produce a three-stage response: alarm reaction, resistance, and exhaustion (see **Figure 31-2** »).

Alarm Reaction

The body’s initial response is the two-part alarm reaction, which begins with the **shock phase**. During the shock phase, as the body prepares for the cascade of physiologic reactions to the stressor, the sympathetic nervous system is suppressed and the individual may experience manifestations such as hypotension, decreased body temperature, and decreased muscle tone. During the second part of the alarm

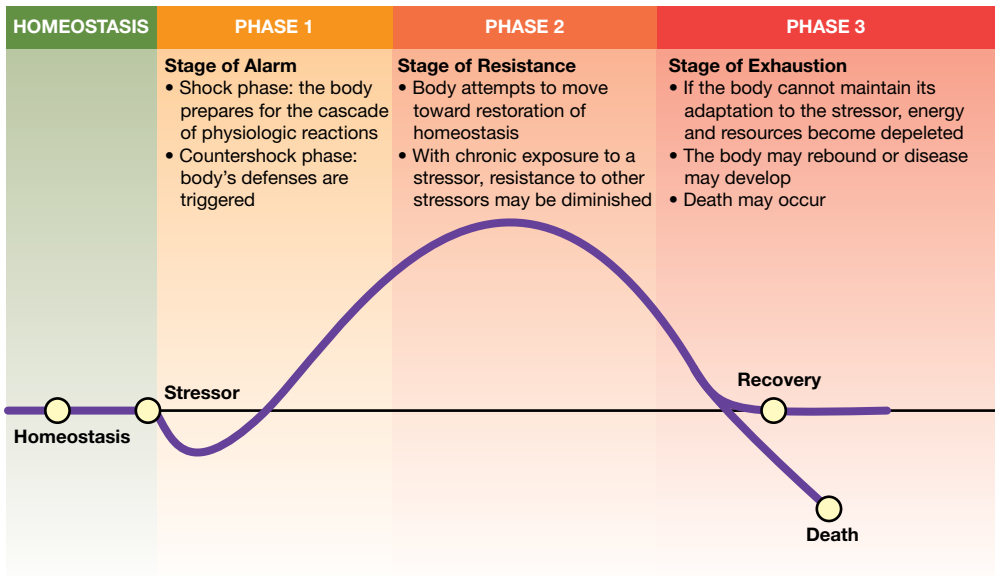

Figure 31-2 » The three stages of adaptation to stress: the alarm reaction, the stage of resistance, and the stage of exhaustion.

reaction, which is referred to as the **countershock phase**, sympathetic nervous system stimulation triggers the body's defenses, which in turn stimulates the hypothalamus. The hypothalamus releases corticotropin-releasing hormone (CRH), which stimulates the anterior pituitary gland to release adrenocorticotropic hormone (ACTH). This sympathetic stimulation, known as the HPA axis, results in secretion of catecholamines (epinephrine and norepinephrine) and glucocorticoids (cortisol) (see **Figure 31-3** >>). Significant body responses to epinephrine include increased myocardial activity, bronchial dilation, and increased fat mobilization. This adrenal hormonal activity prepares the individual for *fight or flight*. This primary response is short lived, lasting from 1 minute to 24 hours.

Stage of Resistance

During the second stage of the GAS, the **stage of resistance**, the body attempts to move toward restoration of homeostasis while continuing to respond to the stressor. With chronic exposure to a stressor, although the body may maintain resistance to the primary stressor, resistance to other stressors may be diminished. For example, an individual who is going through the divorce process may become emotionally and psychologically stable, giving an outward appearance

of effectively coping with the emotional impact of the divorce. However, the prolonged physiologic stress response—which includes increased production of catecholamines (such as epinephrine and norepinephrine), glucose, and cortisol—may lead to increased susceptibility to physical illness, including peptic ulcers and hypertension. Selye (1946) called stress-related illnesses **diseases of adaptation**.

Stage of Exhaustion

During the third stage, the **stage of exhaustion**, if the body cannot maintain its adaptation to the stressor, the stressor will overwhelm the individual's ability to cope or mount a continued defense, resulting in the depletion of energy and resources. The body may rebound from the stressor after a period of rest, or disease may develop. Death also may ensue. The end of this stage depends largely on the adaptive energy resources of the individual, the severity of the stressor, and the external adaptive resources that are provided. An example of this can be seen in the patient who lives with chronic pain. The patient may be able to tolerate the pain during the day, but at night finds the pain far more stressful because energy resources are diminished to the point that the pain is intolerable.

Transactional Model

The transactional model of stress and coping emphasizes the individual's perception, or cognitive appraisal, of a given threat as being the most significant factor in the process. Proposed by Lazarus and Folkman (1984) in their landmark publication *Stress, Appraisal, and Coping*, this model incorporates variations among individuals in terms of the perception of stressors and the response to stress. Within the context of the Lazarus model, a perceived threat or stressor is an event or circumstance that has the ability to negatively impact well-being or that is appraised by the individual as exceeding the coping resources possessed by the individual. The primary danger posed by a stressor is that it threatens the individual's primary values and goals (Monat & Lazarus, 1991). According to Lazarus, the process of cognitive appraisal includes the following steps:

- **Primary appraisal:** evaluation of the transaction, which is the event or circumstance, in terms of its potential to harm, benefit, threaten, or challenge the individual
- **Secondary appraisal:** evaluation of the individual's available coping resources and potential options for responding to the event or circumstance
- **Coping:** application of available coping resources
- **Reappraisal:** ongoing evaluation and reinterpretation of the event or circumstance, as well as continued evaluation of the efficacy of the individual's coping strategies.

Culturally competent nursing care requires recognizing that cultural influences, as well as characteristics that are unique to the individual (including personality and temperament), impact both cognitive appraisal and coping styles.

The nursing transactional model is an adaptation of Lazarus and Folkman's work. The **nursing transactional model** is defined as the relationship between the nurse, the patient, and the environment in which they interact. This interaction or relationship is dynamic—with each transaction, the individual

Figure 31-3 >> Chronic stress results in overactivity of the hypothalamus-pituitary-adrenal (HPA) axis, which results in excessive release of cortisol, which results in more stress.

and the stressor engage to form a new transaction with a particular meaning. This model has numerous implications for the profession of nursing and care of the individual experiencing stress. The emphasis is on the relationship among stress, the patient, the nurse, and both the internal and external environment.

The nursing transactional model emphasizes communication and the development of an interpersonal relationship with the patient with the intent of decreasing the patient's anxiety and increasing or improving the patient's coping resources. This perspective and approach is largely based on the work of nursing theorist **Hildegard Peplau**, who is widely considered to be the mother of psychiatric nursing. In 1952, Peplau published her classic text, *Interpersonal Relations in Nursing*. As opposed to the task-oriented focus traditionally associated with nursing practice, Peplau viewed nursing as a therapeutic interpersonal process (Elder et al., 2013). As described in Peplau's theory, although the nurse begins as a stranger to the patient, during the course of the nurse-patient relationship, the nurse proceeds to assume several roles, including teacher, resource person, counselor, surrogate, and leader (Peplau, 1952).

Manifestations of Stress

Just as each individual is unique in terms of cognitive appraisal and coping methods, individuals also may vary in terms of the internal and external manifestations of stress. In addition to the physiologic domain, stress also may yield manifestations in various other domains, including psychologic and cognitive.

Physiologic Indicators

Physiologic manifestations of stress primarily result from stimulation of the sympathetic and neuroendocrine systems. As previously discussed, the individual's perception of the potential stressor triggers physiologic manifestations of stress. Prolonged exposure to perceived stressors and chronic activation of the stress response can lead to disease and may even be fatal. The relationship between this mind-body connection is illustrated in the Multisystem Effects of Stress feature.

Psychologic Indicators

Individual manifestations of stress within the psychologic domain may include fear, anxiety, anger, depression, and a variety of other responses.

Fear is a sense of apprehension triggered by a perceived threat to safety or well-being, including a painful stimulus or dangerous event. Fear may be aroused by memories of an actual past experience, exposure to a present threat, or anticipated exposure to an event or circumstance. Events that trigger fear may be real or perceived. For example, an individual who has never experienced a motor vehicle accident but who fears the possibility of one may fear driving a car. Even when the origin of fear is not based in reality or founded on an individual's actual experience, fear usually can be tied to a specific source.

Anxiety is characterized by apprehension, dread, mental uneasiness, and a sense of helplessness in response to an actual or perceived threat to the well-being of oneself or others. The degree of anxiety experienced by an individual

may yield effects that range from minimal to debilitating. Unlike fear, an individual's anxiety may not have an apparent identifiable cause. Anxiety is discussed in greater detail in Exemplar 31.A.

Anger is a subjective sense of intense displeasure, irritation, or animosity. For those individuals who are taught that this emotion is unacceptable, development of anger may trigger a sense of guilt or shame. However, processing and expressing anger through constructive communication methods may lead to conflict resolution and personal growth. Constructive communication of anger requires clear identification of the source of the anger and a commitment to preventing escalation of anger during discussions.

Escalation of anger may lead to destructive emotions and behaviors, including hostility, aggression, or violence. Generally, hostility is characterized by open antagonism and may be expressed through both verbal and nonverbal means in combination with behaviors ranging from insensitive to destructive in nature. Aggression describes any behavior that is intended to harm another person, particularly when the other person is motivated to avoid the harm (Warburton & Anderson, 2015). The intended harm can be physical or emotional. Aggression associated with physical harm can lead to violence. Violence is the application of physical force with the intent to abuse or injure one or more individuals.

Depression is a persistent feeling of emptiness, hopelessness, sadness, or despair. It is often accompanied by a loss of interest (apathy) with regard to activities, including those related to daily living. Manifestations of depression include behavioral, emotional, and physical signs and symptoms. Chronic, recurrent, or extended periods of depression signal the need for evaluation and potential treatment (see the exemplar on Depression in the module on Mood and Affect).

Cognitive Indicators

In response to stress, cognitive indicators include changes in mental processes such as problem solving and cognitive structuring. When under stress, impairments in cognitive abilities may manifest as suppression, diminished or impaired self-control, and fantasizing.

Problem solving incorporates evaluating a challenging situation, identifying potential steps to resolve the situation, and then implementing those steps. In addition, problem solving includes evaluating the efficacy of solutions and identifying and implementing alternative approaches to adequately resolve a problem or challenge.

Cognitive structuring refers to the mental processes used to interpret and make sense of environmental stimuli. For example, through cognitive structuring, a nurse working in the hospital environment interprets the sound associated with an activated nursing call light to mean that a patient needs assistance. More complex application of cognitive structuring includes drawing from previous experiences with problem solving and the associated outcomes and then, through general application of those past experiences, forming a plan for resolving a present challenge.

Suppression, which is a defense mechanism, is the active, conscious process of denying unacceptable thoughts or emotions (Kneisl & Trigoboff, 2013). Suppression can be

Multisystem Effects of Stress

Sensory

- Pupillary dilation allows entrance of more light and enhanced visual perception
- Enhanced awareness and alertness in response to severe threats

Endocrine

- ↑ release of glucocorticoids and increased gluconeogenesis, which leads to increased serum glucose

Urinary

- ↑ sodium and water retention due to mineralocorticoid release, which leads to ↓ urine output and ↑ blood volume

Musculoskeletal

- ↑ muscular tension in preparation for fight or flight

Other Disorders

- Cancer
- Accident proneness
- Decreased immune response

Integumentary

- Diaphoresis to offset increased body temperature secondary to increased metabolism
- Skin pallor secondary to vasoconstrictive effects of norepinephrine

Respiratory

- ↑ respiratory rate and depth of respirations
- Dilation of bronchioles to facilitate increased oxygenation

Cardiovascular

- ↑ heart rate and cardiac output to promote transport of oxygen and nutrients throughout the body

Gastrointestinal

- Inhibition of the parasympathetic nervous system leads to:
- ↓ peristalsis and possible constipation
 - ↑ flatus
 - ↓ salivation
 - ↑ serotonin levels in the gut which leads to feelings of nausea

healthy; for example, an individual may suppress anger related to a disagreement with his significant other in order to effectively perform his work-related duties and demonstrate a positive attitude toward his coworkers. However, suppression may also lead to avoidance of facing problems or challenges.

Self-control is the ability to restrain oneself from acting on impulse or to behave in such a manner as to delay gratification. In an extreme example, exercising self-control may prevent fear or panic from overriding logic when faced with a stressful situation. However, attempts at exercising self-control—or a desire to appear to have self-control—can lead to ignoring or denying emotions and neglecting to ask for needed assistance.

Fantasizing, or *daydreaming*, is imagining the fulfillment of desires or wishes or mentally picturing the resolution of a situation in a manner that is more favorable than the resolution that occurred in reality. Fantasizing can be healthy and may even lead to identifying solutions to problems. However, excessive use of fantasy as a form of coping or in an attempt to avoid facing challenges can delay problem resolution.

Ego Defense Mechanisms

Frequently referred to as *defense mechanisms*, **ego defense mechanisms** were proposed and defined by Sigmund Freud (1946) as being unconscious psychologic processes developed for the purpose of defending the personality (or self). Individuals use defense mechanisms to balance the tensions that emerge during times of stress and to protect themselves from anxiety and its adverse effects. See **Table 31-4** » for a description of the primary defense mechanisms, as well as examples of their functional purpose and effects, which may be positive or negative.

Defense mechanisms are essential to psychologic survival. Just as the fight-or-flight response supports individual physical survival, defense mechanisms protect our psychologic state. Nurses must not only identify the defense mechanisms used by patients, but they also must recognize how they themselves use defense mechanisms to gain insight into their own defensive coping patterns. It is important to remember that defenses protect the individual and the ego. Providing a safe and nonjudgmental environment helps patients let go of protective defenses and begin to cope with reality.

Concepts Related to Stress and Coping

Stress and coping are integrally linked to all aspects of nursing care. Patients who experience illness and disease are exposed to increased physical and emotional stress compared to their healthy counterparts, and this stress may extend to their caregivers (American Psychological Association, 2012). Individuals who have been exposed to personal loss or trauma are also susceptible to increased stress. Even on the joyful occasion of a new baby, new parents and siblings experience stress related to disrupted sleep patterns, exhaustion, caregiving demands, and decreased attention to self. This stress is heightened even more for the family if the infant has health problems, especially if it is a chronic illness that will affect the child for years (Cousino & Hazen, 2013).

Individuals exposed to high levels of stress due to personal health problems, caregiving responsibilities, or daily life struggles are more susceptible to emotional and physical health problems such as depression, obesity, and cardiovascular disease. This is because stress is intricately linked to physiologic function. The stress response triggers activation of the sympathetic nervous system, which in turn prompts the release of numerous neurotransmitters and hormones, with the primary stress mediators being catecholamines and glucocorticoids. The development of glucocorticoid receptor resistance associated with chronic stress may produce an environment that fails to downregulate the inflammatory response, thus leading to disease susceptibility (Cohen et al., 2012).

Nursing professionals are not exempt from the stress related to caregiving duties. Left unmanaged, what initially manifests as stress can translate into something far more serious. Because of occupation-specific demands, including irregular work schedules and increased workloads due to staffing shortages, nurses are at particularly high risk for **burnout**. In addition to adverse emotional and physical effects on the nurse, burnout is also associated with reduced quality of care and decreased patient satisfaction with nursing care (Stimpfel, Sloane, & Aiken, 2012).

Although stress may not be a primary diagnosis for all patients, every patient who seeks medical attention and requires nursing care will benefit from knowledge about coping techniques related to their unique situation. Individuals who experience chronic stress are more likely to engage in unhealthy coping behaviors. In contrast, nurses can support healthy coping behaviors by implementing caring interventions, using therapeutic communication, and providing patient teaching. In addition, they can advocate for patients, caregivers, and other nursing professionals when collaborative care is needed. The Concepts Related to Stress and Coping feature lists some, but not all, of the related concepts. They are presented in alphabetical order.

Alterations from Normal Coping Responses

When an individual experiences stress so disabling that functioning is adversely affected, the individual is highly susceptible to the development of a disorder of anxiety, stress, or trauma. The DSM-5 recognizes three different classifications of disorders related to stress and coping (American Psychiatric Association [APA], 2013):

- **Anxiety disorders**, which include separation anxiety disorder, selective mutism, specific phobia, social anxiety disorder (social phobia), panic disorder, agoraphobia, generalized anxiety disorder, substance/medication-induced anxiety disorder, anxiety disorder due to another medical condition, other specified anxiety disorder, and unspecified anxiety disorder. Anxiety disorders and phobias are discussed in detail in Exemplar 31.A.
- **Obsessive-compulsive and related disorders**, which include obsessive-compulsive disorder, body dysmorphic disorder, hoarding disorder, trichotillomania (hair-pulling disorder), excoriation (skin-picking disorder),

TABLE 31–4 Ego Defense Mechanisms

Defense Mechanism	Example(s)	Use/Purpose
Compensation: covering up weaknesses by emphasizing a more desirable trait or by overachievement in a more comfortable area	A high school student too small to play football becomes the star long-distance runner for the track team.	Allows an individual to overcome weakness and achieve success
Denial: attempting to screen or ignore unacceptable realities by refusing to acknowledge them	A woman, though told her father has metastatic cancer, continues to plan a family reunion 18 months in advance.	Temporarily isolates an individual from the full impact of a traumatic situation
Displacement: transferring or discharging emotional reactions from one object or person to another object or person	A husband and wife are fighting, and the husband becomes so angry he hits a door instead of his wife. A student gets a C on a paper she worked hard on and goes home and yells at her family.	Allows for feelings to be expressed through or to less dangerous objects or people
Identification: attempting to manage anxiety by imitating the behavior of someone feared or respected	A student nurse imitates the nurturing behavior she observes one of her instructors using with patients.	Helps an individual avoid self-devaluation
Intellectualization: evading the emotional response that normally would accompany an uncomfortable or painful incident by using rational explanations that remove from the incident any personal significance and feelings	The pain over a parent's sudden death is reduced by saying, "He wouldn't have wanted to live disabled."	Protects an individual from pain and traumatic events
Introjection: a form of identification that allows for the acceptance of others' norms and values into oneself, even when contrary to one's previous assumptions	A 7-year-old tells his little sister, "Don't talk to strangers." He has introjected this value from the instructions of parents and teachers.	Helps an individual avoid social retaliation and punishment; particularly important for the child's development of superego
Minimization: not acknowledging the significance of one's behavior	An individual says, "Don't believe everything my wife tells you. I wasn't so drunk I couldn't drive."	Allows an individual to decrease responsibility for his or her own behavior
Projection: blaming others or the environment for unacceptable desires, thoughts, shortcomings, and mistakes	A mother is told her child must repeat a grade in school, and she blames this on the teacher's poor instruction. A husband forgets to pay a bill and blames his wife for not giving it to him earlier.	Allows an individual to deny the existence of shortcomings and mistakes; protects self-image
Rationalization: justifying certain behaviors by faulty logic and ascription of motives that are socially acceptable but did not in fact inspire the behavior	A mother spansks her toddler too hard and says it was all right because he couldn't feel it through the diapers anyway.	Helps an individual cope with the inability to meet goals or certain standards
Reaction formation: a mechanism that causes people to act exactly opposite to the way they feel	An executive resents his bosses for calling in a consulting firm to make recommendations for change in his department, but verbalizes complete support of the idea and is exceedingly polite and cooperative.	Aids in reinforcing repression by allowing feelings to be acted out in a more acceptable way
Regression: resorting to an earlier, more comfortable level of functioning that is characteristically less demanding and responsible	An adult throws a temper tantrum when he does not get his own way. A critically ill patient allows the nurse to bathe and feed him.	Allows an individual to return to a point in development when nurturing and dependency were needed and accepted with comfort
Repression: an unconscious mechanism by which threatening thoughts, feelings, and desires are kept from becoming conscious; the repressed material is denied entry into consciousness	A teenager, seeing his best friend killed in a car crash, becomes amnesic about the circumstances surrounding the accident.	Protects an individual from a traumatic experience until he or she has the resources to cope
Sublimation: displacing energy associated with more primitive sexual or aggressive drives into socially acceptable activities	An individual with excessive, primitive sexual drives invests psychic energy into a well-defined religious value system.	Protects an individual from behaving in irrational, impulsive ways
Substitution: replacing a highly valued, unacceptable, or unavailable object with a less valuable, acceptable, or available object	A woman wants to marry a man exactly like her dead father and settles for someone who looks a little bit like him.	Helps an individual achieve goals and minimizes frustration and disappointment
Undoing: performing an action or using words designed to cancel some disapproved thoughts, impulses, or acts in which the person relieves guilt by making reparation	A father spansks his child and the next evening brings home a present for him. A teacher writes an examination that is far too difficult, then constructs a grading curve that makes it easy to earn a high grade.	Allows an individual to appease guilty feelings and atone for mistakes

substance/medication-induced obsessive-compulsive and related disorder, obsessive-compulsive and related disorder due to another medical condition, other specified and obsessive-compulsive and related disorder, and unspecified obsessive-compulsive and related disorder. Obsessive-compulsive disorder (OCD) is discussed in detail in Exemplar 31.C.

- **Trauma- and stressor-related disorders**, which include reactive attachment disorder, disinhibited social engagement disorder, posttraumatic stress disorder, acute stress disorder, adjustment disorders, and other specified trauma- and stressor-related disorder. Posttraumatic stress disorder is discussed in an exemplar in the module on Trauma.

Concepts Related to Stress and Coping

CONCEPT	RELATIONSHIP TO STRESS AND COPING	NURSING IMPLICATIONS
Addiction	High chronic stress → unhealthy coping behaviors → ↑ alcohol, nicotine, or substance abuse	<ul style="list-style-type: none"> ■ Assess all patients and caregivers for signs of addiction. ■ Educate patients and caregivers about the harmful effects of substance use and addictive behaviors. ■ Refer patients and caregivers to counseling or support groups as needed.
Collaboration	<p>Multiple health issues → ↑ stress for the patient → ↑ need for collaboration between healthcare providers</p> <p>Conflict between family members or between patients and healthcare providers → ↑ stress for all parties involved → ↑ need for collaboration with a neutral third party</p>	<ul style="list-style-type: none"> ■ Assess stress levels and coping habits of patients with multiple health issues. ■ Identify collaborators who may be able to provide information or patient teaching that will help reduce the patient's stress level and increase the use of healthy coping techniques. For example, a patient with high stress levels related to obesity, diabetes mellitus, and cardiovascular disease may benefit from collaboration with a nutritionist. ■ Assess families for signs of family conflict that may be increasing the stress level for patients and caregivers. ■ Refer patients and families struggling with family conflict to family therapists or mediators.
Mood and Affect	<p>Depression → ↑ stress → ↑ depression</p> <p>↑ depression → ↑ risk for suicide</p>	<ul style="list-style-type: none"> ■ Assess the coping techniques of patients with mood and affective disorders and their caregivers. ■ Use therapeutic communication to encourage patients to engage in positive coping and adhere to their recommended treatment regimen. ■ Refer patients and caregivers to counseling or support groups as needed.
Perfusion	Stress response → release of catecholamines epinephrine and norepinephrine → ↑ blood pressure and ↑ heart rate	<ul style="list-style-type: none"> ■ Assess patients for hypertension and tachycardia. ■ Be aware that prolonged exposure to stress can lead to long-term hypertension and secondary complications, including cardiovascular disease, cerebrovascular accident (CVA, or stroke), and renal damage. ■ Educate patients about stress management techniques, including regular physical exercise. ■ Facilitate referrals to counselors as ordered.
Reproduction	<p>Changing hormone levels associated with pregnancy and childbirth → ↑ feelings of being overwhelmed → ↓ ability to cope</p> <p>Responsibilities associated with caring for a newborn → ↑ stress</p>	<ul style="list-style-type: none"> ■ Assess pregnant women for self-care activities and emotional health. ■ Assess mothers with newborns for self-care activities, sleep patterns, and emotional health. ■ Assess mothers with newborns for postpartum depression. ■ Assess mothers and fathers with premature newborns for signs of stress and inadequate coping techniques. ■ Provide patient teaching on newborn care techniques, breastfeeding, infant sleeping patterns, and other topics that may be contributing to stress in new parents.
Self	Stress → ↑ incidence of feeding and eating disorders	<ul style="list-style-type: none"> ■ Assess individuals with stress for abnormal weight gain or loss. ■ Assess patients' eating habits, including whether stress makes them eat more or less than normal. ■ Provide patient teaching about healthy eating habits to individuals who use unhealthy eating habits to cope with stress. ■ Refer patients and caregivers to counseling or support groups as needed.
Teaching and Learning	<p>Patient teaching about coping techniques → ↓ stress → ↑ healthy coping behaviors → ↑ overall health</p> <p>Mentoring less experienced healthcare providers → ↓ stress → ↑ job performance → ↑ patient satisfaction and health</p>	<ul style="list-style-type: none"> ■ Teach patients and family members struggling with high levels of stress about healthy coping techniques, including relaxation techniques and therapeutic communication. ■ Provide mentoring and encouragement to other healthcare providers to reduce stress. ■ Teach coping techniques to other healthcare providers, which can reduce on-the-job stress, prevent burnout, and increase job performance.

Alterations and Therapies

Stress and Coping

ALTERATION	DESCRIPTION	MANIFESTATIONS	INTERVENTIONS AND THERAPIES
Generalized anxiety disorder	Excessive worry about everyday problems for at least 6 months, with anxiety that is more intense than the situation warrants	<ul style="list-style-type: none"> Anticipation of disaster and preoccupation with health issues, money, familial problems, or challenges at work Difficulty relaxing, tendency to startle easily, trouble concentrating and falling asleep Various somatic complaints, which may include fatigue, headache, muscle tension and aches, digestive issues, irritability, shortness of breath or dyspnea, and hot flashes 	<ul style="list-style-type: none"> Psychotherapy, including cognitive-behavioral therapy (CBT) Pharmacotherapy, which may include antidepressants (e.g., selective serotonin reuptake inhibitors [SSRIs]), anxiolytic medications (e.g., benzodiazepines), beta-blockers, and antipsychotic medications Relaxation techniques, such as massage and guided imagery Mental health counseling
Phobias	An intense, persistent, irrational fear or dread of an object, situation, or activity that elicits panic and automatic avoidance of or compelling urge to stay away	<ul style="list-style-type: none"> Fear and anxiety in response to exposure (or, in some cases, imagined exposure) to the phobia-related object, situation, or activity 	<ul style="list-style-type: none"> Pharmacotherapy, which may include short-term use of benzodiazepines, or administration of SSRIs or tricyclic antidepressants CBT Desensitization and implosion therapy for specific phobias Dietary changes, including alcohol and caffeine restrictions
Panic disorder	A sudden attack of terror that can produce a sense of unreality, impending doom, or a fear of losing control	<ul style="list-style-type: none"> Somatic manifestations may include pounding heart, rapid heart rate (tachycardia), rapid respirations (tachypnea), weakness, sweatiness, light-headedness, or dizziness 	<ul style="list-style-type: none"> Reduced environmental stimuli or placement in a quiet, nonstimulating environment CBT Pharmacotherapy, which may include antidepressants (e.g., SSRIs or tricyclic antidepressants), anxiolytic medications (e.g., benzodiazepines), beta-blockers, and antipsychotic medications Relaxation techniques, such as massage and guided imagery Mental health counseling
Obsessive-compulsive disorder (OCD)	Characterized by obsessive thoughts and compulsive repetitive behaviors formed in response to the obsessive thoughts to lower the level of anxiety experienced	<ul style="list-style-type: none"> Signs and symptoms vary depending on the theme of the specific obsessions and compulsions (see Exemplar 31.C). For example, OCD that features a theme of excessive cleanliness may include a fixation on the need to clean oneself and/or the environment (and fear of contamination), along with repetitive behaviors related to cleaning. 	<ul style="list-style-type: none"> CBT Antidepressants

Prevalence

According to the Anxiety and Depression Association of America (ADAA, 2014), anxiety disorders are the most common mental health disorders in the United States. The prevalence of anxiety disorders is approximately 18%, impacting 40 million individuals (ADAA, 2014). Generalized anxiety disorder (GAD) affects 6.8 million adults in the United States, and twice as many women as men. The disorder can develop at any time in the life cycle, although individuals in early adulthood

are at greatest risk for developing it (ADAA, 2015a). Additional U.S. prevalence rates for disorders that are discussed in this module's exemplars include the following (ADAA, 2014):

- Obsessive-compulsive disorder (OCD) affects approximately 2.2 million individuals or an estimated 1.0% of the population.
- Phobias affect an estimated 19 million individuals, which is approximately 8.7% of the population.

Genetic Considerations and Risk Factors

Gender is a significant risk factor associated with anxiety and stress-related disorders. Overall, women are about twice as likely as men to develop an anxiety disorder. This may be because women are more sensitive to low levels of the stress hormone corticotropin-releasing factor (CRF) (ADAA, n.d.a). However, women are not more susceptible to every type of anxiety disorder. For example, OCD and social anxiety disorder are equally common in men and women (ADAA, 2014).

Both genetic factors and life experiences contribute to anxiety disorders. Anxiety disorders tend to run in families, a trend related partially to genetics and partially to environment. Up to 50% of patients with panic disorder and 40% of people with GAD have close relatives with the disorder, and individuals with close relatives who have OCD are 9 times more likely to develop OCD themselves (University of Maryland Medical Center [UMMC], 2013). In addition, many children develop fears and anxiety that are similar to those of their parents. For some patients, exposure to trauma or a significant event may trigger an anxiety disorder in individuals who are genetically susceptible (Cleveland Clinic, 2014).

Other factors that influence the development of anxiety disorders include personality-related characteristics; for example, shy children are at an increased risk (Mayo Clinic, 2014a). Traumatic events, including a history of spousal or childhood abuse and being bullied, also increase the risk of impairment. Social factors, especially limited or absent socialization and living in a threatening environment, increase an individual's susceptibility to developing an anxiety disorder. Even hypersensitivity of the amygdala—which is the brain's "fear center"—is believed to be a potential factor that may increase the likelihood for development of an anxiety-related disorder (UMMC, 2013).

Case Study » Part 1

Kevin DeLarno is a 23-year-old student who is completing his second year of graduate school in the study of anatomy and physiology. He presents to the university student health services center with complaints of frequent headaches, including a current headache that he describes as "a throbbing in the front of my head." He rates his pain as 7 on a scale of 0 to 10, with 10 being the worst imaginable pain. During his patient interview, he denies any past medical history or any additional complaints, including trauma, visual disturbances, dizziness, weakness, or neurologic changes. According to Mr. DeLarno, his headaches are "interfering with my study schedule. I have exams every week and I can't concentrate on studying. If I don't get these headaches under control, I'm going to end up failing at least one class this semester." He reports that he drinks "about a pot of coffee a day" and occasionally smokes a cigar when he is socializing with his friends.

Upon arrival, Mr. DeLarno's vital signs include temperature 97.9°F oral; pulse 92 bpm; respirations 18/min; and BP 153/82 mmHg. Auscultation of his heart and lungs reveals no abnormal findings. Mr. DeLarno insists he is "fine, except for these stupid headaches. I'm sure it's just stress. I need something to help me get them under control so I can get my work done." During his assessment interview, the nurse asks if Mr. DeLarno has made any recent changes to his daily routine or health habits. He replies, "There aren't any recent changes, but soon, there will be. I'm getting married in 3 months and my fiancé and I will be moving off campus. We're in the process of buying a house."

Mr. DeLarno further states that he is "excited about getting married," but feels the wedding planning has gotten out of hand, as he and his fiancé have already exceeded their wedding budget. When asked what activities he engages in for enjoyment and recreation, he replies, "I don't have time for anything except classes and studying. I used to work out and play racquetball three times a week, but I don't have the time for that right now."

Clinical Reasoning Questions Level I

1. Based on Mr. DeLarno's statements, what are his current potential sources of stress?
2. In addition to his complaints of recurrent headaches, which assessment data might reflect manifestations of the stress response?
3. Describe the effects of coffee and nicotine intake, including how these effects are similar to those evoked by the stress response.

Clinical Reasoning Questions Level II

4. Do positive stressors and negative stressors differ in terms of physiologic effects? Explain your answer.
5. Presuming Mr. DeLarno's headaches are stress related, what nursing diagnoses would be appropriate for inclusion in his nursing plan of care?
6. What nursing interventions could be implemented to promote stress reduction for Mr. DeLarno?

Health Promotion

Health promotion for individuals experiencing anxiety focuses on decreasing exacerbation of symptoms and identifying healthy coping behaviors that the patient is motivated to use. It is important to note that patients who are experiencing severe or panic levels of anxiety will not be able to retain new information and will require different interventions. For those who are able to focus on new information, topics for patient teaching can be found in the Patient Teaching feature.

Family wellness promotion is also essential to enhancing physiologic and psychosocial outcomes for patients of all ages (see the module on Family). The link between the development of mental illness and childhood abuse and neglect serves to emphasize this point. Research suggests that childhood abuse is associated with an increased risk for physical and psychologic disorders, including depression and anxiety. These increased risks remain in effect decades after the abuse occurs (Herrington et al., 2013). Even when overt abuse and neglect are not factors, family dynamics and parenting styles can pose serious threats to a child's psychosocial well-being. For example, frequent changes in caregivers may predispose a child to the development of separation anxiety disorder or reactive attachment disorder (APA, 2013; Mayo Clinic, 2014b).

Nursing Assessment

Just as individuals evaluate (appraise) and prioritize stressors, the nurse assesses and prioritizes health concerns. During the assessment, the nurse will help patients identify stressors that trigger unhealthy coping responses as well as the potential effects of those responses.

Many patients with anxiety will present complaining of physical symptoms. In the case study example, Mr. DeLarno's presenting complaint is a headache, which he then attributes to "just stress." Some patients, however, will be unable to

Patient Teaching

Wellness Promotion for Patients with Stress-Related Disorders

Nurses should provide patient teaching to patients with stress-related disorders to promote wellness and healthy coping techniques. Topics for teaching may include:

- **Physical exercise:** Educate the patient about the benefits of physical exercise (see the module on Health, Wellness, Illness, and Injury). Physiologic benefits of regular physical exercises include improved cardiac and pulmonary function, enhanced muscle tone and joint mobility, and weight control. Psychologic benefits include tension relief, stress reduction, enhanced sense of well-being, and promotion of relaxation following activity.
- **Sleep/rest patterns:** Promote a healthy balance between sleep/rest and activity and teach relaxation techniques to promote relaxation and sleep. Adequate sleep and rest are essential to survival, allow for physical healing and restoration, and enhance cognitive function. Sleep also helps remove free radicals, which are believed to be associated with illness and disease. Promote good sleep hygiene (see the Patient Teaching feature on Sleep Hygiene in the module on Comfort). Consider providing patient teaching about breathing

exercises, imagery, muscle relaxation, movement techniques, and biofeedback.

- **Nutrition:** Provide education related to balanced nutrition and facilitate referrals to dietary professionals and nutritionists. Teach patients that inadequate nutrition reduces physical resistance to illness and increases susceptibility to disease and illness (see the module on Nutrition). Teach patients that the excessive intake of caffeine and use of nicotine may interfere with sleep/rest patterns.
- **Time management:** Teach patients how to balance fulfilling personal responsibilities (e.g., work, family, school) with time for rest, socialization, and extracurricular activities. Teach patients that effective time management is associated with an increased sense of control and decreased sense of stress.
- **Boundary setting:** Teach patients how to identify potential stressors and how to implement personal boundaries. Setting up personal boundaries can aid the patient in determining the appropriateness of requests/demands made by others and can allow the individual to identify which requests/demands can be fulfilled while still maintaining wellness.

articulate anxiety, because of a lack of either awareness or understanding of the source of their symptoms or because of a reluctance to disclose what they consider very personal information. Through developing the therapeutic nurse–patient relationship, the nurse may be able to encourage reluctant patients to disclose necessary information or come to an awareness of how stress and anxiety are impacting their health.

During the nursing assessment, the nurse acknowledges and affirms the patient's concerns. **Box 31–2** describes application of the nursing transactional model with regard to specific communication strategies that may be appropriate for use during assessment of the patient with anxiety.

Observation and Patient Interview

The patient interview should include collection of data related to the patient's current and past illnesses, specific

physical complaints, general health history, patient-perceived stressors or stressful incidents, manifestations of stress, and past and present coping strategies. In addition to an assessment interview, the nurse may use a simple checklist while talking with and observing the patient to note indications of stress (see **Box 31–3** for a sample checklist). The first step in mediating the effect of a stressor is conscious awareness of the manifestations of stress. Review the symptom checklist to increase your awareness of and assess your own stress reactions and behaviors.

SAFETY ALERT Legal requirements to maintain patient confidentiality do not apply in the event of a patient's threat to harm self or others. If a patient indicates during the patient interview or any time during the assessment that he or she intends to injure self or others, the nurse has the responsibility to report this information to the proper authorities.

Box 31–2

Application of the Nursing Transactional Model to Assessment of the Patient with Anxiety

In the nursing transactional model, the nurse is part of the anxious patient's environment and can influence changes in the patient with both verbal and nonverbal cues. From the very first interaction with the patient, the nurse's demeanor conveys a great deal of information to the patient about how the patient can expect to be treated. Initial nursing actions that inspire patient confidence and that may help calm anxious patients include the following:

- Focus on the person: Make eye contact as appropriate and minimize distractions.
- Take a nonthreatening stance.
- Validate the patient's feelings: "I know you are very uncomfortable; we will do everything we can to help you feel better."

- Determine and address the patient's immediate concerns: "What can I do right away to help you?"
- Remember to address the patient by name. Some patients find terms of endearment such as "Honey" or "Sweetie" impersonal or demeaning. Using the patient's first name may be seen as patronizing if the patient is expected to use the nurse's last name. On the other hand, some patients respond positively to the informality of first-name use. Ask patients how they would prefer to be addressed, and never use the first name of anyone over age 18 without permission.

Box 31–3

Stress Assessment Checklist

Behavioral	Cognitive	Emotional	Physical
Always doing too much	Ambivalence	Agitation/anger	Constipation
Argumentativeness	Difficulty concentrating or listening	Anxiety and feeling pressured	Diaphoresis
Grinds teeth during sleep	Fear of the unknown	Crying	Diarrhea
Increase in compulsive behaviors (eating, drinking, nail biting, sexual activity, smoking)	Forgetfulness	Defensiveness	Difficulty falling asleep
Looks at watch or clock often	Lack of creativity	Easily annoyed	Dry mouth
Loud voice	Lack of initiative	Fear	Fatigue
Pacing	Lack of a sense of humor	Feeling overwhelmed	Gastrointestinal upsets or butterflies
Talks too fast	Memory lapses/loss	Feeling powerless	Headaches
Vigilance	Short attention span	Hostility	Increase in blood sugar levels
Withdrawal	Trouble thinking	Irritability	Increase in respiration rate
Work on multiple projects simultaneously	Wanting to run away	Isolation	Insomnia
	Worrying	Jumpiness and nervousness	Muscular stiffness and tension
		Sadness	Pallor
		Suspiciousness	Racing or pounding heart
			Restlessness
			Shakiness
			Sweaty palms
			Urinary frequency

Screening tests are available for use in the identification of many anxiety and stress-related disorders, including GAD, OCD, and specific phobias.

» **Stay Current:** To view a sample of these screening tools, visit the Anxiety and Depression Association of America's online library at www.adaa.org/living-with-anxiety/ask-and-learn/screenings.

Physical Examination

Physical assessment of the patient should include observation and testing of the body systems for physical manifestations of stress. Gastrointestinal signs and symptoms of stress may include constipation, diarrhea, dry mouth, and nausea. Integumentary signs may include diaphoresis and pallor. Neurologic symptoms may include insomnia, fatigue, headaches, and restlessness. Cardiovascular and respiratory signs may include tachycardia and hyperpnea. Endocrine and urinary signs may include hyperglycemia and urinary frequency. Motor symptoms may include sluggish or stiff movements and muscle tension. Stress and anxiety may also manifest in behavioral habits that can be observed, such as cutting, fingernail biting, or evidence of crying. Remember that physical manifestations of distress may not be apparent when cognitive coping is effective.

Diagnostic Tests

For identification of disorders of anxiety and stress-related disorders, diagnostic criteria are collected primarily through patient interviews and reports of subjective symptoms. Medical testing may be conducted to rule out a medical etiology such

Focus on Diversity and Culture

Assessing Patients from Different Cultures

When working with patients from different cultures, nurses must take care not to inadvertently attribute a normal, healthy cultural response as inappropriate or maladaptive. Cultural expressions of distress vary. For example, some Chinese immigrants are less likely to discuss stress but will complain of somatic illnesses as a result (Lee, Suchday, & Wylie-Rosett, 2012). Therefore, a thorough assessment of stressors, the individual patient's perception of the stressors and cultural background, and the patient's efforts to seek help or reduce distress will help distinguish each patient's individual stress responses.

The Cultural Formulation Interview (CFI) outlined in the DSM-5 may be used to assist healthcare providers in interviewing patients as part of a comprehensive mental health assessment. The CFI is a series of 16 questions designed to assess patients in four areas (APA, 2013):

- Cultural definition of the problem
- Cultural perceptions of cause and support
- Cultural factors affecting coping and past help-seeking behaviors
- Cultural factors affecting current help-seeking behaviors.

as cardiovascular dysfunction or an adverse response to a medication. Patients with disorders related to stress and coping, particularly children, may present with somatic (physical) complaints and may not initially articulate any anxiety or trauma. Although patients may present to primary care providers with complaints that appear to be related to exposure to stress or due to impaired coping mechanisms, diagnosis of associated psychiatric disorders requires evaluation by a trained mental health professional, such as a psychiatrist or advanced practice psychiatric nurse.

Case Study » Part 2

Mr. DeLarno is awaiting evaluation by the university healthcare clinic's nurse practitioner. He agrees to dimming of his room lights while he waits. After resting quietly for 10 minutes, he falls asleep. When the nurse awakens Mr. DeLarno to reassess him, he states, "I'm surprised I fell asleep. Usually, I can't fall asleep no matter how hard I try to relax. I'm only sleeping a couple of hours each night." He reports his headache "feels quite a bit better, but I know it's going to come back with a vengeance as soon as I start studying again." He rates his pain as 3 on a scale of 0 to 10, with 10 being the worst imaginable pain. His blood pressure has decreased to 128/72 mmHg and his pulse is now 78 bpm.

Upon arriving to assess Mr. DeLarno, the nurse practitioner introduces herself and asks the patient to describe his current complaints, as well as any similar problems he has experienced in the past. Mr. DeLarno states, "My headache is better, but I need something to help me control it when I'm studying. I think alprazolam would help—I have a friend who takes that when he gets stressed." The nurse practitioner responds by noting that she would like to further assess Mr. DeLarno, as well as ask him a few questions before making any treatment recommendations. Mr. DeLarno replies, "The nurse I saw earlier already listened to my heart and lungs, and she already asked me a bunch of questions. Headaches are my only problem—I don't need any additional workup. I can't stay here all day. Are you able to help me or not?"

Clinical Reasoning Questions Level I

1. Explain the most likely reasons for Mr. DeLarno's decreased headache and decrease in blood pressure and heart rate.
2. What is the significance of Mr. DeLarno's reported sleep habits?

Clinical Reasoning Questions Level II

3. In the event that Mr. DeLarno's complaints are related to anxiety, is a prescription for alprazolam a preferable first approach to treatment? Why or why not?
4. How should the nurse practitioner respond to Mr. DeLarno's seeming frustration with the need for additional assessment?

Independent Interventions

Nursing care of patients with alterations in stress and coping includes independent interventions such as using therapeutic communication, encouraging the patient to maintain or achieve optimal health, and assisting the patient with identifying strategies that will help him meet his goals.

Additional independent nursing interventions include implementing cognitive-behavioral interventions, such as teaching nonpharmacologic relaxation techniques, as well as encouraging patient and family participation in support groups. Validating the patient's feelings is essential to building self-esteem and fostering healthy coping. Reinforcing positive coping efforts, offering hope and reassurance to the

patient about her ability to cope, and helping her identify successes in life can provide a sense of personal power and hope. Spiritual distress occurs when an individual loses hope of ever resolving the problem or coping more adaptively. The chronic nature of anxiety disorders can be devastating and can erode an individual's sense of power and self-worth.

In the care of patients diagnosed with mental illness, one of the nurse's most crucial roles is patient advocacy. Covert discrimination against individuals with mental illness still exists today in society and the healthcare system. According to the U.S. Department of Housing and Urban Development (HUD, 2014), in 2013–2014, an estimated 20% of homeless individuals were experiencing mental illness. Even when provided with housing, these individuals were unlikely to remain off the streets unless they received access to continued healthcare treatment and services. Every individual and nurse who cares enough about the plight of individuals living with mental illnesses has the ability to impact public policy. Organizations such as the National Alliance on Mental Illness (NAMI) provide a platform for individuals to work collaboratively.

» **Stay Current:** To learn more about advocating for individuals with mental illnesses, visit NAMI's website, www.nami.org. NAMI is the nation's largest organization for individuals experiencing mental illness and their families. NAMI has affiliates in every state and in about 1000 communities across the country.

Collaborative Therapies

Collaborative interventions for patients experiencing moderate to severe difficulty coping with stressors include administration of prescribed pharmacologic therapies and facilitation of counseling, psychotherapy, and other therapies as ordered. In addition to being well informed about various interventions and treatment options, such as psychotherapy, nurses should be able to recognize and manage their own responses to stress.

Psychotherapy

Psychotherapy is a preferred method of treating anxiety and other psychiatric disorders. Psychotherapy involves talking with a mental health professional, such as a psychiatrist, mental health nurse, advanced practice psychiatric nurse, psychologist, social worker, or counselor, to explore the nature and symptom management of the disorder (National Institute of Mental Health [NIMH], 2015). The severity of symptoms may warrant hospitalization in a safe therapeutic milieu, or social setting, for the individual. Such an intervention provides needed protection from environmental stressors and the additional support of group therapy. The impact of overwhelming and disabling anxiety can create vulnerability to depression, suicidal thoughts, or self-harm.

Cognitive–Behavioral Therapy

Cognitive-behavioral therapy (CBT) combines cognitive techniques and behavior modification to change detrimental beliefs and thought patterns. The goals of CBT include enhancing problem-solving and coping skills. Usually, the therapist guides the patient in identifying detrimental or distorted thought patterns and assists her with restructuring these

thoughts and beliefs. Through analysis and reinterpretation of past and current experiences, the patient is able to learn and apply new skills that promote healthy behaviors and positive interpersonal interactions (APA, 2013; NIMH, 2013a).

Exposure-based CBT combines the techniques used in CBT with exposure of the patient to a controlled version of the situation that triggers the anxiety. By inducing mild anxiety under the supervision of a mental health expert, exposure-based CBT can help an individual with panic disorder learn that his panic attacks are not heart attacks, for example (NIMH, 2015). Additional cognitive-behavioral techniques are listed in **Box 31-4** ».

Box 31-4

Additional Cognitive-Behavioral Therapeutic Techniques

The following techniques are also commonly used as a part of CBT:

- **A comprehensive assessment interview** is the first step in developing a contract with the goal of behavioral change. The purpose of the interview is to develop a complete picture of the patient's stress responses (e.g., negative thought patterns, feelings of worry or fear, or maladaptive behaviors such as repeated hand washing), so that strategies for changing these responses may be targeted. The interview process identifies problematic behavior and divides it into four areas:
 - The behavioral area, which asks what the patient is doing
 - The cognitive component, which asks what the patient is thinking
 - The affective component, which asks what the patient is feeling
 - The physiologic component, which probes the physical reality of the situation.
- **Thought stopping** is a technique that is used to help the patient change her thinking processes. Many individuals who experience anxiety have difficulty with repetitive, maladaptive thinking, and thought stopping is used to halt destructive thoughts before they get out of control. In this technique, the patient learns to stop destructive thoughts by visualizing a specific image, sensation, or circumstance. The thought-stopping agent can be the image of a traffic stop sign, the sound of the word *stop*, the tactile sensation of leaning against a closed door, or the visualization of pushing one's negative thoughts out the back door. Successful thought stopping should be implemented whenever maladaptive thoughts occur, so that over time, the patient learns to stop such thoughts reflexively.
- **A behavioral contract** outlines the behavioral changes that the patient and the mental health professional agree should take place. When negotiating a behavioral contract, a mental health provider engages the patient and family as colleagues, avoids jargon, and ensures that the patient and family are comfortable with the contract. Possible problems with behavioral contracts include a lack of understanding, a lack of commitment, a lack of adequate follow-up, and the lack of a defined plan of care. Continuing assessment, regular evaluation, and troubleshooting meetings can determine whether adjustments to the contract are necessary. Contracts can be adjusted in many ways, from changes in the prioritization of objectives to the appropriate revision of goals.

Source: Based on Kneisl, C. R., & Trigoboff, E. (2013). *Contemporary psychiatric-mental health nursing* (3rd ed.). Upper Saddle River, NJ: Pearson Education.

Pharmacologic Therapy

The therapeutic goal of psychopharmacology is to manage symptoms and alleviate distress. Generally speaking, pharmacologic therapies are most successful when used in combination with psychotherapy. Many patients require medication for only short periods of time. Some patients, however, may require longer courses of medication. Many patients with anxiety disorders can lead normal, fulfilling lives if they receive proper treatment (NIMH, 2015).

Medications used in the treatment of anxiety disorders include benzodiazepines. These medications may be used for short-term treatment during an acute phase of an anxiety disorder. Patients experiencing anxiety secondary to short-term medical therapies, such as mechanical ventilation, also may find benzodiazepines helpful. Benzodiazepines are generally not recommended for use beyond a few weeks because of their addictive properties. In addition, some research suggests that long-term use of benzodiazepines may cause permanent cognitive dysfunction, including in the areas of information processing and verbal learning (Stewart, 2005). Despite current guidelines that recommend the use of benzodiazepines primarily during the acute phase of treatment for anxiety, in reality these medications sometimes are prescribed for long-term use (Olson, King, & Schoenbaum, 2015). Patients should consult with their prescribing provider about the potential side effects of long-term benzodiazepine use.

For long-term management of certain anxiety disorders, prescribers may consider an antidepressant. SSRIs are helpful in the treatment of phobias, symptoms of OCD, and panic symptoms. Fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft) are examples of SSRIs that may be used in the treatment of patients with disorders of anxiety and stress. Tricyclic antidepressants, such as imipramine (Tofranil) or amitriptyline (Elavil), may also be used. These are contraindicated in patients with a history of heart dysfunction or heart attack (Adams, Holland, & Urban, 2017).

Monoamine oxidase inhibitors (MAOIs) such as phenelzine (Nardil), atypical antidepressants such as serotonin-norepinephrine reuptake inhibitors (SNRIs), and antipsychotic agents may also be prescribed for the treatment of these disorders. Beta-blockers may be used to block the effects of sympathetic nervous system stimulation and reduce manifestations of anxiety. See the Medications feature.

Herbal supplements, including valerian, kava, and passion flower, are used by some individuals in the treatment of anxiety. However, these medications have not been conclusively proven to be effective and may cause various side effects (Mayo Clinic, 2012a). The nurse should caution the patient to consult with his primary healthcare provider before adding herbal supplements to his medication regimen.

SAFETY ALERT The antihistamine diphenhydramine (Benadryl) is not suitable for use in the long-term treatment of anxiety-related disorders. Although diphenhydramine does produce sedation, research suggests that this drug's sedative effects are not effective for achieving anxiolysis (reduction of anxiety) (Baas et al., 2009). Moreover, cessation of diphenhydramine after long-term use can cause withdrawal symptoms. Patients with anxiety-related signs and symptoms should seek professional evaluation and guidance.

Medications

Anxiety- and Obsessive-Compulsive-Related Disorders

CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION/ INDICATIONS FOR USE	NURSING CONSIDERATIONS
Antidepressants Drug examples: <ul style="list-style-type: none"> SSRIs, such as citalopram (Celexa), escitalopram (Lexapro), fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft) Tricyclic antidepressants, such as imipramine (Tofranil) 	<p>SSRIs inhibit reuptake of the neurotransmitter serotonin in the brain, resulting in circulation of increased levels of serotonin.</p> <p>Although primarily used for treatment of depression, certain SSRIs are also effective in the treatment of patients with anxiety, OCD, and panic disorder.</p> <p>Tricyclic antidepressants block presynaptic neuronal reuptake of serotonin and norepinephrine, resulting in increased circulating levels of these neurotransmitters.</p> <p>Tricyclic antidepressants may be used in the treatment of patients with panic disorders.</p>	<ul style="list-style-type: none"> Monitor for development of suicidal ideation or worsening of symptoms. Assess for adverse effects, including dizziness or drowsiness. Counsel patients to avoid alcohol in combination with SSRIs or tricyclic antidepressants. Periodically obtain complete blood count (CBC) with differential, serum electrolyte panel, and liver and kidney function studies. Do not start SSRIs within 14 days of discontinuing MAOI drugs. Women who are pregnant or breastfeeding should not take SSRIs or TCAs.
Atypical Antipsychotics Drug examples: Olanzapine (Zyprexa) Risperidone (Risperdal)	<p>Interfere with action of serotonin and dopamine in the brain; as a result, for some patients, they promote reduction of compulsive behaviors and decreased agitation.</p> <p>In conjunction with other therapies, may be used in the treatment of patients with OCD or panic disorders.</p>	<ul style="list-style-type: none"> Monitor for neuroleptic malignant syndrome and tardive dyskinesia, and immediately report signs and symptoms of these conditions. Assess for side effects, including drowsiness, excess sedation, somnolence, or increased agitation. Monitor CBC, kidney and liver function studies, serum electrolytes, and serum glucose level. Use of atypical antipsychotics is associated with weight gain and obesity, so monitor weight over time.
Nonbenzodiazepines Drug examples: Buspirone (Buspar) Zolpidem (Ambien)	<p>Some act as a dopamine agonist in the brain and also inhibit serotonin reuptake (leading to increased circulating serotonin), producing antianxiety effect.</p> <p>Others are specific to the gamma-aminobutyric acid (GABA) receptor to produce relaxation and anxiolytic effects.</p> <p>Used to treat GAD.</p>	<ul style="list-style-type: none"> Assess for side effects, including nausea, headaches, and dizziness. Use with caution in individuals with impaired liver or kidney function. Advise patient this medication requires daily administration for several weeks to produce antianxiety effect.
Benzodiazepines Drug examples: Alprazolam (Xanax) Clonazepam (Klonopin) Diazepam (Valium) Lorazepam (Ativan) Temazepam (Restoril)	<p>Potentiate the effect of the naturally occurring inhibitory neurotransmitter GABA, leading to promotion of relaxation and a decrease in the subjective experience of anxiety.</p>	<ul style="list-style-type: none"> Not recommended for long-term use because of habit-forming properties. Monitor patient for excess sedation and dizziness. Use cautiously in patients with impaired hepatic function and monitor liver function studies for these patients. Counsel patient to avoid alcohol in combination medications in this classification.
Beta-Blockers Drug example: Propranolol (Inderal)	<p>Selectively block cardiac and bronchial beta receptors, compete with epinephrine and norepinephrine, and reduce effects of sympathetic nervous system stimulation, such as increased heart rate, increased cardiac contractility, and increased blood pressure.</p> <p>Unlabeled uses include management of anxiety states and prevention of acute panic states (such as those related to public speaking).</p>	<ul style="list-style-type: none"> Assess blood pressure and heart rate prior to administration. Withhold medication if systolic blood pressure <90 mmHg or apical pulse rate <60 bpm, or if blood pressure and apical pulse rate do not meet parameters defined by the prescribing provider. Monitor for adverse effects, including bradycardia, confusion, fatigue, and drowsiness. Beta blockers may cause hypoglycemia or hyperglycemia and mask the symptoms of hypoglycemia in patients with diabetes, so any patient with diabetes who is using beta-blockers should be monitored carefully.

Source: Based on Adams, M. P., Holland, L.N., & Urban, C. (2017). *Pharmacology for nurses: A pathophysiologic approach*. (5th ed.). Hoboken, NJ: Pearson Education.

Case Study » Part 3

Following Mr. DeLarno's assertion that he cannot "stay here all day" and his prompting for rapid treatment, the nurse practitioner replies, "I can imagine that your headaches are interfering with every aspect of your life, Mr. DeLarno. In particular, it must be miserable to try to study while you have a pounding headache, much less to take an exam. I want to help you find the best solution, which means I'll need some more information from you." She further explains to Mr. DeLarno that additional assessment is needed to accurately identify the cause of his headaches, as well as to choose the appropriate treatment approach. Initially, Mr. DeLarno is disappointed about not receiving a prescription for alprazolam, which he again suggests will fully resolve his headaches. However, after talking with the nurse practitioner, he agrees with the plan for further assessment.

The nurse practitioner performs a focused neurologic assessment, including assessing Mr. DeLarno's pupillary response to light and his extremity strength. She also interviews him as to the presence of any alterations in sensory perception, including numbness, tingling, or other unusual sensations. With the exception of his headache and sleep disturbances, which Mr. DeLarno reports began about 8 months earlier, his assessment findings reveal no abnormalities.

Based on assessment findings, the nurse practitioner suspects Mr. DeLarno may have developed generalized anxiety disorder (GAD). For further evaluation and treatment, she refers him to a mental health specialist affiliated with the university clinic. She further instructs Mr. DeLarno to avoid caffeine and nicotine and to contact the clinic if his headaches worsen or if he experiences any alterations in sensory perception. In addition, she offers to refer Mr. DeLarno to a local massage therapist who offers one free massage to students referred by the university student health services center. The patient agrees to follow up with the student wellness center and pleasantly accepts the referral for massage, stating, "I'm calling the massage therapist as soon as I walk out of here."

Clinical Reasoning Questions Level I

1. Which of the nurse practitioner's statements represent validation of the patient's complaints? Explain how validation can serve to diffuse a tense verbal interaction with a patient.

2. How could the staff nurse support and facilitate the interventions prescribed by the nurse practitioner?

Clinical Reasoning Questions Level II

3. Identify three nursing diagnoses that are appropriate for inclusion in Mr. DeLarno's nursing plan of care.
4. What additional recommendations could be offered by the staff nurse to promote healthy sleep/rest patterns for this patient?

Lifespan Considerations

Each stage of the lifespan comes with its own developmental stressors (see **Box 31-5 »**). The individual's response to those stressors and the coping mechanisms used to deal with each stressor will differ on the basis of the developmental stage, personality, and environment.

Stress and Coping in Children and Adolescents

Stressors in children and adolescents can be divided into normative and nonnormative stressors. Normative stressors that are common to all children include separation from parents or caregivers, starting school, and making new friends. Normative stressors may also be stressors that many but not all children face, such as being overweight, parents fighting, and getting bad grades (Rice, 2012). Normative stressors for children may also include situations that would not be considered stressful for an adult, including not having enough to do and not spending enough time with parents (Lewis, Siegel, & Lewis, 1984).

Normative stressors change as the child ages. For example, the transition from childhood to adolescence involves stressors such as navigating relationships with peers and completing performance-related tasks, such as academic assignments that require public speaking. Researchers who

Box 31-5**Developmental Stressors Across the Lifespan****Infants and Toddlers**

- Separation from primary caregiver
- Cold stress, heat exposure
- Premature birth
- Maternal consumption of substances, toxins
- Feeding issues
- Impaired maternal bonding or attachment

Children

- Starting school
- Playing with peers/making friends
- Separation from parents/caregivers
- Conflict with parents/siblings

Adolescents

- Puberty
- Performance (sports, academics, arts)
- Independence (driving, job, social life)
- Relationships (peers, friends, dating, teachers, parents)
- Peer pressure
- Spiritual development

Adults

- Dating/marriage
- Birth or death of children
- Career
- Purchasing a house
- Health changes
- Divorce or death of spouse

Pregnant Women

- Hormone changes
- Body changes
- Childbirth
- Financial fears
- Fear of having an unhealthy baby or miscarriage

Older Adult

- Aging
- Retirement
- Loss of independence
- Terminal illness or multiple chronic illnesses
- Loneliness and isolation
- Death of peers or spouse

studied the impact of adolescent challenges in relationship to the stress response have determined that peer rejection stimulates an increase in systolic blood pressure and in the production of saliva α -amylase (sAA), which is an enzyme that is reflective of sympathetic nervous system activation. In addition, stressors related to performance-based challenges are associated with increased cortisol production and increased diastolic blood pressure (Stroud et al., 2009).

In contrast, nonnormative stressors are those that very few children and adolescents face but that produce higher stress levels. Nonnormative stressors may include serious illness of the child or a close family member, death of a parent, child abuse, natural disasters, or homelessness (Rice, 2012). Nonnormative stress can become “toxic” if the child or adolescent does not receive the adult support he needs. Toxic stress can influence a child’s health into adulthood, increasing the risk for developing chronic diseases such as cardiovascular disease, cancer, asthma, and depression (Johnson, Riley, Granger, & Riis, 2013). Prevention of toxic stress often requires intervention at the levels of family, society, and government rather than at the biological level (Johnson et al., 2013).

In the early stages of development, some degree of anxiety is normal, particularly when children are separated from their parents or caregivers. Stranger anxiety is most pronounced during the first 2 years of life. Many young children have not yet developed normal coping processes, so they frequently cry or throw a temper tantrum when faced with stressful situations. However, as a result of normal cognitive development, usually around the toddler stage, children become better able to distinguish between dangerous and nondangerous situations, and fears begin to abate. Along with this developing sense of discernment, toddlers also begin to learn how to cope with fear (Berk, 2012).

As children learn to cope with stressors, they face new stressors such as starting school, making new friends, and feeling pressured to get good grades. Later in childhood, especially during adolescence, stressors often include changes related to puberty, performance, and conflict with parents. If the child does not learn how to cope with these stressors or does not receive appropriate support from a parent or other caregiver (see the Focus on Diversity and Culture feature), anxiety disorders may develop. A child or adolescent whose anxiety or fear persists beyond the expected age of resolution or endures for 6 months or longer may have developed an anxiety disorder and will benefit from referral to a mental health specialist (APA, 2013).

When working with children and adolescents, the challenge for the nurse is to differentiate between true anxiety disorders and normal developmental stressors and fears. Therefore, it is vital to assess not only the presence of emotional and behavioral cues related to stress but also the duration, severity, and timing of symptoms. Psychosocial assessment of the pediatric patient should be age and developmentally specific (see the module on Development) and should take into consideration that children may exhibit manifestations of disorders in ways that vary significantly from those demonstrated by adult patients. Signs of stress or anxiety in children may include irritability, withdrawal from pleasurable activities, clinging to a parent, frequent complaining about feeling ill, new or recurring fears, crying,

Focus on Diversity and Culture

Latchkey Children

Latchkey children are children and adolescents who spend hours at home alone each day between when they get home from school and when a parent or other adult arrives home from work. Latchkey children often come from families with two working parents or from single-parent families in which the parent works long hours at one or more jobs to support the family. In most cases, families with latchkey children cannot afford afterschool care and do not have adequate family or community support to provide the needed child care. Often older latchkey children become responsible for caring for younger children, sometimes even including providing meals and snacks for themselves and their siblings. Latchkey children who are unsupervised for more than 2 hours per day are at high risk of developing physical and social problems and anxiety. They are more likely to become involved in substance abuse and petty crimes when adult supervision is lacking, and they are more prone to aggressive behaviors and somatic complaints. The likelihood of developing negative coping strategies is higher for latchkey children who are experiencing a mental illness or who are genetically or environmentally susceptible to developing a mental illness.

The influence of unsupervised time on elementary school children at high risk for inattention and problem behaviors. *Child Abuse & Neglect*, 38(6), 1120–1127.

sleeping or eating too much or too little, bedwetting, and declining grades at school (American Psychological Association, n.d.a). Signs of stress or anxiety in adolescents may include excessive tiredness, anger and defiance, refusing to participate in favorite activities, becoming involved in substance abuse or criminal activities, sudden drops in grades at school, and social withdrawal.

When assessing children, nurses need to be aware of the language children use to express their stress or anxiety because children often use terms different from those used by adults. Children may not understand the concept of stress, so they may use terms such as “worry,” “confused,” or “mad” to describe their feelings. They may also convey stressful feelings by expressing negative thoughts about themselves or their environment (American Psychological Association, n.d.a). In addition, nurses should be aware that children and adults have different views of what types of circumstances are stressful to children. Children often find constant, minor stressors to be more stressful than one-time, large stressors. In addition, the anticipation of a major stressor may be more stressful to children than the actual experience of the stressor (Lewis et al., 1984). Nurses should also assess how the child’s parents cope with stress, because children often mimic what they see.

When performing a nursing assessment on adolescents, the assessment should include interviewing both the patient and the guardian individually with the approval of

the guardian. Adolescents may feel more comfortable discussing stressful situations when their parents are not present. The nurse should encourage adolescents to be truthful about stressors they are exposed to, including peer pressure to participate in sexual activities, criminal activities, and substance abuse. Because adolescents may feel more comfortable discussing these issues with a healthcare provider of the same gender, the nurse should always ask the patient and the guardian whether a provider of the same gender is preferred.

Several tools are available for nurses to assess the stress levels of children and adolescents. The most widely used diagnostic tool is the Anxiety Disorders Interview Schedule for children and parents (ADIS-C/P). However, the ADIS-C/P follows DSM-IV criteria rather than DSM-5. Another common assessment tool is the Screen for Child Anxiety Related Emotional Disorders-71 (SCARED-71), which may be used to identify anxiety disorders in individuals age 8 to 18 years (Bodden, Bogels, & Muris, 2009). Other tools include the Revised Children's Anxiety and Depression Scale (RCADS) and the Spence Children's Anxiety Scale (SCAS) (Creswell, Waite, & Cooper, 2014). In addition, the Children's Sources of Stress Scale (Ryan-Wenger, Sharrer, & Campbell, 2005) identifies sources of stress that relate to school-age children, and the Feel Bad Scale (FBS) is a 20-item list containing 17 normative stressors and 3 nonnormative stressors (Lewis et al., 1984). These scales were developed by determining what types of situations are most stressful to children rather than using an adult's opinion of what they think causes stress in children. Therefore, they are more applicable to assessing childhood stressors.

If a child or adolescent is experiencing elevated levels of stress, the nurse can teach coping strategies to both the child and the parents. Strategies that may be beneficial for children to practice include talking about their problems with a parent or other trusted adult; practicing relaxation exercises such as listening to calm music, taking deep breaths, or practicing a hobby or favorite activity; participating in physical activity; setting realistic expectations; and asking for help to manage stress. Strategies that may be beneficial for parents to practice to help their child cope with stress include providing a safe and secure home environment, being selective about television programming that young children watch (to decrease their exposure to violence and potential fears), spending time with their child, listening to their child and encouraging the child to talk about fears or worries, building the child's sense of self-worth, and keeping the child informed during potentially stressful changes (Kaneshiro, 2014).

In addition to teaching coping strategies, the nurse, along with the physician, may recommend CBT as a treatment method for childhood and adolescent anxiety. Treatment of children and adolescents with CBT is often based on Kendall's "Coping Cat," a method that involves psycho-education, modification of negative thoughts, exposure to feared stimuli, and training in coping skills (Creswell et al., 2014).

When discussing treatment methods for children and adolescents with alterations in stress and coping, treatment should focus on teaching multiple coping strategies rather than on pharmacologic intervention. Many antianxiety and

antidepressant medications are not approved for children and adolescents, and some medications increase the risk of depression and suicide (NIMH, n.d.a). Therefore, medications are used only in severe cases of anxiety in children and adolescents. If the patient is prescribed an anxiolytic medication or antidepressant, the nurse should teach the patient and guardian about the risks associated with medication use.

Stress and Coping in Older Adults

Stressors for older adults are often related to changes associated with aging: loss of mobility, loss of independence, retirement, loss of peers or a spouse, or being diagnosed with a terminal illness or multiple chronic illnesses. Older adults who experience a loss of mobility or who have lost friends or a spouse to death may also feel a sense of isolation or loneliness, which can cause additional stress. Even the advancement of everyday technology can be a stressor for older adults who don't understand how to use computers or cell phones.

Signs and symptoms of stress in older adults include alterations in sleep patterns, eating habits, and self-care; headaches or other pains; tachycardia; gastrointestinal problems; negative feelings or attitudes; mood swings; social isolation; frequent crying; poor judgment; and lack of concentration. Older adults are more likely to report physical discomforts before they will report mental or cognitive problems. However, the diagnosis of anxiety-related disorders can be complicated by preexisting physical illness or cognitive changes in this population. For example, changes in self-care habits may be in response to stress, or they may be in response to cognitive changes that decrease the patient's ability to remember how to use basic grooming tools. Fear of stigmatization is also a significant consideration. Because many older adults were raised during a time when mental illness carried a heavy stigma, they may be especially resistant to reporting any symptoms of mental disorders (ADAA, n.d.b). Alterations due to anxiety and stress may also be difficult to identify in older adults because older adults often have better emotional control and coping strategies than younger adults (Miller, 2012).

When faced with stressors, older adults tend to use more passive emotion-focused coping strategies, including denial or acceptance. Older adults often choose carefully the events or situations that they worry about because they are attempting to conserve energy for the most important situations. Thus, they may tend to avoid some problems or withdraw from normal activities rather than face the situation that causes anxiety (Miller, 2012). For example, an older adult who has anxiety related to incontinence will often avoid leaving the house in order to prevent potential embarrassment related to their incontinence. This can lead to isolation and depression.

Older adults who maintain their social circles and remain physically active have better mental and physical health than those who isolate themselves (Miller, 2012). Social coping strategies tend to have a greater effect in reducing stress and anxiety than individual or personal coping strategies (McDougle, Konrath, Walk, & Handy, 2015). Nurses can promote wellness in older adults by encouraging them to remain socially and physically active and pursue activities that bring

them joy and fulfillment. Older adults will benefit from spending time with family and friends or by participating in religious practices or volunteering. This support system can help older adults maintain their mental health and feel a sense of well-being rather than a sense of anxiety or stress.

REVIEW The Concept of Stress and Coping

RELATE Link the Concepts

Linking the concept of stress and coping with the concept of communication:

1. Describe the application of therapeutic communication in the nursing care of patients with disorders related to stress and coping.
2. Particularly during the care of patients with disorders related to stress and coping, why is giving advice contraindicated? What specific communication strategies are recommended for these patients?

Linking the concept of stress and coping with the concept of ethics:

3. What is patient confidentiality, and how does this principle pertain to patients who seek treatment for alterations related to stress and coping? Under what circumstances is the requirement to maintain patient confidentiality not applicable?
4. While in the hospital cafeteria, a nurse overhears a nursing colleague discussing a patient's recent hospital admission for treatment related to an unusual phobia. Although the nursing colleague does not specify the patient's name, she includes a detailed discussion of the patient's complaints. How should this situation be addressed?

REFLECT Apply Your Knowledge

Martina Carrillo is a sixth grader at Longview Middle School. Over the past month, she has been to see the school nurse several times with complaints of a stomachache. She has not complained about any other physical symptoms, and her stomachache has not led to vomiting. However, the school nurse notes that her heart rate and respiratory rate have increased slightly over the month. Based on school records and talking with Martina, the school nurse knows that Martina is the oldest of four children in an immigrant family. Her father is still in Mexico, and her mother works a shift from 3 p.m. to 11 p.m. at a local factory. Martina is on the free lunch program at school. In spite of speaking both English and Spanish fluently, Martina's grades have been declining over the past 3 months. When asked about this, Martina states that she often doesn't understand her homework and doesn't have time to spend on it because she is caring for her younger siblings in the evenings after school.

1. What potential stressors might Martina be facing each day in addition to those listed in the case study that the nurse might need to ask Martina about?
2. What physiologic processes might be leading to Martina's complaint of a stomachache?
3. What coping strategies may be advantageous for the school nurse to teach Martina?
4. How can the school nurse be an advocate for Martina during this time?

Exemplar 31.A Anxiety Disorders

Exemplar Learning Outcomes

31.A Analyze anxiety disorders as they relate to stress and coping.

- Describe the pathophysiology of anxiety disorders.
- Describe the etiology of anxiety disorders.
- Compare the risk factors for and prevention of anxiety disorders.
- Identify the clinical manifestations of anxiety disorders.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of individuals with anxiety disorders.
- Differentiate considerations for care of patients with anxiety disorders across the lifespan.

- Apply the nursing process in providing culturally competent care to an individual with an anxiety disorder.

Exemplar Key Terms

Anxiety, 2070
 External locus of control, 2074
 Free-floating anxiety, 2070
 Generalized anxiety disorder (GAD), 2072

 Panic disorder, 2073
 Phobia, 2073
 Vulnerability, 2070

Overview

Anxiety is a response arising in anticipation of a perceived or actual threat to oneself or significant relationships. Anxiety is characterized by feelings of mental uneasiness, apprehension, dread, foreboding, and feelings of helplessness. Generally, anxiety helps people cope; it is a reaction to a stressor and is part of daily living. Anxious energy is a productive force for most people, and the experience of anxiety is influenced by an individual's genetic makeup as well as emotional, developmental, physical, cognitive, sociocultural, and spiritual factors.

Anxiety disorders may occur when normal feelings of anxiety get out of control and begin to impair individual functioning. Anxiety disorders are mental illnesses characterized by feelings of distress or fear during everyday situations. Fear is typically a heightened physical and emotional response to imminent danger, real or perceived (APA, 2013). Left untreated, anxiety disorders can damage personal relationships and the ability to work. Anxiety disorders impair daily activity and can lead to low self-esteem, drug abuse, and social isolation. Anxiety disorders are the most common mental illnesses in the United States, typically afflicting around 20% of the population. Effective treatments exist for anxiety disorders, but many people do not seek treatment because they do not realize how severe their symptoms are or because family, friends, and even physicians have difficulty recognizing the symptoms (NAMI, 2012).

The ability to differentiate healthy and expected stress responses from those that are harmful is an essential psychosocial competency for all nurses. Every individual experiences anxiety at times. The individual's anxiety is no longer healthy when the anxiety level reaches the point at which it prevents the individual from returning to homeostasis through healthy coping and adaptation.

Pathophysiology and Etiology

Pathophysiology

Research suggests that people are more likely to experience anxiety disorders if their parents have anxiety disorders. However, it is not clear whether biological or environmental factors play a greater role in the development of these conditions. Research suggests that traumatic brain injury may increase an individual's susceptibility for development of an anxiety disorder. In any case, scientists have found that certain areas of the brain, including the amygdala, function differently in people with anxiety disorders (NAMI, 2012).

The appearance of an anxiety disorder in an individual of any age requires attention by both healthcare professionals and caregivers. Family and friends may be the first to notice anxiety symptoms. Healthcare professionals recognize that many medical problems—including hormonal and neurologic conditions—may cause symptoms of anxiety. The primary symptom of anxiety disorders is what psychiatrists sometimes refer to as **free-floating anxiety**. This is characterized by excessive worry that is hard to control and whose focus may shift from moment to moment. Free-floating anxiety is anxiety that is not connected to a specific stimulus (Kneisl & Trigoboff, 2013). Examples of anxiety disorders are listed in the Concept section earlier in this module. This exemplar discusses three of them: generalized anxiety disorder, panic disorder, and phobias.

Etiology

Across the range of anxiety disorders, there are some important similarities in the basic causes of the anxiety response. Biological causes seem to play a significant role in the development of anxiety disorders. Abnormal function of structures in the limbic system and certain parts of the cortex appear to be involved. The neurotransmitters most closely involved with the anxiety response are GABA, norepinephrine, and serotonin. Genetic contributions play a role as well, with at least part of the genetic vulnerability being nonspecific, or common across the disorders. Psychosocial and behavioral factors include the classical conditioning of fear and a perception of lack of control over one's environment, an attitude that begins in childhood (Butcher, Mineka, & Hooley, 2013).

Vulnerability refers to the individual's susceptibility to react to a specific stressor. Individual vulnerability stems from biological and environmental sources, both of which have been the subjects of etiologic research. (See Focus on Diversity and Culture: Anxiety Disorders in Immigrant Populations.) Current explanations of the origin of anxiety disorders include neurobiological, neurochemical, psychosocial, behavioral, genetic, and humanistic theories.

Neurobiological Theories

Several areas of the brain orchestrate the experience of anxiety and the expression of the symptoms (see **Figure 31-4** »). The amygdala is known as the "emotional brain" and is the focus of much research related to feelings of anxiety, fear, and anger, which are elicited in this area. The hippocampus stores memory related to fear. The locus coeruleus stimulates arousal and contains almost half of all the neurons that use norepinephrine as a neurotransmitter. Stimulating an animal's locus coeruleus produces anxious behaviors. Heart rate and respirations are regulated by the brainstem, and the hypothalamus activates the entire response. The frontal cortex assists with appraisal of a threat and is the center of cognitive processes. The thalamus integrates all sensory stimuli, and the basal ganglia are responsible for the tremors associated with anxiety (Dubuc, 2013). Individual differences in the structure of the brain or injury to the brain will also alter the anxiety response.

Figure 31-4 » The limbic system. Just above the inner core, yet surrounded by the cerebral cortex, the limbic system plays a role in motivation, emotion, and memory. The system is composed of many structures, including the thalamus, amygdala, hippocampus, and hypothalamus.

Figure 31-5 >> Neurotransmission: How neurons communicate.

Neurochemical Theories

Communication within the brain occurs between neurons through the transmission of electrical stimuli (see **Figures 31-5** >> and **31-6** >>). To transmit a signal, a neuron releases chemicals called neurotransmitters. These chemicals deliver messages by binding to the receptors on the surface of another neuron, causing the neuron to fire and transmit the electrical impulse. Once the message is delivered, the neurotransmitter is taken back to a vesicle in the presynaptic cell (NIMH, 2013b). Any disruption in these transporters, binding sites, or cell structure can cause an alteration in cell functioning, leading to misfiring.

Structural anatomic differences, dysregulation of neurotransmitters, sensitivity of neuronal receptor sites, and the balance of neurotransmitters in the synaptic cleft all have an effect on the anxiety reaction. The brain's benzodiazepine receptor system enhances the activity of GABA, an inhibitory neurotransmitter that "shuts down" or slows excitability in the cell. It is present in the locus coeruleus, where norepinephrine is produced. Norepinephrine is an excitatory neurotransmitter that signals arousal and hyperarousal. Researchers believe that an imbalance in the regulation of these two neurotransmitters produces anxiety disorders: When GABA is decreased and norepinephrine is increased, anxiety results (Kneisl & Trigoboff, 2013). Serotonin is also implicated in the pathology of anxiety. It is thought to produce a feeling of well-being and is believed to be correlated with a decrease in anxiety (Butcher et al., 2013).

Psychosocial Theories

Psychoanalytic theory views anxiety as a sign of internal conflict resulting from the threatened emergence of repressed emotions into consciousness. According to the theory, an individual fears expressing forbidden emotions and so becomes anxious. Neo-Freudian analytical views of

A, Strong agonist activates receptors without transmission.

B, Antagonist blocks receptors. Agonist cannot act.

Figure 31-6 >> Ligands: Agonists and antagonists. Agonists and antagonists bind to the same binding site as transmitters. **A**, An agonist has potency, so it activates the cell biologically, while **B**, antagonists bind and have no potency. An antagonist produces its effect by blocking the binding site, preventing a transmitter from binding and producing its biological effect.

anxiety believe that it can be traced back to birth trauma, whereas interpersonal theorists stress the importance of the transmission of the mother's anxiety to the child (Kneisl & Trigoboff, 2013). Psychosocial theorists actively debate the origin of anxiety, but these debates typically have little to do with clinical practice.

Behavioral Theories

Behaviorists believe that faulty thinking and behavior are learned dysfunctional responses to stressors. They believe individuals can unlearn unhealthy behaviors by engaging in behavior modification, a treatment approach that teaches patients new ways to behave in response to stress. Behavior modification therapies use conditioning techniques—positive and negative reinforcements—in order to produce systematic desensitization, a process in which the patient builds up tolerance to anxiety through gradual exposure to a series of anxiety-provoking stimuli.

Genetic Theories

As stated earlier, research suggests that genetic predisposition may play a part in the development of anxiety disorders. According to twin and family studies, panic disorder,

Focus on Diversity and Culture

Anxiety Disorders in Immigrant Populations

Evidence suggests that the migration experiences of first-generation immigrant parents contribute to the risk for depression and anxiety in first- and second-generation immigrant children. Unique migration stressors such as discrimination, lack of cultural resources, and lack of social acceptance give rise to acculturative stress. *Acculturative stress* is a term used to describe the experiences and reactions involved in adjusting to and integrating into a new culture. High levels of acculturative stress in first-generation immigrant parents are correlated with anxiety symptoms in their children but are not necessarily linked to anxiety symptoms in parents (Leon, 2014).

phobic disorders, and GAD all have a genetic component, with twins and first-order family members of individuals having a higher risk of developing the same disorder compared to more distant relatives. Overall, the estimated heritability of anxiety disorders is between 30% and 60% (Shimada-Sugimoto, Otowa, & Hettema, 2015). Genetic predisposition can produce the biological conditions necessary for an anxiety disorder to develop, priming an individual for anxious behavior.

Humanistic Theories

A humanistic, holistic explanation of anxiety disorders argues that biological, psychologic, behavioral, and genetic causes do not exist in isolation—they interact with one another to produce the complex of symptoms we call anxiety disorders. The humanistic perspective has generated a nuanced approach to patient care that integrates psychotherapeutic interventions, steps to develop social support systems, techniques to reduce external stress, and psychopharmacologic therapy.

Risk Factors

Risk factors for anxiety disorders include the dysregulation of neurotransmitters such as serotonin, norepinephrine, GABA, and a neuropeptide known as cholecystokinin. Other risk factors include the following:

- Childhood adversity, including witnessing traumatic events
- Family history of anxiety disorders
- Social factors, such as lack of social connection
- Serious or chronic illness
- Traumatic events
- Personality factors such as shyness and worrying
- Multiple stressors, such as chronic illness concurrent with loss of employment (UMMC, 2013).

Prevention

Prevention of anxiety disorders depends on an individual's ability to recognize her own growing anxiety. Individuals at risk for anxiety disorders should seek medical help early,

because these conditions become harder to treat as they progress. Keeping track of patterns of worrying can also help stop anxiety before it grows out of control. Mental health professionals advise that individuals at risk for anxiety disorders keep journals to catalog stressors and sources of relief and to manage priorities. Finally, individuals with multiple risk factors should avoid unhealthy substance use, including the abuse of alcohol, illegal drugs, and even nicotine and caffeine. These drugs can stimulate anxiety, and for people who are addicted, quitting can worsen anxiety (Mayo Clinic, 2012b).

Clinical Manifestations

Anxiety disorders are clustered around a range of physiologic, psychologic, behavioral, and cognitive manifestations. Although each of the disorders is distinct (GAD is completely distinct from acute stress disorder, and so on), the symptoms of all the disorders cluster around excessive, irrational fear and dread (NIMH, 2015). Worry is a major component of each of the anxiety disorders. Individuals in anxiety states experience the emotion both as a subjective condition and as a range of physical symptoms resulting from muscular tension and autonomic nervous system activity. Chronic anxiety can lead to physical manifestations and disabilities, including constipation, diarrhea, epigastric distress, and heartburn, as well as musculoskeletal aches and pains. Anxiety can develop suddenly or gradually, and it may be expressed as relatively mild physiologic symptoms or as an incapacitating episode of acute anxiety (Kneisl & Trigoboff, 2013). See **Table 31-5** for an overview of three types of anxiety disorders; each is discussed in more detail in the following sections.

Generalized Anxiety Disorder

Individuals with **generalized anxiety disorder (GAD)** go through their days filled with intense tension and worry, even if no external stressors are present. They anticipate disaster and are preoccupied with health issues, money, familial problems, or challenges at work. GAD may be diagnosed when excessive worrying is out of proportion to stressors (perceived or actual), interferes with daily functioning, and occurs for a period of at least 6 months (APA, 2013). Individuals with GAD cannot rid themselves of their anxious state, although they can usually recognize that their anxiety is more intense than the situation requires. They have difficulty relaxing, startle easily, and have trouble concentrating and falling asleep (see **Figure 31-7**). Somatic symptoms of GAD include fatigue, headache, muscle tension and aches, digestive issues, irritability, feeling out of breath, and hot flashes. Sleep disturbances are common. Adults with mild or well-controlled GAD can function in social situations and hold down jobs, but those with severe, poorly controlled GAD have great difficulty carrying out daily tasks. GAD affects 6.8 million adults in the United States, and twice as many women as men. The disorder can develop at any time in the life cycle, although people are at the highest risk for the condition in early adulthood, between childhood and middle age (NIMH, n.d.b).

GAD can manifest in children with all the same symptoms as in adults. Children with GAD feel significantly distressed and, as with adults, the principal sign of GAD is

Source: From Potter, M. L., & Moller, M. D. (2016). *Psychiatric–mental health nursing: From suffering to hope*. (1st ed.). Upper Saddle River, NJ: Pearson.

Figure 31–7 » Key symptoms of generalized anxiety disorder.

intense worry over a long period of time. GAD is common among children and adolescents and is treated mostly with psychotherapy, the goal of which is to build up healthy and constructive responses to anxiety (Boston Children’s Hospital, 2012).

Panic Disorder

Panic disorder is characterized by sudden attacks of terror, sometimes accompanied by a pounding heart, sweating, fainting, or dizziness. In a panic attack, an individual will feel flushed or chilled, his hands will tingle or become numb, and he may experience nausea, chest pain, and a sense of breathlessness, in addition to a sense of unreality, a fear of impending death, and a terror of losing control. A

fear of one’s own unexplained symptoms is itself a symptom of panic disorder. Individuals in the grip of a panic attack sometimes believe they are dying or losing their minds; between episodes, they may worry intensely about the next panic attack (APA, 2013; NIMH, n.d.c). Attacks can occur at any time of day and even during sleep. An attack usually lasts only around 10 minutes, but some symptoms may last much longer. The disorder affects around 6 million people in the United States and is twice as common in women as men (NIMH, n.d.c).

People who have full-fledged panic disorder can become incapacitated by their condition and should seek treatment before they start to avoid situations where attacks have occurred. In severe cases, people who have panic attacks avoid normal activities. One third of people who have panic disorder become housebound and are able to confront a feared situation only when accompanied by a loved one or trusted friend. If the patient seeks treatment early, however, and the illness is correctly diagnosed, the disorder can usually be cleared up, because panic disorder is one of the most treatable anxiety disorders (NIMH, n.d.c).

SAFETY ALERT Panic attacks and heart attacks have many common symptoms, making it difficult to discern one from the other. Any patient experiencing sudden, severe chest pain should be treated according to your organization’s heart attack protocols.

Phobias

Individuals with **phobias** experience intense, persistent fear or anxiety associated with a particular object or situation, called a stressor, and tend to avoid that stressor at all costs. Contact with the stressor produces severe panic. Stressors can be anything; needles and syringes, airplanes, spiders, dogs, closed areas, performing, and social activities are a

TABLE 31–5 Summary of Criteria for Anxiety Disorders

The following are summaries of the criteria for the anxiety disorders discussed in this exemplar. Refer to the DSM-5 for the complete diagnostic criteria.

Disorder	Summary
Generalized anxiety disorder	<ul style="list-style-type: none"> Characterized by intense tension and worry, even in the absence of external stressors. May demonstrate anticipation of disaster and/or preoccupation with health issues, money, familial problems, or work-related challenges. Affected individuals usually recognize that their anxiety is disproportionate to the circumstances. Manifestations include difficulty relaxing, pronounced startling, trouble concentrating, and difficulty falling asleep. Somatic symptoms include fatigue, headache, muscle tension and aches, digestive issues, irritability, feeling out of breath, and hot flashes. Diagnostic criteria include excessive anxiety about everyday problems for at least 6 months.
Panic disorder	<ul style="list-style-type: none"> Recurrent unexpected panic attacks, when at least one of the attacks has been followed by 1 month of persistent concern about having more attacks, worry about the implications of the attack, or a significant change in behavior related to the attacks. The attacks are not due to the physiologic effects of a substance. The attacks are not better accounted for by another mental disorder.
Phobias Specific phobia Agoraphobia Social anxiety disorder	<ul style="list-style-type: none"> Intense, persistent, irrational fear of an object or situation that compels the individual to avoid the stressor that elicits the fear. Exposure to the stressor produces an anxiety response that may take the form of a panic attack. Anxiety about the stressor is out of proportion to the actual threat of danger posed by the object or situation, after accounting for cultural contextual factors. Symptoms must last at least 6 months for patients regardless of age.

Sources: Based on BehaveNet. (2013). *Panic disorder without agoraphobia*. Retrieved from <http://behavenet.com/panic-disorder-without-agoraphobia>; National Institute of Mental Health (NIMH). few examples. Phobias adversely impact quality of social, occupational, and academic function and also interfere with activities of daily living (APA, 2013). An estimated 8.7% of the U.S. population is affected by a specific phobia, and women are twice as likely to develop a specific phobia as men (ADAA, 2014).

Individuals with phobias and other forms of anxiety may exhibit an external locus of control. Lazarus and Folkman (1984) describe *locus of control* as the extent to which an individual believes he has control over the events in his life. Individuals with an **internal locus of control** believe their actions, choices, and behaviors impact life events. Those with an **external locus of control** believe that powers outside of themselves, such as luck or fate, determine life events.

There are three primary categories of phobias: specific phobia, agoraphobia, and social anxiety disorder (formerly known as social phobia). Specific phobia is intense or extreme fear with regard to a particular object or situation such as spiders, snakes, flying, or heights. *Agoraphobia* is characterized by anxiety associated with two or more of the following situations: being in enclosed spaces, being in open spaces, using public transportation, being in a crowd or standing in a line of people, or being alone outside the home environment (APA, 2013). Social anxiety disorder is characterized by pervasive, extreme fear of one or more social situations that may lead to scrutiny by others.

Phobias are frequently comorbid with other psychiatric alterations, including depressive disorders, anxiety disorders,

bipolar disorders, and substance-related disorders. Treatment focuses on teaching coping strategies and may be paired with pharmacologic interventions and psychotherapy.

Levels of Anxiety

Levels of anxiety range from mild to panic. The patient's level of anxiety greatly impacts nursing care. For patients experiencing panic or severe anxiety, safety is a priority. Because the individual will be unable to take in any new information during these stages, interventions focus on reducing the anxiety level prior to providing any new information. Immediate interventions include reducing exposure to stimuli and providing comfort measures to assist in reducing symptom severity. Distractions and relaxation techniques may be helpful. Once the patient's anxiety level decreases, additional interventions to reduce anxiety, such as beginning a course of medication and starting psychotherapy, may be introduced. Patients who experience mild anxiety may benefit from nonpharmacologic interventions, such as yoga, deep breathing, and journaling.

Collaboration

With the exception of panic disorder, the treatment of anxiety disorders occurs more frequently in the home and community than in the hospital. Considering the level of distress that accompanies anxiety disorders, it is not difficult to understand the vulnerability of individuals with anxiety to

Evidence-Based Practice

Anxiety Disorders and Oxidative Stress

Problem

Psychologic stress has been associated with oxidative stress (OS), which is a loss of balance in the body's oxidation–reduction reactions. In OS, production of reactive oxygen species (ROS) and reactive nitrogen species (RNS) outpaces production of counteracting antioxidants. The result is cellular and molecular damage. Because of its high level of oxygen consumption and its lipid-rich nature, the brain is especially susceptible to OS. Research suggests a connection between OS and anxiety and depression, though the nature of this connection remains unclear (Salim, 2014).

Evidence

OS produces an inflammatory response; when this response occurs in the brain, it is known as neuroinflammation. Research indicates that chronic stress leads to chronic neuroinflammation, which damages neurons. This damage is associated with anxiety behaviors and depression (Xu, Wang, Klabnik, & O'Donnell, 2014).

Studies in mice further suggest that OS progressively increases with repeated exposure to stress, and that chronic stress alters expression of the genes that regulate antioxidant systems (Seo et al., 2012). The hippocampus and frontal cortex of the brain appear to be most affected by the negative effects of OS, but it is unclear whether OS is a side effect or cause of psychologic distress (Xu et al., 2014). Although the causal relationship between the two has yet to be determined, the link between them is well established, with much research focusing on the importance of excess ROS in anxiety (Salim, 2014).

Implications

Antidepressants are often prescribed for anxiety because of their primary effects on norepinephrine and serotonin. Research now suggests that the secondary antioxidant effects of these medications may also be beneficial to patients with anxiety. Few trials have been conducted with human subjects, but animal studies in this area are promising (Xu et al., 2014).

There is also a lack of research into the safety of antioxidants in amounts greater than those found in food (Xu et al., 2014). For patients with anxiety, the principal source of antioxidants remains diet. Vitamin C, vitamin E, carotenoids, selenium, and manganese all have antioxidant properties, as do flavonoids and phenols. Plant-based foods are the best dietary sources of these antioxidants and include fruits, vegetables, whole grains, nuts, and legumes (Harvard School of Public Health, n.d.). In addition, the nutrients found in these foods may benefit health for reasons other than their antioxidant properties.

Critical Thinking Application

1. Consider the relationship of OS and anxiety. How do you think this relates to an individual's environment and upbringing?
2. Do you think OS is triggered by an individual's lifestyle, or might a state of OS impact the way an individual handles stressors in his or her environment?
3. Is the OS theory of anxiety relevant to clinical practice? With this theory in mind, would you recommend dietary or lifestyle changes to patients with anxiety?

Clinical Manifestations and Therapies

Anxiety Disorders

LEVEL OF SEVERITY OF ANXIETY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Mild	<ul style="list-style-type: none"> ■ Increase in sensory perception and arousal ■ Increase in alertness ■ Sleeplessness ■ Increase in motivation ■ Restlessness and irritability 	<ul style="list-style-type: none"> ■ Mild anxiety typically is resolved by an individual's coping mechanisms. Mild anxiety may be helpful to the patient to accentuate focus and concentration. ■ Patients who are distressed by mild anxiety may benefit from <ul style="list-style-type: none"> Improved sleep hygiene Relaxation techniques Behavior therapy Massage Aromatherapy.
Moderate	<ul style="list-style-type: none"> ■ Narrowing of perceptual field and attention span (a process called "selective inattention") ■ Reduction in alertness and awareness of surroundings ■ Feeling of discomfort and irritability with others ■ Self-absorption ■ Increased restlessness ■ Increase in respirations, heart rate, and muscle tension ■ Increase in perspiration ■ Rapid speech, louder tone, and higher pitch 	<ul style="list-style-type: none"> ■ Cognitive and behavior therapy to identify triggers and learn improved coping techniques. ■ Relaxation techniques. ■ Integrative therapies such as yoga, acupuncture, massage. ■ Low-dose antianxiety medications if symptoms do not improve with other therapies or if the medications exacerbate chronic conditions.
Severe	<ul style="list-style-type: none"> ■ Perceptual field greatly reduced ■ Difficulty following directions ■ Feelings of dread, horror ■ Need to relieve anxiety ■ Headache ■ Dizziness ■ Nausea, trembling, insomnia ■ Palpitations, tachycardia, hyperventilating, diarrhea 	<ul style="list-style-type: none"> ■ Cognitive and behavior therapy to learn to identify triggers and to learn better coping techniques. ■ Antianxiety medications (may include benzodiazepines). ■ Relaxation techniques. ■ Integrative therapies such as yoga, acupuncture, massage. ■ Hospitalization may be required initially to manage severe anxiety until improved coping mechanisms are developed.
Panic	<ul style="list-style-type: none"> ■ Inability to focus ■ Perception distorted ■ Terror ■ Feelings of doom ■ Bizarre behavior ■ Dilated pupils ■ Trembling, sleeplessness, palpitations, pallor, diaphoresis, muscular incoordination ■ Immobility or hyperactivity, incoherence 	<p>Immediate, structured intervention required.</p> <ul style="list-style-type: none"> ■ Immediate therapies include the following: <ul style="list-style-type: none"> Placing patient in a quiet, less stimulating environment Use of repetitive or physical task to diffuse energy Administration of antianxiety medications. ■ Long-term therapies include the following: <ul style="list-style-type: none"> Psychotherapy (cognitive, behavioral, or CBT) Pharmacologic therapy Relaxation techniques Improved sleep hygiene Integrative health therapies such as massage, acupuncture, yoga, hydrotherapy Nutrition consultation Mental health counseling.

substance abuse and/or depression. This combination is a threat to treatment success and positive outcomes for the individual. Because the individual is part of a family and a larger community, nurses need to support positive outcomes for individuals by involving both the individual and his or her family in the treatment process. Such treatment is multimodal and involves the assessment of age, education, health and health practices, spirituality, and culturally specific needs (NIMH, 2013a).

Diagnostic Tests

Evaluation of an individual with symptoms of an anxiety disorder includes a complete medical history and physical exam. Currently no laboratory tests are available to diagnose any of the anxiety disorders, but various diagnostic tests may be used to rule out physical illness as the cause of the symptoms. If no physical illness is found, the patient may be referred to a mental health professional trained to diagnose and treat mental illnesses. Mental health providers use specially designed interview and assessment tools to evaluate an individual for an anxiety disorder. The mental health professional bases the diagnosis on the patient's subjective report of the duration and intensity of symptoms, including any interference with daily functioning. The diagnosis is typically made according to the criteria in the DSM-5.

Pharmacologic Therapy

Medication does not cure anxiety disorders, but it can control or diminish the severity of the associated signs and symptoms while the patient enters psychotherapy. Medication may be prescribed by a psychiatrist, advanced practice psychiatric/mental health nurse, or primary care provider (e.g., physician, nurse practitioner). The medications usually used for anxiety disorders are antidepressants, antianxiety drugs, and beta-blockers, although antipsychotics are sometimes used. See the Medications feature in this module's Concept section for more information.

Antidepressants were developed to treat depression, but they are also effective for anxiety disorders. Although they begin to alter brain chemistry after the first dose, their full effect requires a few weeks because a series of neurobiological changes must take place before antidepressants achieve efficacy. SSRIs alter the levels of the neurotransmitter serotonin in the brain and are commonly prescribed for anxiety disorders. SSRIs are generally started at low doses and then increased as their effectiveness becomes apparent. SSRIs have fewer side effects than previous generations of antidepressants, but they sometimes generate nausea, agitation, and occasionally sexual dysfunction. Related to the SSRIs, SNRIs inhibit the reabsorption of serotonin and norepinephrine to elevate mood. Examples of SNRIs include venlafaxine and duloxetine.

The most commonly used antianxiety drugs are benzodiazepines. When used for a short time, these drugs have few side effects other than drowsiness. However, higher and higher doses may be necessary over a long period of time, so benzodiazepines are typically not prescribed for long-term use. Because they take only hours to reach efficacy, they often are prescribed for patients experiencing severe or panic levels of anxiety. Patients

with panic disorder can typically take benzodiazepines for up to a year without harm. Examples of benzodiazepines used in the treatment of anxiety include alprazolam (Xanax), diazepam (Valium), lorazepam (Ativan), and clordiazepoxide (Librium) (Adams et al., 2017).

Some patients experience withdrawal symptoms if they stop taking benzodiazepines abruptly, and anxiety can return immediately after cessation. Their potential for tolerance and withdrawal have led some physicians to avoid prescriptions for benzodiazepines. Buspirone (Buspar), an azapirone, is a newer antianxiety medication used to treat GAD. It has the benefit of no risk of dependence. Possible side effects include nausea, headaches, and dizziness. Unlike benzodiazepines, buspirone must be taken consistently for at least 2 weeks to achieve an antianxiety effect.

SAFETY ALERT Benzodiazepines can be habit forming and should be used cautiously in individuals with a history of drug or alcohol addiction. Abruptly discontinuing use of benzodiazepines can result in withdrawal, and patients discontinuing benzodiazepines should slowly taper down following their doctor's instructions. In addition, benzodiazepine use in older adults is linked to an increased incidence of dementia, so they should be used with caution in older adults (de Gage et al., 2012)

MAOIs may be used to treat anxiety. MAOIs inhibit the action of monoamine oxidase (MAO), which is responsible for terminating the action of neurotransmitters such as serotonin, norepinephrine, and dopamine. Because of their high side effect profile (e.g., insomnia, hypertensive crisis, sexual dysfunction, respiratory and circulatory collapse, and serotonin syndrome), MAOIs are often the last line of treatment for patients who do not respond to other treatments. MAOIs also have several drug-drug interactions and food-drug interactions that make their use more complicated in patients with multiple diseases.

Beta-blockers, such as propranolol (which is used to treat heart conditions), can prevent the physical abnormalities (such as blushing and hyperventilation) that accompany certain anxiety disorders, particularly social anxiety disorder. When a feared situation can be predicted (such as speaking before a large group or flying in an airplane), the physician may prescribe a beta-blocker to manage the physical symptoms of anxiety (NIMH, n.d.d).

At times, antipsychotic medications—drugs typically reserved for conditions such as bipolar disorder and schizophrenia—are used to treat anxiety disorders. Typical antipsychotics, the first drugs of this type, include haloperidol, chlorpromazine, and loxapine. These drugs have been shown to produce a significant reduction in neurotic anxiety. Atypical antipsychotics, a later generation of antipsychotics, provide potential benefits for patients with GAD. Extended-release quetiapine has been shown to prevent relapse anxiety in patients with GAD, but more studies need to be performed to examine the risks and benefits of using antipsychotic medications for anxiety disorders (Jewell, 2015).

Nonpharmacologic Therapy

Nonpharmacologic therapy is very effective in the treatment of anxiety disorders. Integrative health practices can be used in conjunction with pharmacotherapy to bring relief to

patients with anxiety disorders, but the most effective non-pharmacologic therapy is psychotherapy, including CBT. Psychotherapy involves talking with a mental health professional, (e.g., psychiatrist, psychologist, advanced practice psychiatric nurse, social worker, counselor) to uncover what triggers the anxiety disorder and to determine how to work through its symptoms. The most effective treatment strategy for most people with anxiety disorders is a combination of CBT and medication (NIMH, 2015).

Cognitive-behavioral Therapy

CBT is a useful nonpharmacologic intervention for treating anxiety disorders. The cognitive aspect of this treatment helps the patient recognize and change the thought patterns that support his fears, and the behavioral aspect helps the patient change the way he reacts to anxiety-provoking situations. This intervention has been proven to reduce the symptoms of all types of anxiety disorders. For additional discussion of CBT, refer to the Concept section of this module.

Integrative Health

Although conventional medical therapies have been consistently shown to ease the symptoms of anxiety disorders, integrative therapies also have been shown to ease the symptoms of anxiety. These therapies include herbal preparations, massage and touch, and yoga and meditation.

Herbal Preparations

Overall, herbal preparations show little promise as potential therapies for the symptoms of anxiety. However, a few different plant species seem to have moderate effects on anxiety disorders. Scientific studies provide evidence that kava, a member of the pepper family, may be beneficial for anxiety management, but the U.S. Food and Drug Administration (FDA) has warned that kava supplements have been linked to a risk of severe liver damage. In addition, kava has been associated with cases of dystonia, drowsiness, and scaly, yellowed skin. It is also suspected to interact with drugs used to treat Parkinson disease.

Lavender is commonly used for aromatherapy, in which the essential oil from the flowers is inhaled. Dried lavender flowers can be used to make teas or liquid extracts that can be taken orally. Small studies on lavender show mixed results, and topical use of diluted lavender and the use of the oil for aromatherapy is considered safe for adults. However, the undiluted oil irritates skin, is poisonous by mouth, and may cause drowsiness (National Center for Complementary and Integrative Health [NCCIH], 2012).

Chamomile is a traditional remedy in widespread use, and a recent study has found that the plant has modest benefits for some people with mild to moderate GAD. Chamomile is generally well tolerated. However, there are reports of allergic reactions in people who have eaten chamomile products, especially individuals who are allergic to plants in the daisy family, including ragweed, chrysanthemums, marigolds, and daisies (UMMC, 2015).

Massage and Therapeutic Touch

Scientific research on massage and touch therapy is limited, but evidence suggests that massage may benefit some patients. A single session of massage therapy can reduce

state anxiety (a reaction to a particular situation), blood pressure, and heart rate, and multiple sessions can reduce “trait anxiety” (an individual’s predisposition to anxiety), depression, and pain. It is not currently known how massage therapy has these effects on the body. *Gate control theory*, for instance, suggests that massage may provide stimulation to block pain signals sent to the brain. Other theories suggest that massage may stimulate the release of chemicals such as serotonin or endorphins or cause mechanical changes in the body.

Relaxation Techniques, Yoga, and Meditation

In addition to being a state of mind, relaxation physically changes the way the body functions, relieving stress in the process. When the body relaxes, breathing slows, blood pressure and oxygen consumption decrease, and well-being increases. Being able to produce the relaxation response by using relaxation techniques may counteract the long-term stress that can lead to anxiety disorders. Relaxation techniques often combine breathing and focused attention to calm the mind and body, and usually only require brief instruction from a practitioner before they can be done without assistance. Common relaxation techniques include autogenic training, biofeedback, deep breathing, guided imagery, progressive relaxation, and self-hypnosis.

Yoga, a tradition linked to Indian spiritual practice, can also be used to produce a relaxation response. Yoga is currently widely used as an integrative health practice and for exercise purposes. Many people who practice yoga do so to maintain well-being, improve fitness, and relieve stress, in addition to addressing specific health conditions such as back pain, arthritis, and anxiety (NCCIH, 2013).

Evidence also suggests that religious or secular meditation can be used to combat the effects of anxiety. Several studies have found that transcendental meditation (TM) helped participants decrease psychologic distress and increase coping ability. In one particular study, TM was shown effective for reducing stress, burnout, and depression in teachers and support staff working with students who have behavioral problems (Elder, Nidich, Moriarty, & Nidich, 2014).

Lifespan Considerations

Anxiety is common in every age group, but stressors, coping mechanisms, and treatment options are different depending on the patient’s developmental level. For children, adolescents, pregnant women, and older adults, specific knowledge of their unique situations is required in order to provide appropriate care.

Anxiety in Children

Symptoms of anxiety disorders in childhood are more prevalent in girls and children from low socioeconomic backgrounds. All children from disadvantaged socioeconomic backgrounds are more vulnerable to emotional illness than their more advantaged peers. Familial predisposition is also a contributing vulnerability factor. Studies suggest that, in general, 3–5% of children and adolescents have an anxiety disorder of some kind. Similar to adults, children with anxiety disorders run the risk of

TABLE 31–6 Symptoms of Anxiety in Children and Adolescents

Symptoms common to both children and adolescents	<ul style="list-style-type: none">■ Excessive worrying■ Headaches and body aches■ Stomachaches■ Muscle tension
Symptoms common in children	<ul style="list-style-type: none">■ Frequently missing school or social activities■ Tiredness/exhaustion/fatigue■ Declining grades at school■ Trouble sleeping/nightmares■ Restlessness■ Trouble concentrating■ Irritability■ Extreme homesickness when away from family■ Shyness■ Frequent crying
Symptoms common in adolescents	<ul style="list-style-type: none">■ Withdrawal from social activities■ Inner restlessness■ Continual nervousness■ Perform poorly in school■ Dependency■ Easily startle, sweat, blotch, or flush■ Engage in substance abuse■ Impulsive sexual behavior■ May also have depression or an eating disorder■ Interferes with their ability to function■ Suicidal ideations■ Changes in eating habits and sleeping patterns■ Self-injury/cutting■ Trembling■ Frequent need to urinate

developing other anxiety disorders, depression, and substance abuse (UMMC, 2013). Common signs and symptoms of anxiety in children are listed in **Table 31–6** ».

One of the most common anxiety disorders in children is separation anxiety disorder (SAD). Children with SAD fear being lost from their family or fear something bad happening to a loved one. They may have inappropriate or excessive worry about being apart from people to whom they are most attached, may refuse to sleep alone or have repeated nightmares with a theme of separation, may worry excessively about family members, and may refuse to go to school. Other symptoms may include a reluctance to be alone, frequent physical complaints, muscle aches, excessive worry, and an excessive “clinginess” even when at home. Symptoms of fear must be powerful enough to interfere with everyday life and must last for at least 4 weeks to be considered SAD.

Symptoms of SAD are more severe than those of normal separation anxiety, which is a developmental phase that most children experience between the ages of 18 months and 3 years. SAD is also distinct from stranger anxiety, which is normal for children between 7 and 11 years old. In children, SAD occurs equally in boys and girls, and the first indications of the condition often occur between the ages of 7 and 9. Approximately 4% of younger children have SAD, and the

estimate for adolescents is slightly lower (Children’s Hospital of Pittsburgh, 2013). In some cases, separation anxiety can persist or recur in adulthood as adult separation anxiety (ASAD), though ASAD may have its first onset in adulthood (Milrod et al., 2014). Some phobias also develop during childhood. Social anxiety disorder, for example, typically develops between the ages of 11 and 15 and almost never after the age of 25. Situational phobias, on the other hand, generally develop by the mid-20s. Unlike adults with phobic disorders, children are not always able to understand that the fear created by a phobic stressor is irrational.

Anxiety in children is often treated with CBT, medication, or a combination of both. SSRIs are the medications of choice for children with anxiety. Tricyclic antidepressants and benzodiazepines are less commonly used to treat children. Other forms of therapy, including acceptance and commitment therapy (ACT) and dialectical behavioral therapy (DBT), may also be used in children in place of CBT (ADAA, n.d.c). However, the most effective treatment is a combination of SSRIs with CBT. Children may also benefit from family therapy and parent education (Cleveland Clinic, 2013).

Anxiety in Adolescents

An estimated 8% of adolescents between ages 13 and 18 have an anxiety disorder, with symptoms often manifesting in childhood. Only 18% of adolescents with a diagnosed anxiety disorder receive professional mental healthcare (NIMH, n.d.e). The difficulty in distinguishing anxiety from the normal developmental challenges of adolescence contributes to this low rate of treatment. Girls are more than twice as likely as boys to be diagnosed with anxiety during adolescence (Steingard, 2014).

Issues of social acceptance and independence are common stressors for adolescents, as is dissatisfaction with physical changes to the body during the teen years. Adolescents with anxiety disorders may appear shy or withdrawn in social situations and may refuse to engage in new experiences. They may also avoid activities that they previously enjoyed. Extremes of emotion may occur, with responses being either overly emotional or overly restrained. In an attempt to lessen feelings of anxiety, individuals may engage in dangerous or uncharacteristic behaviors. Anxiety tends to be comorbid with other mental health problems, and adolescents believed to have an anxiety disorder should be assessed for depression, developmental conditions, and language problems (Creswell et al., 2014). Treatment of anxiety in adolescents is similar to treatment of anxiety in children.

SAFETY ALERT Studies have indicated that adolescents, as well as some children, have an increased risk of developing suicidal ideations when taking SSRIs (Gibbons et al., 2015), so medical professionals should discuss the risks and rewards of pharmacologic therapy with adolescents and their parents before prescribing SSRIs.

Anxiety in Pregnant Women

Psychologic stress is common during pregnancy, with mild anxiety presenting frequently both before and after giving birth. Reliable data about the prevalence of prenatal anxiety do not exist; however, one study estimates that as many as 18% of pregnant women and 20% of new mothers develop

severe anxiety (George et al., 2013). Maternal anxiety leads to negative physical outcomes for mother and child and inhibits parental bonding.

Common stressors during pregnancy include concerns about resources, employment, and personal responsibilities, as well as fears related to the birth process and pregnancy complications. In addition, individuals at the greatest risk for anxiety during pregnancy tend to be insecure in personal relationships, have a history of infertility, and lack psychosocial resources (Schetter & Tanner, 2012). Common symptoms of anxiety such as fatigue and sleep disturbance are not reliable predictors of anxiety in pregnancy because they are commonly experienced during pregnancy; other symptoms such as panic attacks and muscle tension may be indicative of maternal anxiety.

Pregnant women must be very careful about treating anxiety with medication. Studies indicate that birth defects occur two to three times more frequently in babies born to women who took certain SSRIs during early pregnancy, specifically fluoxetine and paroxetine. However, other SSRIs, including sertraline, do not carry these same effects (Reefhuis et al., 2015). In addition, use of SSRIs in the third trimester is associated with an increased risk of pulmonary hypertension and other problems in the newborn (ADAA, 2015b). However, abruptly stopping SSRI use could be harmful for both mother and baby, so women with mild anxiety who are considering getting pregnant should taper off anxiety medications several months before attempting to become pregnant. Untreated anxiety in a pregnant woman is also hazardous, potentially leading to low birth weight, premature birth, and difficulty adapting to life outside the womb for the infant and to pregnancy termination, postpartum depression, impaired attachment to the baby, substance abuse, and other complications for the mother. Therefore, nonpharmacologic approaches such as CBT and relaxation techniques are a high priority for treatment of anxiety in pregnant women. In addition, women with severe anxiety may decide to continue their medication after discussing all options with their healthcare provider, because even though the risk of birth defects is higher for women who take SSRIs and other antianxiety medications, the risk is still very low (less than 1%).

Anxiety in Older Adults

Older adults with cognitive impairments or one or more chronic physical impairments are at increased risk for developing anxiety. Significant emotional loss, such as the death of a spouse, also increases the older adult's risk for anxiety. In older adults, manifestations of anxiety may overlap with medical illness, resulting in older adults presenting first to their primary care provider. Although the prevalence rates of anxiety disorders in older adults are lower than in the general population, this may be due to misdiagnosis rather than to an actual lower rate of anxiety in older adults. Risk factors for anxiety disorders in older adults include lower education levels, presence of multiple chronic illnesses, and being unmarried (D'Arrigo, 2013).

Older adults have differences in drug absorption, action, metabolism, and excretion compared with younger adults. They also are more likely to experience side effects associated with antianxiety medications, especially if they take

medications for physical illnesses that may have drug–drug interactions with medications prescribed for anxiety. Pharmacologic treatment should begin with low doses in this population and be titrated to higher doses based on effectiveness and occurrence of side effects. In addition, benzodiazepines should be avoided in the older population because of harmful side effects such as a decrease in cognition. Similar to other age groups, older adults may find that CBT is effective for treating their anxiety.

NURSING PROCESS

Nursing interventions are focused on reducing the severity of the symptoms of anxiety. Specific interventions include establishing a rapport, communicating therapeutically, supporting and enhancing coping skills, assessing and identifying maladaptive coping, fostering mental health, maintaining a therapeutic milieu, minimizing the deleterious effects of anxiety, and promoting the health of the individual. The generalist nurse provides case management, home health-care, psychoeducation, and medication administration.

Assessment

- **Observation and patient interview.** Assessment of patients with anxiety includes interviewing the patient with regard to current and previous illnesses, medication (and supplement) regimen, and past and present stressors. In addition, the nurse should tactfully interview the patient about current and previous methods of coping, including the use of alcohol and drugs, particularly because certain coping methods may actually compound the individual's sense of anxiety and may predispose the patient to developing an illness or other health alteration.

In particular, the nursing assessment for individuals experiencing mild anxiety should focus on appraisal. To gain understanding about the individual, the nurse acquires information about how the person appraises and prioritizes stressors. To facilitate the adaptive coping process, the nurse critically evaluates thoughts that may be increasing the person's anxiety. In addition, the nurse should do the following when appraising the patient's anxiety or fear:

- Observe for physical symptoms associated with anxiety. Muscle tension or twitching, trembling, body aches and soreness, cold or clammy hands, dry mouth, and sweating are common in individuals with anxiety disorders. Nausea, diarrhea, and urinary frequency may also occur (UMMC, 2013).
- Review the medical history for conditions that commonly occur with anxiety. Depression, bipolar disorder, substance abuse, and eating disorders often occur in addition to anxiety disorders (UMMC, 2013).
- Consider family history of anxiety disorders or depression. Individuals with blood relations diagnosed with anxiety or depression are more likely to have these conditions (UMMC, 2013).
- Assess the patient's emotional and psychologic well-being. Levels of life satisfaction and happiness are often lower in individuals with excessive anxiety (Centers

for Disease Control and Prevention [CDC], 2013). Self-acceptance, openness to new experiences, hopefulness, and sense of purpose are impacted by anxiety. The number and positive or negative nature of personal relationships should also be considered (CDC, 2013).

- Gauge the patient's social well-being. Anxiety may affect an individual's sense of social acceptance and usefulness to society, as well as his or her beliefs about society as a whole (CDC, 2013).
- Consider socioeconomic pressures the patient is facing. Pressures such as unemployment or financial loss pose risks to individual mental health and create anxiety (World Health Organization [WHO], 2014).
- Assess the patient's home and work conditions. Stressful or violent home life, high-pressure work conditions, and rapid change in either the home or workplace contribute to anxiety (WHO, 2014).
- **Physical examination.** Physical assessment should include a general assessment, as well as a focused assessment of any body systems that are relevant to the patient's current complaints.

Diagnosis

Selection of nursing diagnoses should be patient-specific and depends on numerous factors, including the degree to which anxiety is impacting the patient's daily life and social interaction. Examples of nursing diagnoses that may be appropriate for inclusion in the plan of care for the patient with an anxiety or a phobic disorder may include the following:

- *Anxiety*
- *Fear*
- *Knowledge, Deficient*
- *Coping, Ineffective*
- *Social Interaction, Impaired*
- *Sleep Pattern, Disturbed*
- *Health Management, Ineffective.*

(NANDA-I © 2014)

Planning

The nursing plan of care, designed in collaboration with the patient, may include the following goals:

- The patient will report a decrease in level of anxiety and frequency of anxiety episodes.
- The patient will report a decrease in the frequency and severity of phobic episodes.
- The patient will articulate successful coping mechanisms.
- The patient will report increasing use of successful coping mechanisms.
- The patient will verbalize healthy ways of responding to fear.
- The patient will demonstrate effective implementation of relaxation techniques.
- The patient will participate in psychotherapy or group counseling activities as outlined by the primary care provider.

Implementation

Interventions appropriate for patients with anxiety symptoms vary depending primarily on the severity of the individual's symptoms. Patients with severe anxiety or panic require immediate intervention and close supervision. The safety of the individual is at risk because of the narrowing of perception and inability to process information and think rationally. Patients with mild or moderate anxiety can benefit from several nursing interventions, including helping them identify triggers for their anxiety, providing patient teaching, and promoting effective coping and healthy behaviors (see **Figure 31-8** >>). Patients with severe anxiety or panic will also benefit from these interventions when their anxiety has subsided to a manageable level.

Interventions for Mild Anxiety

Patients experiencing mild anxiety are often able to learn information and acquire new behaviors easily. The nurse is able to provide valuable information to these patients, teaching them ways to manage stress and modify thinking processes and behaviors. The nurse should review the following when teaching the patient about anxiety disorders:

- How to recognize triggers and symptoms of anxiety. Early recognition of triggers can help patients respond with healthy coping strategies before anxiety levels rise.
- How to identify anxiety levels. Mild levels of anxiety can sometimes improve motivation and learning, whereas moderate and severe anxiety impact concentration and perception. Differentiating among the various levels helps patients determine if they are having a useful, appropriate anxiety response or an inappropriate anxiety response with potentially negative effects.
- Self-management and diversion techniques for coping with anxiety. Stepping back from a situation in order to reassess it and learning to accept that some things cannot be controlled are important self-management skills. Exercising, engaging in hobbies, and spending time with friends or family are often effective diversions. Both types of techniques help the patient refocus the mind away from stressors to lessen anxiety (Mayo Clinic, 2014b).

Source: Alexander Rath/Shutterstock.

Figure 31-8 >> Nurses can help patients cope with anxiety through a number of interventions.

- Introducing the concept of positive self-talk for coping with anxiety. Positive self-talk helps patients replace anxious thoughts with more rational and realistic ones. Self-talk typically involves the patient repeating a set of statements to herself in an effort to curtail anxiety. The first statement is generally a firm but gentle admonition designed to stop anxious thoughts. This may be followed by one or more positive coping statements.
- Encouraging the use of muscle relaxation and mental visualization to refocus attention away from anxiety. Meditation, deep breathing, and yoga are popular relaxation techniques that patients can do in their own homes (UMMC, 2013).
- The importance of taking medications as prescribed. The majority of medications used to treat anxiety disorders influence activity of neurotransmitters and typically take up to several weeks to achieve efficacy. Skipping a dose on days when anxiety levels are low will negatively impact a medication's overall effectiveness. It may also increase the patient's risk for relapse of anxiety symptoms. Medication should only be discontinued as instructed by a healthcare provider.
- The importance of attending therapy sessions as prescribed. The goal of psychotherapy and CBT is the reduction of anxiety symptoms. Throughout the therapy process, symptoms improve as initial successes are built upon. Failure to participate in therapy sessions hinders the building process (Mayo Clinic, 2014b).
- Information about community resources for everyday and emergency situations. Everyday resources include support groups, message boards, and local and national organizations dedicated to anxiety disorders. Emergency resources include crisis hotlines, emergency departments, and trusted mental health professionals familiar with the patient's disorder.

For additional information, see the Patient Teaching feature.

Interventions for Moderate Anxiety

Patients with moderate anxiety need appropriate intervention to prevent escalation of symptoms. Interventions may include:

- Encourage participation in diversional activities, such as exercise, to reduce stress. For example, walking briskly, running, or working out large muscle groups assists the individual to manage her own physical responses to anxiety.
- Help the patient identify current stressors. When the patient knows and can identify the situations that cause anxiety, he can develop a systematic approach to addressing or eliminating the stressor. Eliminating the stressor rather than simply avoiding it reduces the anxiety associated with it in the long term.
- Help the patient identify what coping strategies have been successful in the past. When the patient knows and can identify strategies he has used successfully in the past, he may be able to return to earlier patterns that are helpful in reducing his anxiety.
- Encourage the patient to adhere to the treatment regimen and discuss the addition of integrative therapies with the primary care provider. Patients can become discouraged

while waiting for pharmacologic interventions to take full effect or while learning new strategies for coping in psychotherapy. Adding one or more integrative therapies as adjuvant treatment may help relieve symptoms of anxiety until medications or psychotherapy begin to take effect.

Interventions for Severe Anxiety

Patients with severe anxiety benefit from clear, direct communication and simple questions rather than questions or instructions that require the patient to process more than one thing at a time. Some interventions for moderate anxiety, such as identifying triggers and determining helpful strategies that have worked in the past, are also appropriate when working with patients with severe anxiety. As always, the nurse should administer medications as ordered and encourage patients to adhere to the therapeutic regimen (e.g., therapy, exercise, use of previously identified integrative therapies such as yoga). Some patients may require inpatient hospitalization until they are able to reduce their anxiety level and develop new strategies for coping.

Interventions for Panic

Patients who are at a panic level of anxiety require active supervision and clear, direct communication. Remain with the patient to ensure his own and others' safety. Patients at this stage may require assistance from the nurse to meet basic needs, such as nutrition and fluids, pain relief, elimination, or rest.

- Maintain a calm demeanor. Speak slowly using a low-pitched voice. High-pitched voices can increase anxiety, and the nurse's calm presence may help reduce patient anxiety and fear.
- Reduce environmental stimuli. A calm environment promotes calmness in the patient.
- Reinforce reality when thought processes are altered because of fear. Help the patient focus on what is real.
- Set limits as necessary to ensure safety. Use simple statements and speak in an authoritative voice.
- Allow pacing or harmless repetitive physical tasks, as these can help diffuse negative energy.
- Administer medications as ordered.

Patient Teaching

Techniques to Reduce Anxiety

Essential teaching for the individual experiencing an anxiety disorder or phobia includes deep breathing and progressive relaxation techniques to lower anxiety responses. Avoidance of stimulants, caffeine, and nicotine is essential. Instructing the patient on the use of cognitive techniques can be helpful in lowering the individual's response to the threat. Strategies such as thought blocking, self-talk, and conversation with a support person all assist the individual to manage and empower more adaptive coping skills. Physical exercise that makes use of large muscle groups, such as walking, running, weight lifting, hiking, and various sport activities, can dissipate pent-up energy. Exercising also releases natural chemicals such as endorphins, improving mood and natural pain relief.

Evaluation

Evaluation of the patient experiencing anxiety is based on the symptoms with which she presented and her strengths and weaknesses. Suggested expected outcomes may include:

- The patient's anxiety has diminished as reflected by vital signs returning to baseline and patient's report of a decreased level of anxiety.
- The patient demonstrates new or improved coping measures to reduce anxiety.
- The patient self-moderates the anxiety response when stressors occur.
- The patient engages in healthy behaviors related to sleep, exercise, and nutrition.

- The patient demonstrates a desire to overcome anxiety and a willingness to follow the treatment regimen.

If the patient is still experiencing anxiety during the evaluation phase, the nurse should provide secondary interventions. In all cases of unresolved anxiety, the nurse should provide patient teaching related to additional nonpharmacologic coping techniques that the patient may use. For example, if the patient was taught only relaxation exercises, the nurse may advocate for CBT or teach deep breathing exercises. If the patient has tried CBT with little success, the nurse may advocate with the physician to prescribe an anti-anxiety medication. Using multiple coping strategies in addition to nonpharmacologic and pharmacologic therapies may be needed to successfully reduce anxiety over the long term in patients with anxiety disorders.

Nursing Care Plan

A Patient with Agoraphobia

Mrs. Randolph is 43 years old, married, and the mother of four daughters in their late teens and early twenties. She is referred to the psychiatric outpatient clinic from the local emergency department fol-

lowing an acute panic attack with symptoms of racing heartbeat, sweating, feeling faint, and the belief that she was dying.

ASSESSMENT	DIAGNOSES	PLANNING
<p>She could not identify any events, thoughts, or feelings that precipitated the incident; it seemed to occur "out of the blue." She felt unable to cope with the severity of the symptoms of the attack: "I tried to talk myself out of it; to tell myself it would go away, but it only got worse." Mrs. Randolph reports she has had similar attacks lasting from 2 minutes to 2 hours in the past with no physical cause found by her family physician. Her daily routine has become restricted, and she will not leave the house without a family member. She is not comfortable alone in her home and can't sleep if any family member is still out. She is ashamed and angry about her growing disability and often tries to cover up her fears to friends and family. Recent life events include a hysterectomy 4 weeks ago and loss of employment resulting from hospitalization; the second anniversary of her father's sudden death is upcoming. She has no other history of mental health issues. She saw a therapist for her panic disorder when the attacks first started, "about the time I left home to marry," but did not follow up because she felt ashamed ("I've always been a strong and effective person!"), because the episodes were not so severe then, and because she found relief from the panic attacks after she had children. Her mother rarely left the house, never participating in social events unless they were in the home. She described her relationship with her husband as emotionally warm and supportive. She dreads seeing her daughters move from home.</p> <p>Assessment findings:</p> <ul style="list-style-type: none"> ■ Is an attractive, carefully groomed woman who looks her stated age. ■ Appears somewhat tense. ■ Answers questions cooperatively, but at times with some hesitation, as if expecting criticism or judgment from the interviewer. ■ Oriented to time, place, and person. ■ Memory intact, good recall, no difficulty with calculations. ■ Affect appears normal, with occasional evidence of anger in the form of irritability or sarcasm. Mood is within normal limits. ■ Speech normal in flow and volume, pressured at times when she corrects an impression. ■ Posture rigid at times, but she relaxes as she becomes more comfortable with the interview. 	<ul style="list-style-type: none"> ■ <i>Role Performance, Ineffective</i> related to fear and anxiety level ■ <i>Coping, Ineffective</i> related to overwhelming fears (NANDA-I © 2014) ■ Disturbed thought processes related to high level of anxiety 	<p>Goals of care include:</p> <ul style="list-style-type: none"> ■ The patient will describe specific changes in role function. ■ The patient will demonstrate appropriate decision making. ■ The patient will demonstrate effective coping as evidenced by employing behaviors to reduce stress and reporting fewer negative feelings.

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Maintain a calm manner.
- Stay with the patient.
- Use short, simple sentences.
- Direct patient's attention to a repetitive or physical task.
- Administer pharmacologic agents as ordered.
- Encourage patient to identify previous coping skills.
- Help patient identify coping resources (including social supports).
- Teach patient relaxation techniques.
- Encourage patient to verbalize feelings.

EVALUATION

Expected outcomes to evaluate the patient's response to care include:

- The patient demonstrates role performance as evidenced by the ability to meet role expectations, knowledge of role transition periods, and reported strategies for role changes.
- The patient demonstrates ability to choose between two or more alternatives.
- The patient uses actions to manage stressors that tax personal resources.

CRITICAL THINKING

1. What factors may be contributing to Mrs. Randolph's agoraphobia?
2. What interview questions would you like to ask Mrs. Randolph's family?
3. What strategies would you recommend to help Mrs. Randolph overcome her fear of leaving her house alone?

REVIEW Anxiety Disorders

RELATE Link the Concepts and Exemplars

Linking the exemplar of anxiety disorders with the concept of perfusion:

1. What impact does anxiety have on perfusion?
2. What medications normally prescribed for anxiety would be contraindicated for an individual with a history of heart disease?

Linking the exemplar of anxiety disorders with the concept of acid–base balance:

3. How might anxiety impact acid–base balance?
4. What nursing interventions might the nurse recommend for the patient with anxiety that is altering acid–base balance?

REFLECT Apply Your Knowledge

Heather O'Malley is a 34-year-old woman who is newly separated from her husband. She has been a stay-at-home mother of children ages 7, 5, and 4, along with a 3-month-old infant. Her days are very busy caring for her young children, and she wonders how she will manage on her own, especially because she will need to find a job in order to provide for the financial needs of the household now that her husband has moved out. Although he is paying court-ordered child support, it is not enough to meet the living expenses of Ms. O'Malley and all four children. Her attempts to work with a lawyer to get additional money in the form of alimony are on hold because she does not have money to pay the lawyer.

Ms. O'Malley worked as a nurse before quitting when the oldest child was born. She looks into taking a refresher course so she can return to nursing and learns that several hospitals provide the course free of charge if she agrees to work for them after successful completion. She applies to one of these hospitals and is called for an interview. Ms. O'Malley wakes up early on the morning of the interview, feeds the older children and sends them to school, then takes the youngest child to the house of a neighbor who has agreed to babysit. She returns home to dress for her interview, thinking about how she will find good child care if she takes a full-time job and trying to figure out what salary she will need to meet her financial obligations if they are to stay in their home. As she is starting the car, Ms. O'Malley suddenly finds she can't catch her breath, feels light-headed and dizzy, and has acute chest pressure. She sits in the car concentrating on her breathing until the feeling subsides and then returns to the house to cancel her interview. She reschedules twice, and each time the same physical symptoms begin before she can get to the interview. When she calls to reschedule a third time the hospital declines to set up another interview.

1. What stressors are impacting Ms. O'Malley at this time?
2. If Ms. O'Malley came to the clinic and you were admitting her to the office, what assessment questions would you ask to explore her methods of coping?
3. Describe three nursing diagnoses that may be appropriate for inclusion in Ms. O'Malley's nursing plan of care.
4. For each nursing diagnosis, list at least two relevant nursing interventions.

Exemplar 31.B

Crisis

Exemplar Learning Outcomes

31.B Analyze crisis as it relates to stress and coping.

- Describe the characteristics of crisis.
- Describe factors that affect individual response to crisis.
- Identify the clinical manifestations of a crisis response.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual in crisis.
- Differentiate considerations for care of patients in crisis across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual in crisis.

Overview

By necessity, life and the human condition include the experience of crisis. A **crisis** occurs when an event or circumstance overwhelms an individual's inherent ability to resolve, manage, or process the event. A crisis refers to any acute incident that can evolve from a situation or event and that overwhelms an individual's normal coping process. Such a situation or event may involve a developmental, biological, psychosocial, environmental, or spiritual stressor. Crises occur when the typical or normal methods an individual uses to cope with stressful situations no longer reduce the anxiety or resolve the situation. This failure produces an acute state of emotional and psychologic turmoil. Adaptation and successful resolution of a crisis may involve a number of adjustments and may result in a change in the individual's coping process. A crisis also affords the individual an opportunity to grow and change as a result of successful adaptation to the crisis.

Crisis as an Individual Event

Characteristics of Crisis

A crisis is, by definition, an acute situation and is precipitated by an event that creates disequilibrium. Crises occur in the lives of all individuals. The experience of crisis is an individual event. What is a crisis for one person may not constitute a crisis for someone else. The characteristics of a crisis are:

- Something all individuals will experience as a part of living
- Presence of a specific stimulus or event
- Defined individually
- Acute event that will resolve (usually 4–6 weeks)
- Affords the opportunity for growth or deterioration

All crises provide opportunities for growth or deterioration (Townsend, 2014). Typically, an individual resolves a crisis in one of three ways: (1) adapt to the crisis and return to the previous level of functioning, (2) use the opportunity to improve as an individual and cope with life more effectively, or (3) deteriorate to a lower level of functioning. The first possible resolution preserves the individual's status quo, the second changes it for the better, and the third changes it for the worse.

 Situational crisis, 2084

The contributions of Caplan (1964) to the prevention of mental illness have long provided the groundwork on which to build what is known today as *crisis theory*. Individuals interact constantly with the environment; internally, they struggle to meet Maslow's hierarchy of needs (see Figure 31–1). These needs—physical, psychologic, social, and spiritual—manifest differently as an individual progresses through the lifespan. The individual's ability to fulfill needs, maintain homeostasis, regulate affect, mobilize resources, and maintain reality testing affects the individual's capability for adaptation. The individual's perception of the crisis, resources, support, and ego strength all influence his or her capacity to return to prior levels of functioning after crisis.

Types of crises include both situational and maturational crises. A **situational crisis** involves an unexpected stressor or circumstance that occurs in the course of daily living (see **Figure 31–9**)). Acute stressors may arise from the external

Source: DIIMSA Researcher/Shutterstock.

Figure 31–9 In August and September of 2017, hurricane Harvey hit the Houston area of Texas (shown here) and hurricane Irma hit lower Florida, and the winds, rain, and storm surges damaged and/or flooded hundreds of thousands of homes, creating crises for many families.

environment, such as tornadoes or earthquakes; the internal environment, such as critical illness or disfigurement; and interpersonal sources, such as the death of a loved one or a lost relationship. **Maturation crisis** occurs normally as individuals progress through the life cycle. Everyone experiences predictable stages of human growth and development as outlined by Erikson (1968) (see Table 25.2 in the module on Development). During each stage, the individual is subject to unique stressors. A failure at any one stage compromises the next stage of development.

Holistically, achievement of growth and development milestones requires a tremendous amount of energy. Unexpected life events may alter the person's ability to adapt successfully to either a maturational or a situational crisis. This increases an individual's vulnerability, often requiring supportive interventions from healthcare providers.

Resilience

The American Psychological Association defines **resilience** as "the process of adapting well in the face of adversity, trauma, tragedy, threats or significant sources of stress" (American Psychological Association, n.d.b). Although resilience may be thought of variously as a trait, a process, or an outcome, it involves numerous biological, psychologic, social, and cultural factors and determinants (Southwick et al., 2014). As a process, resilience is the way in which individuals adapt successfully to crisis events to develop positive outcomes (Reyes et al., 2015). Resilience exists on a continuum, manifesting in varying degrees at different times depending on the event and the individual (Southwick et al., 2014). Resilience is dynamic in nature. That is, an individual may demonstrate varying degrees of resilience when exposed to the same or similar stressors throughout the lifespan. Individuals may also be more or less resilient in different domains of life—better able to adapt to stress in their professional life than in their personal life, for example (Southwick et al., 2014).

Individual resilience is strongly influenced by the person's optimistic sense of perceived self-efficacy (see **Figure 31-10** >>). Psychologist Dr. Albert Bandura posited that an individual must have a strong feeling of personal efficacy to successfully persevere in the face of adversity (Bandura, 1994). Optimism refers to a sense of confidence and hope with regard to positive or favorable resolution of a situation or set of circumstances. Perceived self-efficacy refers to an individual's beliefs concerning his or her capability to influence and exercise control over the events that shape his or her life (Bandura, 1994).

Bandura, whose contributions to the field of psychology include his famous *social learning theory*, conducted in-depth research in the area of self-efficacy. According to Bandura (1994), an individual's perception of self-efficacy is shaped by the following influences:

- **Mastery experiences:** Personal experiences with conquering obstacles through tenacious efforts and perseverance; a pattern of easy achievement of success may lead an individual to expect victory and to be discouraged by failure.
- **Vicarious experiences:** When observing the success or failure of someone similar to himself performing a task, an individual will tend to believe that he will perform similarly given the same task.

- **Social persuasion:** The extent to which an individual is verbally persuaded by others to believe he or she is capable of achieving success and to accomplish given tasks.
- **Somatic and emotional states:** Incorporates self-judgments regarding an individual's stress response and physical abilities, as well as mood state. Individuals may be self-critical of their stress response or sense of tension when faced with stressors; in turn, these same individuals may perceive their physical response to stress as rendering them susceptible to failure. In comparison to a negative mood, a positive mood is associated with greater perceived self-efficacy (Bandura, 1994).

Resilience, along with factors such as cognitive appraisal and coping style (as discussed in the Concept section of this module), affects both the physical and psychologic manifestations of an individual's response to crisis.

Clinical Manifestations

Individuals in crisis need immediate assistance and support. The Clinical Manifestations and Therapies feature outlines the common clinical symptoms and manifestations of individuals in crisis.

Source: XiXinXing/iStock/Getty Images

Figure 31-10 >> Resilience is the ability to adapt successfully in the face of adversity.

Clinical Manifestations and Therapies

Crisis

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
<ul style="list-style-type: none"> Physical trauma (including rape, assault, and exposure to violence) Emotional trauma (including psychologic and verbal abuse) Exposure to violence, including in the school or workplace settings Illness- and health-related alterations Significant loss (including death of a loved one or significant other) Exposure to natural and environmental disasters Exposure to acts of terrorism Financial stressors Legal stressors (including divorce, child custody disputes, and identity theft) 	<ul style="list-style-type: none"> Difficulty problem solving Disorganized thought processes with difficulty processing information Disorientation Vulnerability Increased tension and helplessness Fearfulness and sense of being overwhelmed Intense emotional reactions Increased sensory input and bombardment Hypervigilance Intense physical reactions depicted in the fight-or-flight response By definition, event usually is time limited and resolves within 6 weeks 	<ul style="list-style-type: none"> Counseling Crisis intervention Inpatient hospitalization and intensive counseling Couple, family, and/or group therapy Pharmacologic treatment for specific stress-related manifestations, if indicated (e.g., short-term administration of benzodiazepines for treatment of anxiety) or as indicated based on patient-specific needs (e.g., prophylactic antibiotics)

The goal in crisis is to stabilize the reactions of the individual, thereby initiating the process of adaptation by reducing the disruption created by the crisis. To facilitate adaptive coping, it is essential that nurses encourage patients to express their feelings and listen attentively and supportively. The nurse is an active participant in the intervention process. The generalist nurse serves as communicator, facilitator, and resource expert for the patient.

Collaboration

Caring for patients during times of crisis may include facilitating counseling referrals, connecting patients and families with community agencies, and implementing crisis interventions. For some patients, an extended or severe response to crisis may warrant pharmacologic intervention.

Diagnostic Tests

The patient interview and physical assessment provide the most valuable data for use in planning patient care. In addition, tools are available for use in evaluating the impact of a crisis event. For example, the Horowitz Impact of Event Scale (IES), which originally was developed in 1979 and revised in 1997, allows for measurement of an individual's stress response following traumatic or impactful life experiences (Horowitz, Wilner, & Alverez, 1979; Weiss & Marmar, 1997). Some researchers found the IES-R to be especially useful in helping to identify signs and symptoms associated with posttraumatic stress disorder (PTSD).

» **Stay Current:** To view the IES-R, visit http://consultgerirn.org/uploads/File/trythis/try_this_19.pdf

Focus on Diversity and Culture

Expression of Emotion

Cultural factors may influence how an individual expresses emotions. In certain cultures, expressions of pain, sorrow, or fear are viewed as signs of weakness. The nurse should be aware of the patient's cultural background and, while maintaining respect for the patient's privacy, gently offer the patient the opportunity to express himself.

Emotional expression tends to be congruent with what the culture values. Individuals in a culture that values independence and individuality will be more likely to express emotions such as irritation and anger in a time of crisis (De Leersnyder, Boiger, & Mesquita, 2013). In contrast, individuals from cultures that value relationships will be more likely to express emotions such as guilt or shame (De Leersnyder et al., 2013). Therefore, individuals from relationship-focused cultures may be at greater risk for suicide if

they feel that the poor choices of others are their fault, such as a mother taking responsibility for the poor choices of her children (Galanti, 2015).

Nurses need to be aware of cultural differences in values and how these may affect the expression of emotions during a time of crisis. Some individuals may openly express their feelings, whereas others may interpret their emotions in terms of physical symptoms (Galanti, 2015) or fail to show an emotional response at all. In some cases, lack of an emotional response or failure to engage with a healthcare provider may be a result of previous negative experiences with the healthcare system (Spector, 2017). Taking the time to understand each patient's emotions through the patient's cultural viewpoint can help provide a supportive and calming environment for the patient.

Pharmacologic Therapy

Pharmacologic therapies may be prescribed to address immediate medical needs, which vary widely depending on the nature of the crisis. Immediate needs that may require pharmacologic treatment include:

- Pain following injury (e.g., associated with a motor vehicle crash)
- Threat of infection following injury or exposure to a bacterial infection (e.g., prophylactic treatment for tuberculosis following a lengthy stay in a hurricane shelter)
- Sleep disturbance
- Anxiety or depression

For additional discussion about medications used in the treatment of patients with manifestations such as anxiety and depression, see the Medications feature in the Concept section of this module.

Nonpharmacologic Therapy

Nursing care of patients in crisis includes:

- Establishing a therapeutic relationship
- Ensuring patient safety from the first moment of contact
- Mobilizing support through the significant other, family, relatives, friends, church support groups, healthcare institutions, and organizations such as the American Red Cross
- Collaborating with mental health professionals

Directive suggestion may be helpful, such as gently advising the mother of a critically sick child to go home and sleep while assuring her that she will be called immediately if her child's condition changes. Offering time, attention, and direction is most critical during a crisis. An arrangement for a follow-up care appointment suggests concern for the individual's well-being. The opportunities to offer care in crisis are endless and may involve only a moment of time.

Therapeutic Communication

Communicating with individuals in crisis requires frequent, brief, simple, and often directive communication. Biologically, the brain of the individual in crisis is in the process of being bombarded with electrochemical reactions. Concentration and the ability to remember and retain information can be impaired. The nurse must continually reassess what the individual has heard or interpreted. In applying the transactional model, it is important to remember primary appraisal. What does the individual believe is happening? How can the nurse add resources and information to the reappraisal process to facilitate adaptive coping? Continual observation of patterns of communication within the family and/or group is essential. Because of the hyperarousal that occurs during the crisis, the nurse must monitor and assess nonverbal communication, tone, inflection, and mannerisms while communicating. See **Box 31-6** for guidelines concerning how to conduct effective therapeutic communication with patients. For more information, see the exemplar on Therapeutic Communication in the module on Communication.

Box 31-6

Guidelines for Therapeutic Communication in Crisis

- Incorporate verbal and nonverbal communication.
- Maintain eye contact, nod when appropriate, and avoid distractions to signal genuine concern for the patient.
- Maintain congruence between the verbal and nonverbal messages communicated by the nurse (Kourkouta & Papathanasiou, 2014).
- Paraphrase and repeat the patient's statements to validate the nurse's understanding of the patient and seek clarification; for example: "I hear you saying that you feel like everything's a mess." "Tell me what that means to you."
- Avoid making statements or comments that invalidate or judge the patient's experience instead of listening to and trying to understand it. Examples include statements such as "That doesn't sound important" or "I doubt it happened like that."
- Although encouraging the expression of emotions is important, when appropriate, silence is also an effective communication tool. In addition to demonstrating respect for the patient's privacy and willingness to share, periods of silence also allow the patient to reflect on her thoughts and emotions in order to more effectively express them.

In times of crisis, the nurse may be the one responsible for communicating bad news regarding injury or death of loved ones. As in all care settings, the nurse uses therapeutic communication strategies to impart this information and to provide support to family or friends as they process the information (see **Box 31-7**).

Box 31-7

Communicating Painful Information

One of the uncomfortable roles of the nurse is to communicate painful information to individuals. This task can be unnerving. A few simple guidelines convey a professional attitude of concern and care for those receiving dire news:

1. Greet the individuals with warmth, a kind smile, and an introduction.
2. Inform them that you are there and will assist during this difficult time.
3. Provide privacy, go to a place to sit down to discuss the information, and offer tissues and drinks.
4. Inquire about what they know, answer questions, and provide support.
5. Apprise them of the current circumstances in terms that they can understand.
6. Respond to their feelings and offer support.
7. Ask what they need from you and what has helped them in the past to cope with difficult situations.
8. Incorporate cultural and religious practices of the individuals in crisis to provide comfort.
9. Inform them you will facilitate communication and provide direction about the best means of accessing information.
10. Focus on the immediate reaction and needs of the individuals in crisis.
11. Write down specific contact numbers and instructions.
12. Check back with them as needed to see how they are doing and update them with any new information.

Crisis Counseling

Crisis counseling is focused on brief solutions, focused interventions, and supportive care. During the course of a crisis, nurses should consider each individual's physical vulnerability and degree of emotional stability, with special emphasis on determining the patient's risk for self-harm or potential for harming others. While prioritizing the safety of the patient and others, the nurse should assess the patient's perception of and response to the crisis while also ensuring that the patient's basic needs are met. The alarm reaction, anxiety, and fear may prevent the person from resting, sleeping, or eating. In hospital and other clinical settings, important members of the healthcare team during a crisis may include the hospital chaplain or family minister, a grief counselor, a social worker, a child and family therapist, and a teacher. However, crisis counseling is often performed in a community context. For example, the Federal Emergency Management Agency's Crisis Counseling Program (2015) emphasizes that crisis counseling should be:

- **Outreach oriented**, delivering counseling services in the communities affected instead of waiting for survivors to seek out the services themselves
- **Conducted in nontraditional settings**, contacting survivors in their homes and communities, outside of clinical or office settings
- **Designed to strengthen existing community support systems**, supplementing and supporting existing community response systems

See **Box 31-8** » for an overview of the components of crisis counseling.

Crisis Intervention

A **crisis intervention** is an emergent approach to care that is intended to assist patients with recognizing a crisis situation and identifying and implementing an immediate, short-term solution. For the patient, the ultimate goal of crisis intervention is restoration to a level of functioning that is at or above the level of the precrisis state. This approach often incorporates the patient's family members and loved ones as well as those individuals who are significant to the patient in terms of providing social support. Depending on the circumstances, a crisis intervention also may include professionals from a variety of specialties, such as school guidance counselors, law enforcement or probation officers, rescue workers, and clergy members. Successful completion of a crisis intervention depends on the patient's needs; for example, some crisis interventions may culminate in the patient's receiving outpatient counseling or guidance, while others may require immediate hospital admission or transfer to a facility that provides treatment for patients with substance abuse disorders. Crisis interventions may happen in a community setting outside of a hospital context if that is what an individual patient's particular needs dictate. For example, the Minnesota Department of Human Services (DHS) lists potential mobile crisis intervention services as (Minnesota DHS, 2013):

- Coping with immediate stressors to lessen suffering
- Identifying and using available resources as well as the strengths of the individual receiving the intervention
- Avoiding unnecessary hospitalization and the loss of the ability to live independently

Box 31-8

ABCs of Crisis Counseling

Achieve Rapport

In the first stage of crisis counseling, the nurse or therapist works to achieve rapport with the patient by using therapeutic communication. Helping patients clarify feelings and perceptions of the event first will assist them in venting initial emotions, lower their anxiety levels, and create an environment that will support building of the therapeutic relationship and development of a plan of care. Additional goals at this stage include assessing immediate needs and ensuring the patient's immediate physical and emotional safety.

Boil Down the Problem (Identify, Validate, and Intervene)

At this stage, the nurse or therapist helps the patient identify the problem, providing validation and intervention. Communication with the patient at this stage focuses on identifying the problem, assessing how the patient is thinking and feeling about the problem, and evaluating the patient's functional ability since the crisis event. Goals at this stage include helping patients identify their most pressing problems, encouraging patients to talk about the present, and assessing and addressing ongoing safety concerns, such as risk for suicide, abuse, and substance abuse.

In some situations, patients may not have a previous experience and coping mechanisms that they can articulate. Giving patients small choices, such as asking what they would like to drink or if they would like to make a phone call, can help build their confidence.

Assessment and intervention will vary greatly depending on the patient and the crisis. The safety assessment of a patient with asthma following a natural disaster will be very different from the safety assessment of a patient who is being abused by her partner.

Cope with the Problem (Resolution and Referral)

At this stage, the nurse or therapist determines what is necessary to help the patient cope with the problem. Using Maslow's hierarchy of needs to focus on the patient's basic needs of shelter, food, water, and physiologic safety is a good framework to use when prioritizing care for patients in crisis. For patients who are victims of violence, physiologic and emotional safety needs will be very closely related. Consider both short- and long-term needs for resolution and referral. Goals at this stage include determining what the patient wants to happen and what will help the patient to meet his or her needs and to support the patient's need for validation and hope for the future.

Sources: Jones, W. L. (1968). The A-B-C method of crisis management. *Mental Hygiene*, 52(1), 87-89; Kanel, K. (2015). *A guide to crisis intervention* (5th ed.). Stamford, CT: Cengage Learning; Mental Health Academy. (n.d.) *Crisis counseling: The ABC model*. Retrieved from https://www.mentalhealthacademy.com.au/video_details.php?catid=15&vid=68.

- Developing action plans
- Returning the individual to a precrisis level of functioning

Crisis intervention centers provide telephone consultation for patients in crisis. Some organizations also offer consultation by way of email and online chatting. In most cases, call-in crisis intervention centers, also known as crisis hotlines, are staffed by trained volunteers who follow protocols to assist the patient and who have professional consultation available to them, such as mental health counselors and psychologists. These 24-hour services allow callers to remain anonymous. For individuals who use crisis hotline services, primary goals include preventing the caller from inflicting harm directed at herself or others, giving the individual an opportunity to share her emotions and conflicts, and encouraging follow-up care with a local mental health professional if needed.

A step-by-step intervention is outlined in **Box 31–9** ». A crisis connection provides a lifeline for the patient in crisis and allows the nurse to determine immediate needs.

Temporary Relocation

Patients in crisis—in particular, those who are homeless and those who are subject to abuse—may require assistance with meeting one of the most basic needs: finding shelter. Nurses should be aware of community organizations and representatives who can assist patients with finding emergency living arrangements.

Lifespan Considerations

The response to trauma varies throughout the lifespan. For all age groups, nurses should carefully assess the particular cultural, social, and family factors that may influence how each patient speaks about their feelings and needs. Nurses may also identify and recommend community resources and organizations that can assist patients in crisis in their area.

Children and Adolescents in Crisis

Children and adolescents are highly susceptible to crisis. Because of their developmental level and lack of experience dealing with crises, they are less able to cope with extreme circumstances than are adults. This is especially true for children with disabilities. Types of crises to which children and adolescents may be exposed include bullying, divorce or separation of parents, child abuse, school shootings, death of a parent or sibling, failed attempts at suicide, friends committing suicide, unexpected pregnancy, and trauma from accidents, natural disasters, sports, and other events.

Box 31–9 Crisis Connection

1. Make contact and connect with the individual.
2. Assess immediate safety needs.
3. Determine thought processes.
4. Scan for physical distress.
5. Listen intently, supporting emotional reactions.
6. Explore perceptions of the crisis.
7. Identify coping strengths.
8. Develop a support plan and a follow-up plan.

Focus on Integrative Health Prayer

As discussed in the Concept section of this module, the mind-body connection has been established through research. Elicitation of the stress response by way of cognitive appraisal of a stressor is a classic example of this connection. Building on this relationship, a holistic approach to nursing care acknowledges a connection between not only the mind and body, but also the spirit.

In the United States, a study of findings from the adult Alternative Medicine supplement of the National Health Interview Survey (NHIS) in 2002 and 2007 focusing on the use of prayer as an integrative treatment for depression revealed that general prayer among those surveyed increased from 40.2 to 45.7% between those years. Compared to those who were neither depressed nor prayed, women, unmarried individuals, individuals with a high school education, and individuals age 50–64 were more likely to use prayer while depressed. The study suggested that it is essential for healthcare providers to be aware of their patients' use of prayer as a means of coping with depression as well as with other healthcare concerns (Wachholtz & Sambamthoori, 2013). Concerning the effects of prayer on healing and wellness, research is hindered by obvious limitations, including that psychosocial wellness is largely subjective and, as such, is difficult to measure quantitatively. Moreover, the inclusion of treatments that are in addition to prayer, such as pharmacologic interventions, complicates the study of the effects of prayer alone. What is clear is that prayer is a widely used approach in the quest for healing. For nurses, the implications of this finding include assessing and respecting the spiritual beliefs of each individual patient, including those who are atheists.

Children and adolescents will respond to and cope with crisis events differently depending on their age, developmental maturity, support resources, life experiences, and association with the event. Nurses should work closely with parents to assess and care for children and adolescents after a crisis, because parents know their children best and can report changes in behavior that may signal a poor coping response to the crisis that requires additional intervention.

All children and adolescents dealing with crisis should receive emotional support from parents and healthcare professionals. Nurses can provide support by reassuring the child that he is safe; encouraging the child to express her feelings; telling the child that it is appropriate to feel emotions such as sadness, anger, grief, or fear; and keeping the child informed about what is happening in the crisis situation. Nurses should encourage parents to spend extra time with their child, talk to the child about the event at a developmentally appropriate level, monitor the child for changes in behavior, limit their child's television viewing about the event, and help the child maintain a normal routine. Nurses should teach parents that behavior changes often associated with crisis events that may signal a poor coping response include clinginess, nightmares, bedwetting, irritability, a decrease in normal play activity, changes in eating patterns, reporting headaches or stomachaches, aggression, and behavior problems at school. Adolescents

should be monitored carefully for signs of depression and risk for suicide.

If a child or adolescent continues to respond to the crisis event with abnormal behavior and poor coping beyond a reasonable time for the severity of the event, the nurse should advocate for the child and family to receive additional counseling from a child or family mental health professional. The nurse may also encourage the child and family to find creative ways to respond to the crisis. For example, the death of a sibling or friend may be commemorated by planting a tree in their honor or making a donation to their favorite charity.

Pregnant Women in Crisis

In addition to crises that other adults face, pregnant women may face crises related to miscarriage, having a child with a disability or other chronic illness, and preterm birth. Some pregnant women may experience a crisis if they are pregnant as the result of a rape, and teen mothers may experience crisis related to rejection by family and friends and the fear of raising the child while still in school. Other women may experience a crisis if they decide to have an abortion or give up the baby for adoption. These crises may take on an even greater magnitude if the pregnant woman does not receive support from the child's father.

Nurses can provide a safe and calming environment in which the pregnant woman can express her fears and other emotions. Nurses should validate the pregnant woman's emotions and correct any misconceptions the woman might have. Nurses should provide pregnant women with information specific to their situation. For example, if a pregnant woman has been told she will have a child with Down syndrome, the nurse can provide the woman with literature about what to expect when caring for a child with Down syndrome. Nursing interventions that increase knowledge about the crisis situation will increase the woman's ability to cope with the stressor.

For women who are pregnant as a result of rape, the nurse can encourage the woman to work with the police and court personnel and provide support and a listening ear as the woman expresses her distress over the situation. If the pregnant woman is a teenager, the nurse can ensure that the teen's parents will provide a stable environment for the teen and baby or work with the teen and social system to find a stable home for the new family.

If a pregnant woman must deal with a crisis unrelated to her pregnancy, she may be more open to receiving nursing care and more likely to implement suggestions for maintaining her emotional and physical health (Littleton-Gibbs & Engebretson, 2013). However, pregnant women experience many hormonal changes during pregnancy that can affect their moods and their ability to deal with crisis situations. For example, they may be more susceptible to depression and anxiety disorders. In addition, behavioral and physical changes, especially changes that affect the pregnant woman's health, can affect the development of the baby. For example, high blood pressure from high levels of stress increases the potential for preterm labor or a low-birth-weight infant (National Institutes of Health, 2012). Coping with a crisis situation by drinking alcohol or smoking can lead to fetal alcohol

spectrum disorders or problems with placental attachment (American Congress of Obstetricians and Gynecologists [ACOG] 2013). Therefore, pregnant women in crisis should be monitored carefully, and the nurse should provide support for the mother and baby throughout the pregnancy and after birth.

Older Adults in Crisis

Older adults are often more susceptible to injury during crisis events that involve natural disasters, home fires, motor vehicle accidents, wandering from home, and other traumatic events. Older adults also have higher incidence of chronic disorders such as diabetes and heart disease, so they are more susceptible to changes in health related to lack of access to medications and nutrition. Older adults may be more susceptible to confusion and disorientation.

The nurse caring for an older adult during a crisis should begin by orienting the older adult to person, time, and place, and asking what the patient remembers about the crisis event. If the older adult is properly oriented, the nurse should provide any emergency care needed and begin a full physical, mental, and emotional assessment. In particular, the nurse should determine the older adult's health history and gain access to any medications the older adult might need during the time they are in the nurse's care. The nurse should encourage the older adult's family and friends to provide support during and after the crisis, as isolation and loneliness can lead to further deterioration of the patient's physical and mental health.

NURSING PROCESS

Initially, the primary focus of crisis intervention is to ensure safety. Once safety is established, the ideal goals include helping the patient acknowledge and manage the crisis and assisting the patient to identify and access resources needed to achieve resolution.

Assessment

The nurse systematically assesses the patient in crisis, beginning with making contact and connecting with the patient. Assess and identify patient safety issues such as:

- Safe and adequate shelter
- Access to food and healthcare
- Feelings of hopelessness or threat to self or others
- Risk for harm or violence (to/from self or others).

To ensure the patient's safety, emergent admission to a hospital or treatment center may be necessary. Ideally, assessment also includes interviewing the patient's family or significant others.

Individual Assessment

During the assessment process, the nurse must determine the patient's thought processes, orientation, and ability to process information. Assessment of the patient's physical condition includes any physical complaints and determining if the patient is able to fulfill basic needs such as eating, resting, sleeping, and self-care. Because of the intensity of

the fight-or-flight reaction, vulnerable individuals may be at risk for physical illness during a crisis.

Psychosocial assessment includes assessing the patient's perception of the precipitating event, impact of the crisis, and his ability to cope with the crisis. The nurse should also interview the patient regarding his current and past coping methods, as well as his support system. Particularly for disaster survivors, the issue of survivor's guilt should be explored. For these patients, guilt may stem from the act of surviving while knowing others have died. Survivors may also harbor guilt as a result of the actions they took to survive.

Scaling assessment questions involve asking the patient to rate the severity of symptoms or problems. This allows the nurse to determine the perceptions of the patient. For example, the nurse may ask, "Mr. Smith, on a scale of 0 to 10, with 10 being absolutely intolerable, how would you score your distress right now?" Assessment information is prioritized on the basis of input from the individual.

It is important to remember that the expression of feelings about and interpretations of an event are culturally influenced and must be considered within the context of the individual's life. Sociocultural factors greatly impact an individual's interpretation of a crisis or traumatic event, as well as her response to the event. For example, among members of some cultures, persistent anxiety is considered to be a sign of weakness, as opposed to being a potential sign of a stress-related disorder. This belief is particularly prevalent among some women in the Pacific Islander and Asian cultures; as a result, these women may not reach out for help until they enter a crisis stage (Nydegger, 2012).

Cultural competence extends beyond the identification of a patient's cultural and ethnic background; it encompasses being aware of a patient's health practices and beliefs and demonstrating respect for the patient's preferences. However, the nurse also has a responsibility to identify health practices that may be detrimental to the patient's well-being. Identification and evaluation of the patient's culturally based health practices requires sensitive, nonjudgmental exploration of the topic. For example, the patient interview may include items such as "I want to try to understand how this experience may be affecting you. Please tell me more about how you feel," and "How would you expect your family or close friends to react to a similar experience?"

Family Assessment

House fires, motor vehicle crashes, serious illness or injury or death of an immediate family member, and natural disasters are just a few of the crises that families can experience. Emotional crises such as divorce, bankruptcy, and abuse also affect families. Each individual family member's response to a crisis will impact family functioning. Family communication patterns may promote or hinder family members' response to crises. Nurses working with families in crisis situations will benefit from assessing how family members have coped in previous crises as well as assessing immediate individual and family needs. If the crisis results in serious injury or illness to one or more family members, nurses can assist by offering a variety of interventions, including:

- Obtaining and providing information regarding the health status of the loved one

- Facilitating communication between the family and the healthcare team
- Ensuring access to and promoting communication with the loved one
- Providing privacy and emotional support (Ball, Bindler, Cowan, 2017, p. 449).

Community Assessment

Nurses may be among the first civilians called on to offer assistance in the wake of a disaster. For the community faced with crisis, assessment begins with triage and treatment of patients in need. Next follows assessment of living conditions and availability of basic resources, such as food, water, and shelter. Identification of the community's mental health and support resources, as well as the availability of financial and organizational resources (such as disaster assistance organizations), is also essential.

Diagnosis

Selection of nursing diagnoses depends on the patient's crisis response and associated manifestations. Examples of nursing diagnoses that may be appropriate for inclusion in the nursing plan of care for a patient in a state of crisis may include the following:

- *Injury, Risk for*
- *Anxiety*
- *Self-Neglect*
- *Coping, Ineffective*
- *Confusion, Acute.*

(NANDA-I © 2014)

Planning

Planning involves the selection of realistic goals and identified outcomes that promote resolution of the selected nursing diagnoses. Examples of patient goals and outcomes that may be relevant to the nursing care of a patient in crisis may include the following:

- The patient will remain free from injury.
- The patient will identify and use necessary resources and social support.
- The patient will report a reduction in perceived anxiety.
- The patient will actively participate in counseling and group therapy activities as outlined by the primary care provider.
- The patient will express understanding of coping techniques that can be used during times of crisis.
- The patient will respond appropriately to questions and conversation and show no signs of confusion.

Implementation

Implementation involves assisting patients with meeting needs identified in the assessment phase. Establishment of trust and application of therapeutic communication techniques serve as the foundation for building a relationship with the patient in crisis. The nurse should avoid minimizing the patient's feelings or offering false reassurances of hope.

Reduce Risk for Injury

Patients may be at greater risk of injury during a crisis because they are overwhelmed and unable to properly cope with or respond to changes in their environment. Depending on the type of crisis, patients may be at risk for injury directly due to the crisis, or they may be at risk for injury inflicted by self or others. For example, a woman who has been beaten by her husband may be at risk for further injury from her husband either at the hospital or when she returns home. Similarly, that same woman may be at risk for self-inflicted injury if she decides to attempt suicide. To reduce the risk for injury:

- Identify risk factors for injury in the patient's home environment that the patient can control and remove. Depending on the patient's situation, this may include fixing stairs, installing lights, removing hazardous materials, and removing weapons, among other interventions. Discuss potential risk factors with patients to make them aware of ways to reduce their risk for injury.
- Monitor the patient's community for ongoing threats and changes that could produce new risk factors. Especially in a crisis situation affecting the community at large when the crisis and the response to it are ongoing, the situation on the ground could change rapidly.
- Isolate patients from any potential sources of injury. If the potential injury is from another person, isolate the patient from the threatening individual. If the potential injury is from self, remove any potential weapons from the patient's immediate surroundings. If the potential source of injury is the environment, remove the patient from the environment and place the patient in a safe location.
- If the patient is in a hospital environment and the patient is a source of risk for injury to self, a patient companion may be assigned to the patient, the patient may be moved to a location where he can be easily observed by nursing staff, or restraints may be used as a last resort. Use of restraints should always be consistent with the level of risk and the patient's need to be kept from harm.

SAFETY ALERT Nurses need to be constantly aware of the potential dangers and risk of injury involved in responding to patients in crisis. These threats may come from the environment, particularly if the crisis is a natural disaster or community crisis; or threats may come from other people involved in the crisis, and even from the patients themselves. Also, nurses must be careful to ensure that in responding to crises they are aware of the possibility of becoming overwhelmed psychologically, emotionally, or physically themselves, to the point where they are no longer able to monitor effectively for risks to their safety.

Decrease Anxiety

Anxiety may accompany the patient's feeling of being overwhelmed by the crisis and unable to properly cope and make recovery from the crisis difficult. Almost all patients who are dealing with a crisis will experience anxiety at some point, although when they experience anxiety, the magnitude of anxiety that they experience and how they cope with it will differ with each individual. To learn more about nursing interventions associated with anxiety, see Exemplar 31.A.

Promote Self-Care

A crisis creates a strong potential for patients to fall into habits of self-neglect, with overwhelmed individuals falling out of established routines of self-care. Patients may ignore self-care activities such as bathing and other hygiene rituals, neglect home responsibilities such as caring for family or paying bills, or neglect work responsibilities that could result in loss of a job and further crisis. To promote patient self-care and reduce the risk for self-neglect:

- Encourage family members to assist the patient in meeting self-care needs. Monitor for signs of self-neglect such as unwashed hair or clothing the patient has worn for several days or that is mismatched, inadequate, or inappropriate.
- Encourage family and friends to help with home responsibilities such as providing child care or making sure bills are paid to prevent further crisis for the patient.
- Ensure the patient is eating and hydrating enough at home and has support from family or friends in ensuring proper routines of hydration and nutrition. If needed, recommend community nutrition resources such as Meals on Wheels.
- Help patients reduce stress associated with returning to work during a time of crisis. Help patients research family leave, vacation, and other work resources that may allow them to be away from work for an extended period of time without losing their jobs.
- In a hospital setting, encourage patients to follow routines of self-care that are within their control. Also ensure that they are taking in appropriate nutrition and hydration.

Promote Effective Coping

Depending on the type of crisis, the patient or the patient's family members and friends may display ineffective coping. Ineffective coping is often evidenced by blank emotions, shock, a lack of appetite, self-neglect, ineffective communication, ineffectual learning, excessive crying, or hysteria. The nurse can promote effective coping by:

- Providing information about community resources that may help the patient return to independence after a crisis. This may include resources for housing, furniture and clothing, transportation, food, jobs, physical therapy, counseling, and support groups (see Patient Teaching feature). Resources needed will vary depending on the patient's situation.
- Presenting a calm and collected demeanor to the patient and family at all times. Seeing others display calmness can help calm individuals who are anxious or upset.
- Removing the patient or the patient's family from visual reminders of the crisis situation. For example, the patient should be taken to a hotel or hospital after their house has burned down rather than being allowed to stay at the site. Similarly, nurses may discourage parents from viewing procedures that are required to care for a child who has been in a severe motor vehicle accident, especially if the child is unconscious and will not benefit from the presence of the parent. Placing the patient or

the patient's family in a quiet environment and minimizing external stimuli will help them achieve a sense of calmness.

- Encouraging the patient or the patient's family members to drink water and eat small snacks to sustain nutrition and hydration.
- Encouraging the patient or the patient's family members to participate in self-care activities such as sleeping and bathing. The nurse may need to encourage family members of hospitalized patients to go home to get some sleep or a change of clothing.
- Contacting next of kin for the patient to reduce isolation and provide a support system for the patient.
- Providing patients or their family members with small, simple tasks that they can perform. Completing simple tasks may help them feel like they are helping or achieving some control over the situation.
- Keeping patients informed about their medical status or the medical status of their loved one using therapeutic communication techniques. See Boxes 31–6 and 31–7. Consider also providing written information about the patient's situation or status so that patients or family members with ineffective learning can review the information when they are more emotionally stable. Offer to answer any questions and be available to talk with the family as needed.

Decrease Acute Confusion

Patients who have had a head injury or a major shock associated with a crisis may display acute confusion. This confusion may pertain to disorientation about location, events, time and date, or even personal identity. The nurse can decrease a patient's confusion by:

- Providing orienting information, such as a reminder about the events that caused the crisis or a reminder of the individual's location and the time and date.
- Providing written instructions related to treatments and care.
- Helping patients remember who they are (if their identity is known by the nurse). This may include showing patients their own ID card, such as a driver's license, or allowing them to see family and friends.
- Repeating information as needed in a calm and soothing manner until the patient begins to feel oriented to the situation and less confused.

Evaluation

Expected outcomes that may be appropriate for the patient experiencing a crisis include:

- The patient has identified and removed risk factors for injury from the environment.
- The patient reports using community resources and sources of social support such as family and friends.
- The patient reports feeling less anxiety associated with the crisis.
- The patient maintains proper hygiene, nutrition, hydration, and other self-care tasks, as evidenced by lack of

Patient Teaching

Benefits of Support Groups

Nurses should be ready to provide patients with information and recommendations regarding support groups that may be helpful in general or helpful specifically for people coping with their particular crisis. Potential benefits of support groups include:

- Participation in regular, judgment-free contact with people whose needs are similar to the patient's
- Empowerment and a feeling of being in control
- Improved coping skills and better adjustment increases the chance of moving forward from the crisis
- Freedom to speak openly and honestly
- A support network and sounding board for emotional responses to crisis
- A reduction in feelings of distress, depression, anxiety, or fatigue caused by putting problems in perspective
- An increase in feelings of self-worth and self-esteem, improved assertiveness, and improved personal relationships
- A reduction in feelings of isolation caused by realizing that others are struggling with the same problems, leading to increased social reconnection
- Development of a better understanding of the patient's situation, including providing a space for the patient to break down misconceptions and reduce harmful self-talk
- Practical advice and information about treatment options, including integrative treatments
- Diversity within the group gives new perspectives on how to approach the problem
- Comparison of notes regarding resource and physician options.

fatigue, maintenance of appropriate weight, and clean clothes and body.

- The patient displays effective coping techniques that are appropriate to the situation and expresses a regained sense of control over the crisis.
- The patient is independently oriented to self, time, place, and can describe the precipitating event.

The nurse may have to evaluate the patient in crisis multiple times before the situation is resolved and the patient appears to be in good health again. Each time, the nurse should reevaluate the patient for safety, adequate self-care, anxiety levels, coping techniques, and social support. Any areas that still require improvement to stabilize the patient should be prioritized to promote the patient's physical and mental health. Once the patient is stabilized, additional nursing interventions for milder symptoms or needs can be implemented.

Nursing Care Plan

A Patient in Crisis

ASSESSMENT

Deborah Smith is a 30-year-old woman who comes to the emergency department following a fall down the stairs outside her apartment. She breaks down in tears during the assessment. Not only is her ankle painful and swollen, but the father of her two small children has recently been arrested for nearly killing his girlfriend. She has no idea when he will be able to pay child support again, and she is afraid she will not be able to return to work at her job as a waitress if her ankle is sprained. The physical assessment reveals the following:

- Vital signs include temperature 99.0°F oral; pulse 96 bpm; respirations 18/min; and BP 136/86 mmHg.
- Hands are trembling, patient is tearful and crying
- Circular scars noted on both forearms the size of pencil erasers
- Left ankle is edematous and painful to touch, unable to perform range of motion in ankle
- Abrasions on the palm of the right hand, left elbow, and both knees.

DIAGNOSES

- *Pain, Acute*
- *Anxiety*
- *Caregiver Role Strain, Risk for*
- *Impaired Resilience, Risk for.*

(NANDA-I © 2014)

PLANNING

- Identify community resources that can provide assistance until Ms. Smith can return to work.
- Identify Ms. Smith's strengths in terms of available resources and family support.
- Manage pain to allow Ms. Smith to maintain comfort.
- Teach patient crutch walking and self-care for injured ankle.

IMPLEMENTATION

- Encourage Ms. Smith to express her feelings.
- Ask Ms. Smith whom she can look to for help. Are the children's grandparents supportive? Does she have a supportive spiritual community? Does her workplace have a sick leave policy? Are there resources within the community that can provide support and assistance?
- Provide referral to the hospital's department of social services to determine potential community resources.

- Encourage Ms. Smith to identify her strengths that can help her resolve her current crisis.
- Establish a follow-up plan for Ms. Smith's physical as well as psychosocial needs.
- Provide teaching on care of ankle injury, symptoms to report to provider immediately, crutch walking, and wound care.

EVALUATION

Social services assisted Ms. Smith in obtaining unemployment insurance during her medical leave of absence and provided **anticipatory guidance** to help her retain her job until she was able to return. Ms. Smith developed a stronger relationship with her

church community, whose members assisted in picking up the children from school, delivered meals, and helped to perform tasks such as laundry that Ms. Smith could not perform with limited mobility.

CRITICAL THINKING

1. If you were the nurse caring for Ms. Smith and lived in the same community, would it be appropriate for you to offer to provide home care for her and the children when you had time available? Why or why not?
2. Is it appropriate for you, as the nurse caring for Ms. Smith, to solve problems for her? Explain your answer.
3. What functions can social service provide to help patients in crisis like Ms. Smith?

REVIEW Crisis

RELATE Link the Concepts and Exemplars

Linking the exemplar of crisis with the concept of addiction:

1. When a crisis results from addiction behavior, what is the nurse's priority intervention? Explain your answer.
2. When a patient's spouse is demonstrating addiction behavior that has caused the patient's crisis, what community referrals might you consider suggesting to help the patient?

Linking the exemplar of crisis with the concept of culture and diversity:

3. Why might one series of events trigger a crisis for one patient but not another?

4. How do coping strategies differ during times of crisis for patients from vulnerable populations versus those who are less vulnerable? How would your nursing interventions differ for each patient?

REFLECT Apply Your Knowledge

Carol Holland is a 51-year-old mother of three. She is a nurse educator and works full time at a community college. Her son Paul recently moved back to live with her to attend college full time. Along with Paul,

Mrs. Holland lives with her husband Tom and their other son Mike. Her oldest and only daughter Angela lives in an apartment nearby. The Hollands receive a call in the wee hours of the morning. One of Mike's friends tells them that Mike has been in a terrible accident, and they need to come to the hospital immediately. Arriving at the trauma unit at 3:00 a.m., the Hollands and their son Paul enter the satellite unit. Mike is intubated and requires mechanical ventilation. Mrs. Holland scans Mike's body for signs of independent life, but he is motionless. His face is so swollen that he is nearly unrecognizable to her. What appears to be a blue cable cord holds together a laceration that encompasses most of his head. His left arm is swollen three times its size, and is blue and seeping from lacerations. As Paul collapses in a nearby chair and

begins weeping, the nurse quietly gathers vital information from Mrs. Holland. She directs Mike's family to the lounge where they will wait during a procedure to insert a ventricular shunt. The neurosurgeon is unsure Mike will survive the night.

1. What type of crisis is this family experiencing?
2. Given the information presented thus far, which nursing diagnoses might be applicable?
3. What are some possible psychosocial interventions for the patient and the family?
4. What basic needs might this family have throughout the night?

Exemplar 31.C

Obsessive-Compulsive Disorder

Exemplar Learning Outcomes

31.C Analyze obsessive-compulsive disorder (OCD) as it relates to stress and coping.

- Describe the pathophysiology of OCD.
- Describe the etiology of OCD.
- Compare the risk factors for and prevention of OCD.
- Identify the clinical manifestations of OCD.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with OCD.

Overview

Obsessive-compulsive disorder (OCD) is a disabling disorder characterized by obsessive thoughts and compulsive, repetitive behaviors that dominate an individual's life (see **Figure 31-11** »). An **obsession** is a recurrent, unwanted, and often distressing thought or image that leads to feelings of fear and anxiety. A **compulsion** is a repetitive behavior or mental activity (such as counting) used in an attempt to mitigate the obsessive thoughts and reduce feelings of anxiety (APA, 2013). To be diagnosed with OCD, the individual must experience distress and lose time (more than 1 hour a day) due to the consuming rituals and repetitive behaviors associated with the disorder (APA, 2013).

Pathophysiology and Etiology

Pathophysiology

A malfunction in the cortico-striato-thalamo-cortical (CSTC) circuit in the brain is the possible cause for OCD (see **Figure 31-12** »); the neurotransmitters serotonin, dopamine, and glutamate are all involved in OCD (Bokor & Anderson, 2014). A specific gene has not yet been isolated, but research has identified many candidate genes and found that some regions of the genome might include disease genes (Privitera et al., 2015). The neurobiology of OCD involves several areas of the brain: the orbitofrontal cortex, anterior cingulate gyrus, and basal ganglia (Bokor & Anderson, 2014). Neuroimages of individuals with OCD indicate abnormalities in the basal ganglia and the orbitofrontal cortex. Imaging data, genomic studies, and animal models of aberrant grooming behavior have contributed to the idea that the glutamatergic system plays a role in OCD. These findings are compatible

- Differentiate considerations for care of patients with OCD across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with OCD.

Exemplar Key Terms

Compulsion, 2095

Obsession, 2095

Obsessive-compulsive disorder (OCD), 2095

with circuit-based theories of OCD and have driven interest in testing the efficacy of pharmacologic treatments for OCD that modulate glutamate function (Goodman et al., 2014). Over the past decade, studies of OCD's pathogenesis have produced mounting evidence that increased immune system activation plays an important role (Rao et al., 2015).

Figure 31-11 » Individual resilience is influenced by the person's own confidence in, and hope for, a positive resolution to stressful circumstances.

Figure 31-12 » A combination of environmental and genetic factors can result in a malfunction in the CSTC circuit in the brain. This malfunction is thought to play a role in the development of OCD.

Diagnosis of OCD may be challenging for those who are untrained or uninformed about the disease. Variances that occur in the disorder, and which are explained in detail in the Clinical Manifestations section, also contribute to difficulty in diagnosing OCD. Contamination obsessions combined with washing and cleaning compulsions are probably the best-known variant of the disorder.

Etiology

Approximately 1.2% of the U.S. population has OCD within a 12-month span, and this number increases to 2.3% for lifetime prevalence (Ruscio et al., 2010). However, this is based on DSM-IV criteria; a true analysis of the epidemiology of OCD based on the DSM-5 criteria has not been published as of the time of this writing. Obsessive-compulsive disorder typically begins in adolescence or early adulthood, although some cases do begin in childhood. OCD affects men and women equally, but men develop the disorder earlier. Among males, approximately 25% of

those with OCD demonstrate onset before 10 years of age (APA, 2013). Without treatment, the rate of remission is estimated to be low. However, for individuals who experience childhood onset of OCD, approximately 40% may experience remission by the time they reach early adulthood (APA, 2013).

Risk Factors

Risk factors for OCD include having a first-degree relative with the disorder. A history of childhood sexual or physical abuse also increases the risk, as does exposure to other stressful or traumatic events during childhood (APA, 2013).

Clinical Manifestations

Obsessive-compulsive disorder is not to be confused with *obsessive-compulsive personality disorder*. The clinical manifestations of the personality disorder involve more of a preoccupation with perfection and are characterized by inflexibility.

The most frequently reported obsessions in OCD are repeated thoughts about contamination from shaking hands; repeated doubts with fear of having hurt someone or leaving a door unlocked; and a need to have things in a certain order. Common themes of the associated intrusive, repetitive thoughts include those which are considered by the individual to be forbidden or taboo; for example, religious or sexual obsessions and fears related to self-harm or injury of others (APA, 2013). Aggressive impulses are often of a sexual nature or obscene. The obsessions are not rational or real-life problems. The patient with OCD is, at some point, aware that the obsessions are not real (APA, 2013).

Compulsions are also part of OCD. Commonly reported repetitive behaviors include hand washing, ordering, checking, and counting. Note that hoarding, a behavior associated with OCD in DSM-IV, is recognized in DSM-5 as a distinct and separate disorder, hoarding disorder, within the category of Obsessive-Compulsive and Related Disorders (APA, 2013). For additional examples of commonly occurring obsessions and their related compulsions, see the Clinical Manifestations and Therapies feature. Compulsive behavior does not produce a sense of pleasure for the patient with OCD. Rather, the individual feels driven to perform the compulsion to reduce the anxiety produced by the obsession.

Collaboration

Diagnosis of OCD is made by a licensed clinical mental health professional. Care often occurs in the community and may include the nurse in collaboration with the patient's mental health provider, primary care provider, and school counselor or social worker. Because the impact of OCD can range from mild to disabling, the patient's needs will vary. The most common therapy for OCD is pharmacotherapy, followed by psychotherapies. Guidelines for treatment of OCD are summarized in **Box 31-10** ».

Diagnostic Tests

No definitive laboratory findings have been identified for diagnosing OCD.

Clinical Manifestations and Therapies

Obsessive-Compulsive Disorder

ETIOLOGY (OBSESSIONS)	CLINICAL MANIFESTATIONS (COMPULSIONS)	CLINICAL THERAPIES
Aggressive, sexual, and religious obsessions with checking compulsions	<ul style="list-style-type: none"> Checks doors, locks, appliances, written work Confesses frequently (to anything) Needs to ask others repeatedly for assurance 	<ul style="list-style-type: none"> Pharmacologic therapies include SSRIs: fluoxetine (Prozac), sertraline (Zoloft), fluvoxamine (Luvox), paroxetine (Paxil) Antipsychotic medications such as risperidone (Risperdal) may be helpful for those who do not respond to SSRIs. Cognitive behavior therapy may include desensitization therapy, in which the person is carefully exposed over a period of time to an object that promotes fear. For example, the therapist and patient may, at an appropriate time, agree that the patient will touch the doorknob. Other therapies such as deep brain stimulation may be helpful to those who are treatment resistant.
Symmetry obsessions with ordering, arranging, and repeating compulsions	<ul style="list-style-type: none"> Needs to have objects in fixed and symmetrical positions Repeats movements, such as going in and out of doorways, getting in and out of chairs, touching objects Counts or spells silently or aloud 	
Contamination obsessions with washing and cleaning compulsions	<ul style="list-style-type: none"> Repeatedly washes hands, showers, bathes, brushes teeth Cleans personal space frequently 	

Focus on Diversity and Culture

Lack of Diversity in Research

Evaluation of clinical studies on OCD shows that the majority of studies focus on White populations. Black and Hispanic populations are underrepresented in many clinical studies, even though prevalence rates and many manifestations of OCD of those populations are similar to those experienced by White populations (Wetterneck et al., 2012; Williams, Elstein et al., 2012). Limited studies on cultural differences between White and other cultural or ethnic groups indicate that Blacks and Hispanics are less likely to receive treatment for OCD based on the negative stigma associated with mental health conditions and socioeconomic barriers (Wetterneck et al., 2012; Williams, Domanico et al., 2012). However, Black patients report contamination symptoms more frequently than White patients and are twice as likely to report excessive concerns about animals (Williams, Elstein et al., 2012). In addition, religious differences often have a role in the development of OCD: Individuals who adhere to religions that practice rituals, such as Jewish, Catholic, and Islamic faiths, are more likely to develop OCD with repeated and excessive practice of religious rituals such that they interfere with everyday obligations (Himle, Taylor, & Chatters, 2012; Grant, 2014).

Pharmacologic Therapy

For the patient with OCD, SSRIs are often prescribed as part of the treatment regimen. Clomipramine, which is a tricyclic antidepressant (TCA), also may be administered (Mayo Clinic, 2015b). While SSRIs tend to have fewer side effects than TCAs, all medications carry risks and potential adverse effects. The nurse's role includes educating the patient about the safe administration of medications, as well as the potential side effects.

Nonpharmacologic Therapy

Psychotherapy is an integral component of treatment for the patient with OCD. In addition to focusing on the patient, therapy and counseling sessions may include the patient's family members or significant others. In particular, a kind of CBT called ERP has proven to be most effective for patients with OCD. Using ERP, the affected individual is gradually exposed to the object of his or her obsession or fear and is taught healthy methods of coping with the associated anxiety (Mayo Clinic, 2013). Other CBT therapies, especially those that involve restructuring thought patterns and behavior, have been found effective for these patients. For a discussion of CBT, refer to the Concept section of this module.

Box 31–10

Guidelines for the Treatment of Individuals with OCD

- **Psychiatric management.** OCD is usually a chronic illness. Treatment is necessary when the symptoms interfere with functioning or cause significant distress. Therapeutic management consists of a variety of therapeutic interventions throughout the course of the illness.
- **Psychiatric assessment.** The psychiatrist or psychiatric nurse practitioner will usually consider a medical evaluation and assessment of common comorbid conditions, such as depression, bipolar symptoms, other anxiety disorders, tics, impulse-control disorders, anorexia nervosa, bulimia nervosa, alcohol use, attention-deficit/hyperactivity disorder, and a history of panic attacks.
- **Pharmacotherapy.** Successful medication treatment should be continued for 1–2 years before gradually tapering and while observing for symptom exacerbation. Clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline are approved by the FDA for treatment of OCD. The SSRIs have fewer side effects than clomipramine and are recommended for the first medication trial.
- **Psychotherapy.** CBT that relies primarily on behavioral techniques such as exposure and response prevention (ERP) is recommended because it has the best evidentiary support. Family therapy may reduce interfamily tensions due to the individual's OCD symptoms.

Lifespan Considerations

OCD most commonly begins in children, adolescents, and young adults. Understanding the differences in younger and older populations of individuals with OCD is essential to the proper care of these individuals.

OCD in Children and Adolescents

The mean age of onset of OCD symptoms in children is around age 7.5, but it is often not recognized or diagnosed until much later. Diagnosis of OCD generally peaks in prepubescent children and then again in early adulthood. An estimated 1 to 2% of school-aged children have OCD (Geller & March, 2012). In children and adolescents, boys appear to develop symptoms of OCD earlier than girls, but the ratio of boys to girls with OCD evens out as children age and go through puberty.

Symptoms of OCD in children are often hidden or ill defined, causing them to be missed by parents and clinicians. Younger children in particular are not able to articulate their fears, which often relate to fear of a major disaster such as the loss of a parent (Geller & March, 2012). Obsessions and compulsions are often similar to those experienced by adults, but they may change over time, with the same individual experiencing different obsessions or compulsions as they age. Compulsions are often related to sensory stimuli, including the perception of both physical (tactile, musculoskeletal) and mental (tactile, auditory, visual) sensations (Geller & March, 2012). Children and adolescents are also more likely than adults to experience rage attacks in relation to their OCD, a phenomenon that is enhanced if their family accommodates or reinforces their OCD behaviors (Storch et al., 2012).

Studies conducted by the U.S. Surgeon General, as well as other researchers, suggest that the development of OCD in some children may be linked to streptococcal infection (Swedo, Leckman, & Rose, 2012). Initially referred to by the acronym PANDAS, which stands for pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections, researchers have proposed revision of this condition to pediatric acute-onset neuropsychiatric syndrome

(PANS). Its hallmark is a sudden and abrupt exacerbation of OCD symptoms after a strep infection. The cause of this form of OCD appears to be antibodies mistakenly attacking a region of the brain. Another major risk factor for the development of OCD in children is association with a first-order relative (parent or sibling) who also has OCD (Geller & March, 2012).

Many children with OCD will spontaneously resolve their symptoms as they age. However, a younger age of onset, increased duration of OCD, inpatient treatment, and some subsets of symptoms tend to persist (Geller & March, 2012). When possible, CBT and ERP therapy should be used as a first-line treatment for OCD in children. For more severe cases, such as children with declining grades and stronger compulsions in a school setting, medication may be needed. SSRIs appear effective in alleviating symptoms of OCD in children. Several randomized, controlled trials revealed SSRIs to be effective in treating children and adolescents with OCD (Geller & March, 2012).

OCD in Older Adults

Older adults are more likely to report their physical complaints and avoid discussing their mental complaints (ADAA, n.d.d). As a result, it is commonly thought that symptoms of anxiety and related disorders decrease with age. However, OCD and subclinical obsessive-compulsive symptoms (OCS) are common in older adults, especially those with depression and decreased mental and social functioning (Klenfeldt et al., 2014). Subclinical obsessive and compulsive symptoms appear to be much more frequent than clinical OCD in older adults, and the patients often find these symptoms very distressing (Pulular, Levy, & Stewart, 2013).

Because older adults are less likely to discuss their mental symptoms, a general assessment of older adults should include assessment for changes in mental status, including obsessive and compulsive symptoms. Older adults with one or more mental or anxiety disorders should be given a thorough psychiatric assessment, because OCD is often comorbid with other mental disorders. This comorbidity may interfere with responsiveness to treatment and increase the time it takes for medications to be effective in older adults.

NURSING PROCESS

The primary nursing goals for the patient with OCD are to ensure patient safety and to alleviate anxiety and distress. Care must be taken not to prevent the performance of rituals that the patient uses to reduce anxiety but rather to promote new behavioral patterns and coping mechanisms to make the rituals unnecessary while maintaining the safety of the patient.

Assessment

- **Observation and patient interview.** The nursing assessment interviews of patients with OCD share many similarities to those used with patients who have anxiety disorders. Suggested interview questions include:

Current and Past Medical History

- Does anyone in your family experience an anxiety disorder?
- Have you experienced intrusive or unwanted thoughts? Please describe the nature of the unwanted thoughts.
- Do you find yourself performing repetitive actions and behaviors to alleviate your anxiety? Please describe.
- Describe how these compulsions have interfered with your life.
- How old were you when you first experienced these obsessive-compulsive thoughts and behaviors? Age at diagnosis?
- Approximately how much time out of your day is spent dealing with these obsessions and compulsions?
- On a scale of 0–10, please rate your current level of distress (0 = no distress, 10 = intolerable anxiety).
- What have you tried in the past to alleviate the anxiety? What do you think was successful?
- Describe any repetitive or ritualistic behaviors.
- Do you use counting when feeling anxious?
- Have you experienced depression? Have you considered suicide? If yes, please rate on a scale from 0 to 10 how likely you are to act on these thoughts or impulses (0 = not at all, 10 = I will kill myself).
- Do you drink or use illicit drugs to manage your anxiety? If so, please list name, frequency, and amount.

Activities of Daily Living

- Is your health at risk as a result of the obsessions and compulsions?
- Describe a typical day (sleep, eating, activities, employment).
- How has this disorder affected your relationships?
- How has this disorder affected your spirituality?
- How has this disorder affected your emotional well-being and mental health?
- **Physical examination.** A thorough examination may determine physical problems resulting from manifestations of OCD. For example, excessive hand washing or the use of irritating cleansing agents may result in loss of tissue integrity.

Diagnosis

Appropriate nursing diagnoses for OCD may vary depending on the nature of the obsessive thoughts and compulsive behaviors and the severity of the illness. In addition to *Anxiety*, possible nursing diagnoses for OCD patients include the following:

- *Fear*
- *Coping, Ineffective*
- *Role Performance, Ineffective*
- *Impaired Tissue Integrity, Risk for*
- *Social Interaction, Impaired.*

(NANDA-I © 2014)

Planning

Planning in collaboration with the patient should be prioritized according to what the patient identifies as most important and may include the following goals:

- The patient will identify triggers for obsessive-compulsive behaviors.
- The patient will experience reduced anxiety without performing associated compulsive behaviors.
- The patient will incorporate coping techniques to decrease the need to perform compulsive behaviors.
- The patient will decrease time spent performing compulsive behaviors so that they no longer interfere with everyday role performance.
- The patient will participate in appropriate social activities previously avoided because of obsessive or compulsive tendencies.

Implementation

A supportive and nonjudgmental demeanor is essential when working with patients with OCD. Often the individual is aware that the compulsive behaviors are unreasonable and feels embarrassed. Compulsive behaviors serve as coping mechanisms to lower the level of anxiety or defensively “undo” the obsessive thoughts. Interrupting an individual during a ritual or compulsive behavior creates more anxiety and frequently leads to the individual redoing or repeating the behavior to reduce anxiety. If a patient with OCD is admitted to the hospital, the hospital staff may need to collaborate with the patient to accommodate the rituals until the patient experiences relief from anxiety. Administration of medications to lower anxiety and reevaluation of the patient’s response to the medication are the responsibility of the nurse in collaboration with the healthcare provider and the patient.

Alleviate Fear

Patients with OCD often perform ritualistic behaviors to help alleviate fears associated with contamination or causing harm to others. These fears are often based on distortions of reality that the patient believes. Most of the time, the patient is aware that the compulsions are unnecessary. The patient’s mental health professional will help the patient work to alter beliefs and correct perceptions. However, the

nurse can implement several nursing interventions to help reduce a patient's fears:

- Provide a calm presence for the patient that will encourage the patient to verbalize fears. Validate the patient's feelings without encouraging the patient's belief in a distorted reality.
- Provide facts related to the patient's fears that are based in reality. For example, a patient who is afraid of contamination may benefit from knowledge about the immune system and the benefit of limited exposure to germs.
- For patients who are hospitalized for treatment of their OCD or for any other reason, take steps to reduce environmental stimulation. Remove or hide items associated with any triggers associated with the patient's obsession or compulsion. Teach patients to remove triggers from their home or work environment as much as possible.

Promote Effective Coping

When patients with OCD experience fears or obsessions, they are unable to use normal coping strategies to prevent the practice of compulsive behaviors. Instead, they perform compulsive behaviors as a coping mechanism. This often disrupts the performance of normal roles and may cause them to feel embarrassed or isolated from society. Nurses can teach patients effective coping behaviors, as described in the Patient Teaching feature.

Promote Effective Role Performance

The ritualistic behaviors and shame associated with OCD often interfere with the ability of the patient to perform normal roles, including family, home, and work responsibilities. OCD behaviors may also interfere with the patient's ability to perform self-care activities. The nurse can help patients adequately perform their roles by:

- Encouraging patients to have healthy conversations with their family members about the disorder.
- Listening to the patient describe how the ritualistic behaviors are disrupting his or her ability to perform normal roles. This includes having the patient describe normal roles that the patient is not performing because of the disorder. This may help the patient discover why he or

she feels compelled to perform compulsive behaviors and to discuss ways in which the patient can begin to perform normal roles again in the future.

- Promoting self-awareness for the patient to understand his reaction to environmental triggers. Understanding his own thought processes and the reasons behind those thoughts can promote changes in thought patterns necessary to decrease disruptive behaviors and increase performance of normal roles.
- Encouraging the patient to participate in individual or family behavioral therapy or counseling. In addition to medication, therapy or counseling is one of the most effective ways to help patients with OCD regain control over their life and behaviors. The nurse can provide references to therapists or counselors who specialize in the treatment of OCD.

SAFETY ALERT Patients who perform excessive washing rituals are at a high risk for impaired tissue integrity, especially on the hands. Excessive handwashing with soaps and antibacterial gels can dry the skin and leave it susceptible to cracking and bleeding. Teach the patient about consequences of excessive hand washing and techniques to help maintain skin integrity, including the regular use of lotions.

Promote Social Interaction

Patients with OCD who spend hours each day performing ritualistic behaviors may find that they are no longer able to participate in social activities. Performing rituals or checking behaviors often delays the patient's arrival at an event or prevents the patient from leaving home altogether. Friends may avoid spending time with the patient because of the patient's odd behaviors and time wasting. As patients progress through treatment, nurses can promote social interaction of the patient by teaching time management techniques so patients can plan to arrive at social events on time and encouraging patients to be open with their friends about the disorder and to enlist their support during social interactions. The nurse may also encourage the patient to invite close friends and family to a counseling session so they can be a part of the healing process.

Evaluation

Patients with OCD have a low rate of successful response to treatment; about 50% improve with treatment, but only 10% recover completely (Harvard Health Publications, 2009). Therefore, the nurse will need to continually evaluate the patient and develop new nursing diagnoses and interventions. Successful response to nursing care may be evaluated by using the following expected outcomes:

- The patient verbalizes a reduction in anxiety associated with the compulsive need to perform ritualistic behaviors.
- The patient demonstrates an understanding of appropriate coping behaviors and verbalizes successful use of healthy coping behaviors to reduce the need to perform compulsive behaviors.
- The patient demonstrates an ability to effectively perform expected roles, including family, home, and work roles.
- The patient verbalizes increased social interaction and a decrease in missed events due to the performance of ritualistic behaviors.

Patient Teaching

Adaptive Coping

Establishing a therapeutic relationship provides the nurse with an opportunity to promote healthy adaptive coping. Patient teaching about the nature of obsessive thinking is critical to lowering the patient's feelings of shame and anxiety. The nurse can help the patient realize that fears arise from the disease, not from any real threat. Nurses can help patients reframe how they think about their disease and help them reframe thought processes in order to reduce ritual performance, such as helping the patient meditate instead of performing a ritual and then recognizing that nothing bad happened as a result of the absence of the ritual. The nurse has an essential role in helping the patient with OCD understand that he or she can decrease anxiety and gain control over the disease through pharmacologic and behavior therapies.

The nurse should understand that complete healing from OCD will likely take many years for most patients. During this time, the nurse should continually reevaluate the patient and suggest changes in treatment modalities depending on the success or failure of previous treatment plans. The nurse may need to teach additional coping

strategies or advocate for the patient to receive different medication or to add CBT or family counseling to the treatment plan. Importantly, the nurse should encourage the patient to continue treatment, not give up, and not accept the disorder as normal or inevitable.

REVIEW Obsessive-Compulsive Disorder

RELATE Link the Concepts and Exemplars

Linking the exemplar of obsessive-compulsive disorder with the concept of mood and affect:

1. How might mood be impacted in the patient who is unable to control his ritualistic compulsive disorders?
2. Is assessment for suicidal ideation important when admitting a new patient with OCD? Why or why not?

Linking the exemplar of obsessive-compulsive disorder with the concept of advocacy:

3. If a patient's rituals involve an act that places her in danger, what actions can the nurse take to advocate for the patient while not causing increased anxiety that can result from not being able to perform the ritual?
4. While working on a medical unit in a local hospital, you admit an adult patient for surgery. While collecting the admission assessment, you note what you suspect is ritualistic compulsive behavior. How can you best advocate for this patient?

REFLECT Apply Your Knowledge

Karleen Lassiter, a married, 40-year-old mother of three children, is admitted to a hospital psychiatric unit with complaints of anxiety,

inability to relax, and intrusive thoughts that she states are "horrific." When asked to describe her thoughts, she states, "I'm afraid I'm going to hell as punishment for what goes through my mind sometimes. It's really dark stuff." In conjunction with her intrusive thoughts, Ms. Lassiter recites the same prayer up to 50 times daily. Ms. Lassiter is trained as a respiratory therapist, but she has not practiced in the clinical setting for the past 5 years. In part, she reports that her departure from her position as a respiratory therapist was related to her need to complete her prayer rituals. Ms. Lassiter explains that her employment was terminated due to her being late for work on several occasions, because "I needed to finish praying before I could leave for work." She is aware that her behavior is irrational and that it is negatively impacting her life; however, she is unable to control or cease the behavior.

Ms. Lassiter's medical history includes panic attacks between the ages of 18 and 21, during college enrollment. She denies suicidal ideation; however, she states, "I don't think I can handle living like this. My husband and kids think I'm crazy, and they're right."

1. Based on the available assessment data, identify Ms. Lassiter's apparent obsessions and compulsions.
2. Describe appropriate communication strategies for encouraging Ms. Lassiter to further describe her intrusive thoughts.
3. Based on the patient's statements, identify the priority nursing diagnosis for Ms. Lassiter.

Module 32

Trauma

Module Outline and Learning Outcomes

The Concept of Trauma

Interpersonal Violence

32.1 Analyze interpersonal violence as a component of trauma.

Community and Systemic Violence

32.2 Analyze community and systemic violence as components of trauma.

Unintentional Trauma

32.3 Analyze unintentional trauma.

Concepts Related to Trauma

32.4 Outline the relationship between trauma and other concepts.

Health Promotion

32.5 Summarize health promotion as it relates to trauma.

Nursing Assessment

32.6 Differentiate common assessment procedures and tests used to examine trauma.

Independent Interventions

32.7 Analyze independent interventions nurses can implement for patients who have experienced trauma.

Collaborative Therapies

32.8 Summarize collaborative therapies used by interprofessional teams for patients who have experienced trauma.

Trauma Exemplars

Exemplar 32.A Abuse

32.A Analyze abuse as it relates to trauma.

Exemplar 32.B Multisystem Trauma

32.B Analyze multisystem trauma as it relates to trauma.

Exemplar 32.C Posttraumatic Stress Disorder

32.C Analyze PTSD as it relates to trauma.

Exemplar 32.D Rape and Rape-Trauma Syndrome

32.D Analyze rape and rape-trauma syndrome as they relate to trauma.

>> The Concept of Trauma

Concept Key Terms

ABCs, 2117	Cycle of violence, 2107	Major trauma, 2107	Predisposing factors, 2114	Simple assault, 2109
ABCDEs, 2118	Instrumental aggression, 2107	Minor trauma, 2107	Protective factors, 2114	Trauma, 2105
Aggravated assault, 2109	Interpersonal violence, 2107	Multisystem trauma, 2107	Risk factors, 2114	Triage, 2120
Blunt trauma, 2107		Penetrating trauma, 2107		Vulnerability factors, 2114
		Precipitating factors, 2114		

According to the Substance Abuse and Mental Health Services Administration (SAMHSA) (2015), **trauma** “results from an event, series of events, or set of circumstances that is experienced by an individual as physically or emotionally harmful or life threatening and that has lasting adverse effects on the individual’s functioning and mental, physical, social, emotional, or spiritual well-being.” The term *trauma* has been associated with the word *accident*. Accident means that the injury occurred without intent. In contrast, trauma professionals generally define trauma as either intentional or unintentional. Intentional and unintentional trauma encompass a variety of physical and emotional

injuries resulting from motor vehicle crashes, pedestrian injuries, gunshot wounds, falls, violence toward others, or self-inflicted violence (see **Table 32-1** >>).

Trauma can be either acute or chronic. Acute trauma occurs when a person experiences a traumatic event that occurs only once. Examples include being a victim or witness to a violent act; natural disasters such as hurricanes, tornadoes, earthquakes, and fires; a motor vehicle crash; or the loss of a loved one. Repeated exposure to traumatic events, such as war, abuse, neglect, or an accumulation of traumatic events throughout the lifetime, may result in chronic trauma.

TABLE 32–1 Types of Trauma

Type of Trauma	Description
Bullying	Aggressive (often repeated) behavior among school-age children related to a perceived imbalance of power. Both children, the bullied and the bully, may experience trauma leading to mental illness, substance abuse, and suicide. Nursing implications include: <ul style="list-style-type: none"> Educate staff, parents, and students on how to identify signs of bullying and what actions to take if it is identified; on the need to closely supervise large groups of children such as at recess; and on the need to maintain age-appropriate groups, limiting the contact between older children and younger children. Report bullying to parents and proper authorities per established facility protocol and state guidelines.
Emotional abuse or psychologic maltreatment	Verbal or emotional abuse or excessive demands and expectations in which the individuals may experience behavioral, emotional, affective, and other mental disturbances.
Forced displacement	Forced displacement of individuals or communities from their homes due to conflict, violence, persecution, or human rights violations. Forced displacement is long term or permanent, and many individuals become immigrants or refugees. Nursing implications include: <ul style="list-style-type: none"> Work with authorities per established facility protocol and state/federal guidelines (World Bank, 2015).
Historical trauma	Cumulative emotional and psychologic injuries as a result of traumatic experiences spanning across generations in a community. This is often associated with racial or ethnic groups that have sustained major losses and attacks on or discrimination against their culture or well-being.
Military trauma	Results from the effects of deployment and trauma-related stress on military personnel and their families. Returning service personnel may experience mental illness and substance abuse issues. Nursing implications include: <ul style="list-style-type: none"> Assess for safety. Assess individual and family mental health needs. Make referrals as necessary.
Natural or manmade disasters	Trauma resulting from a major accident or disaster such as tornadoes, hurricanes, mudslides, earthquakes, floods, wildfires, and drought. There are also human causes of this type of trauma, such as mass shootings, chemical spills, and terrorist attacks. Nursing implications include: <ul style="list-style-type: none"> Work with authorities for identification of survivors as well as assisting patients in locating family members per established facility protocols. Provide for immediate safety and psychologic needs.
Neglect	Failing to provide basic human needs such as food, clothing, or shelter as well as medical treatments and medication. Exposing someone to dangerous environments, abandonment, or forcing the individual out of the home are also forms of neglect. Neglect is the most common form of abuse reported to child welfare authorities; however, neglect can also occur with caregivers not meeting the needs of adults even though they have the means to do so.
Physical abuse or assault	Causing or attempting to cause physical pain or injury to another by physical means such as hitting, punching, burning, kicking, or striking with an object.
School violence	Violence that occurs in a school setting, which includes school shootings, bullying, violence, and suicide.
Serious accident, illness, or medical procedure	Unintentional injury or accident, illness, or medical procedures such as surgery that result in extreme pain; may be life threatening.
Sexual abuse or assault	The U.S. Department of Justice's (DOJ's) Office on Violence Against Women defines sexual assault as "any type of sexual contact or behavior that occurs without the explicit consent of the recipient to include forced sexual intercourse, forcible sodomy, child molestation, incest, fondling, and attempted rape" (DOJ, 2016). The U.S. Government defines human trafficking as a two-part statement: "Sex trafficking in which a commercial sex act is induced by force, fraud, or coercion, or in which the person induced to perform such act has not attained 18 years of age; and the recruitment, harboring, transportation, provision, or obtaining of a person for labor or services, through the use of force, fraud, or coercion for the purpose of subjection to involuntary servitude, peonage, debt bondage, or slavery" (National Institute of Justice, 2012).
System-induced trauma and retraumatization	Systems in place to assist and protect the public may cause trauma. For example, the Child Welfare Department abruptly removing children from their home, causing separation of siblings and time in foster care, may traumatize children. Another example would be the use of seclusion or mechanical restraints on a previously traumatized individual, which may cause traumatic memories to surface or potentiate a relapse of an existing mental illness.
Traumatic grief of separation	Death, abrupt and/or unexpected or accidental death, premature death, or homicide of a family member, caretaker, or friend; unexplained indefinite separation from a parent, caretaker, family member, or friend due to circumstances beyond control. Nursing implications include: <ul style="list-style-type: none"> Provide support services for both the patient and the family to include support related to grief and potential survivor's guilt (a survivor may experience guilt associated with having survived a situation when another or others have died).
Victim of or witness to domestic or family violence	According to DOJ's Office on Violence Against Women (DOJ, 2014), domestic violence is defined as: "a pattern of abusive behavior in any relationship that is used by one partner to gain or maintain power and control over another intimate partner. Domestic violence can be physical, sexual, emotional, economic, or psychologic actions or threats of actions that influence another person. This includes any behaviors that intimidate, manipulate, humiliate, isolate, frighten, terrorize, coerce, threaten, blame, hurt, injure, or wound someone."
Victim of or witness to extreme personal violence	Witnessing or experiencing extreme violence, including homicide, suicide, or any other violent acts. Nursing implications include: <ul style="list-style-type: none"> Provide support services for both the patient and the family, including support related to grief and potential survivor's guilt.
War, terrorism, or political violence	Exposure to war, terrorism, or politically motivated acts of violence such as bombings, shootings, and looting.

Nurses are an integral part of medical care for all trauma victims. The nurse must know the fundamental care of all types of trauma victims. There is no way to provide an all-inclusive list of nursing implications, as each situation and each individual will present differently, and the nursing care plan will need to be adapted to each patient. However, there is one common nursing implication for all trauma cases that is critical: Assess and monitor for safety. The nurse will also ensure that every patient who experiences trauma is provided with a supportive, safe environment during care while remaining culturally sensitive to the patient's needs.

For patients experiencing physical trauma, interventions will include the following: Assess the patient, identify injuries sustained; prioritize care of each injury; assess and monitor pain level; assess and monitor mental status; and document clearly and precisely, including all specifics about wounds, as the documentation may be used for legal purposes at a later date.

Interventions appropriate for patients experiencing emotional trauma include the following: Assess and monitor mental status; prioritize mental health needs; validate expressed feelings; and provide community support services information, including a crisis hotline number.

Nursing implications for all criminally related situations (e.g., abuse, neglect, sexual assault) include reporting to proper authorities per established facility protocol and state guidelines; verifying the patient has a safety plan established; ensuring the patient has a safe environment to go to following discharge; and, as stated earlier, documenting wounds and injuries clearly and precisely, as the documentation will likely be used in a legal manner.

Interpersonal Violence

Interpersonal violence is violence that occurs within relationships between family members (also called *family violence*), intimate partners (*intimate partner violence*), and acquaintances or strangers (*community violence*) that does not aim to further the goals of a formal group or cause. Violence of this nature may include physical or sexual assault, abusive relationships, stalking, or homicide (World Health Organization [WHO], 2013a).

A violent crime can involve one of four offenses: murder, rape, robbery, or aggravated assault. Of the most recent data available, aggravated assaults constituted 62.4% of these crimes, robbery represented 29.4%, rape accounted for 6.9%, and murder made up the final 1.2% (Federal Bureau of Investigation [FBI], 2012a). However, violence also represents all instances of abuse, including sexual abuse, child abuse, elder abuse, intimate partner abuse, physical abuse, and emotional abuse.

Violence may result in minor or major trauma. **Minor trauma** involves minor injury to a single part or system of the body. A fracture of the clavicle, a small second-degree burn, and a laceration requiring sutures are examples of minor trauma. **Major trauma** involves serious single-system injury (such as the amputation of a leg) or multiple-system injuries (simultaneous injuries such as a punctured lung, traumatic brain injury, and crushed bones in the arms and legs; also called **multisystem trauma**). Multisystem trauma is often the result of a motor vehicle crash.

Violence may also result in blunt or penetrating trauma. **Blunt trauma** occurs when there is no communication between the damaged tissues and the outside environment. For example, a baseball batter being hit by a pitch may cause damage to the underlying vascular tissue, muscles, and bones. Blunt trauma is frequently caused by motor vehicle crashes, falls, assaults, and sports activities. **Penetrating trauma** occurs when a foreign object enters the body, causing damage to body structures. Examples of penetrating trauma are gunshot or stab wounds and impalement.

Both the attacker and the victim in an incident of interpersonal violence feel aggression during the encounter. Baron and Richardson (1994) offer the following definition of aggression: "any form of behavior directed toward the goal of harming or injuring another living being who is motivated to avoid such treatment." Frequently, a display of aggression is associated with feelings of anger or stress and an overall high emotional response. However, aggression involved in interpersonal violence can also be **instrumental aggression**, which is aggression executed in the absence of emotional arousal. Instrumental aggression frequently takes place in individuals with antisocial disorders. A chronic physiologic activation in response to stress can be one of the causes of the development of an aggressive personality. Stress can also lead to depression characterized by anxiety, anger, and aggressive outbursts, especially if early life experiences such as maltreatment or neglect are involved (Buchanan et al., 2012).

Particularly in families or among intimate partners, violence may occur with a patterned frequency, generally referred to as the **cycle of violence**. The cycle of violence consists of three phases. In the first phase, tension builds between individuals in a relationship as communication fails or expectations are not met. An abusive or threatening incident occurs in the second phase. During this phase, the victim feels traumatized and the aggressor blames the victim for the incident. The third phase of the cycle is known as the honeymoon period, a time during which the aggressor may show love and affection and may also promise to change. During this phase, the victim may feel responsible for the abuse, consider reconciliation, and recant or minimize the incident. However, if the relationship or attitudes are not repaired, communication often fails again, starting the cycle over.

Sometimes, the phrase *cycle of violence* (or cycle of abuse) refers to violence that occurs across multiple generations within a family. In this context, children witness or are subjected to patterned family violence committed by their parents. Physical or emotional damage incurred by children during these experiences increases the likelihood of subjecting their own children to maltreatment (Child Welfare Information Gateway, n.d.).

Although violence in the United States may not be on the rise (see Focus on Diversity and Culture), it is certainly a cause for concern that impacts both the law enforcement community and the healthcare community. Victims of violent acts may seek treatment at emergency departments, urgent care centers, or physician's offices. For injuries that are psychologic in nature, individuals may seek treatment from counselors, therapists, or other mental health specialists.

Focus on Diversity and Culture

Violent Crimes

In the United States, the South, which has the largest population in the country, accounted for 41.3% of violent crimes; the West accounted for 22.9%; the Midwest 19.5%; and the Northeast 16.2% (FBI, 2012b). According to the Bureau of Justice Statistics (BJS) (2015), violent crimes decreased in the Northeast and West during 2013–2014; however, no differences were noted in the Midwest and South. The District of Columbia had the highest rate of violent crimes at 1300.3 per 100,000 people, followed by Alaska at 640.4 per 100,000 people (FBI, 2013a).

Abuse and Neglect

Both victims and perpetrators of abuse are seen across all age, race, and socioeconomic groups. Therefore, nurses must continually assess for signs of abuse while caring for patients, especially those from vulnerable populations such as children, older adults, and the disabled.

Federal law defines child abuse as “Any recent act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation” of a child or “An act or failure to act which presents an imminent risk of serious harm” to a child (U.S. Department of Health and Human Services [USDHHS], 2010). Child abuse involves any intentional mistreatment of a child under the age of 18 by someone in a custodial role. It is the state’s responsibility to define definitions of child abuse and neglect. Most states recognize four types of child abuse: physical abuse, neglect, sexual abuse, and emotional abuse.

Elder abuse represents the abuse and neglect of individuals 65 years of age and older. The perpetrator is typically the individual’s trusted caregiver. Failure of the intended caregiver to provide care or protect an older adult from harm also constitutes maltreatment. Types of elder abuse include physical abuse, sexual abuse, emotional or psychological abuse, neglect, abandonment, and financial or material exploitation (National Center on Elder Abuse, n.d.a).

Another group of individuals vulnerable to abuse and neglect include those with developmental disabilities. Children with disabilities are 1.68 times more likely to experience abuse or neglect than children without disabilities (Child Welfare Information Gateway, 2012). Furthermore, the U.S. Department of Justice (2015) reports that adults with disabilities, with the exception of those 65 years of age and older, are victim to abuse and neglect at more than double the rate of those without disabilities. Individuals age 65 years and older with developmental delays showed no significant statistical difference from those without disabilities.

Physical Abuse

Healthcare providers must be able to identify manifestations of all forms of abuse. One indicator noted with all age groups is withdrawal from friends, other family members, and activities. Other common, less overt, symptoms of abuse include behavioral changes, depression, and even suicide attempts. Children and teenagers may miss school and

scheduled activities. They also may attempt to run away from home. More recognizable symptoms of physical abuse include unexplained injuries, bruising, or fractures. Incongruence between the explanation of the injury and the injury itself is a red flag that may indicate abuse.

Neglect

Assessing for neglect is just as important as assessing for other types of abuse. Symptoms of neglect may present differently based on the age group and population. For example, a child who lives in an area with cold winters may be wearing a coat that is not warm enough or may not have warm clothing at all. Poor hygiene, lack of medical or dental care, poor growth and development of a child, or weight loss of a dependent or older adult are indicative of neglect. Behavioral issues, such as inability to focus or pay attention, stealing food, and apathy, may also be observed.

Sexual Abuse

Sexual abuse differs from sexual assault. With sexual abuse, an individual who has perceived power over the victim (e.g., parent, teacher, coach, family friend, or relative) takes advantage of the trust established, luring the victim into sexual activity. The victim of sexual abuse is usually compliant and may even be protective of the perpetrator. In contrast, sexual assault is forced, and the possible violent, nonconsensual sexual act may result in serious emotional and physical injury to the victim. Overt symptoms of sexual abuse may include knowledge about sexually related topics that are inappropriate for the child’s age, minors who present with pregnancy or sexually transmitted diseases, appearing to be experiencing pain upon sitting or walking, and blood in underwear. When a child sexually abuses another child, it may indicate that the abuser has also been a victim of sexual abuse (Mayo Clinic, 2015). Because overt symptoms of sexual abuse are not always present, the nurse must also observe for passive manifestations common with sexual abuse, including depression, anxiety, fear, shame, guilt, nightmares, eating disorders, self-neglect, withdrawal, and mistrust of adults. Sexual promiscuity and substance abuse are also common behaviors for victims of sexual abuse.

Emotional Abuse

Symptoms of emotional abuse may not be easy to identify, as the manifestations are emotional in nature without identifiable injuries. Social withdrawal, apathy, and diminished self-confidence and self-esteem may be noted. Children may not want to go to school or may avoid certain situations. The child may also have an intense desire to obtain attention and affection. Psychosomatic issues, such as complaints of not feeling well, unexplained headaches, and stomachaches, may also be reported. A pattern of these behaviors warrants assessment. Victims of domestic violence should also be assessed for the presence of emotional abuse.

Complex Trauma

Complex traumas are interpersonal traumas that generally begin in childhood. These traumas occur repeatedly and are cumulative. Generally, complex trauma occurs from direct harm, such as severe abuse, neglect, abandonment, and exploitation (Firestone, 2012). Effects of complex trauma

include children having difficulty forming attachments and relationships. They may have difficulty later in life maintaining romantic relationships and friendships, and they may have problems with authority figures. Becoming over-reactive or over-responsive to a normal daily stressor may become prevalent. Children may exhibit somatic complaints, whereas adults may turn to risky behaviors such as substance abuse. Children who have sustained complex trauma may also have difficulty controlling their emotions and may have limited ability to express emotions. Dissociation is another reaction when faced with a traumatic situation. For instance, if a child with a history of past sexual abuse is exposed to another episode of sexual abuse, the child may undergo dissociation as a form of self-preservation. During dissociation, the child becomes mentally separated from the event. Children who experience complex trauma often demonstrate inability to reason or make decisions, and they frequently have learning disabilities (NCTSN, n.d.b).

In 2005, the media brought national attention to the true story of “The Girl in the Window,” Danielle, a 6-year-old girl who was reported to law enforcement as a possible child neglect case. She had experienced a lifetime of complex trauma. When she was found, she was so severely neglected that she couldn’t speak; was covered in feces, bug bites, and sores; had matted, lice-infested hair; had a swollen diaper on; was emaciated at only 46 pounds; and could only drink from a bottle. After tests were performed, she had no physical ailments and there was no organic cause for her severe delays. She will be developmentally delayed for life due to the degree of neglect she experienced. She continues to have tantrums, rarely speaks, is food aggressive, and has difficulty with forming relationships or socializing, especially with women. This is an extreme case demonstrating lifelong effects of complex trauma sustained during the developmental years.

Physical Assault

Assault is defined by the Bureau of Justice Statistics (BJS, 2016a) as “An unlawful physical attack or threat of attack. Assaults may be classified as aggravated or simple. Rape, attempted rape, and sexual assaults are excluded from this category, as well as robbery and attempted robbery. The severity of assaults ranges from minor threats to nearly fatal incidents.” A **simple assault** is generally considered a physical attack by an individual against another in which a weapon is not used and the attack does not result in serious physical injury. In contrast, **aggravated assault** is “An attack or attempted attack with a weapon, regardless of whether an injury occurred, and an attack without a weapon when serious injury results” (BJS, 2016a).

Sexual Assault and Rape

Sexual assault is any type of sexual contact without the consent of the victim, such as fondling and molestation. Rape is nonconsensual penetration orally, vaginally, or anally. The victim may experience physical and emotional trauma related to the acts of sexual assault or rape. Rape-Trauma Syndrome is a psychologic response that elicits negative emotional and physical responses that can last months after the rape or assault. In the United States, an estimated 32.3% of multiracial women were raped during

their lifetime, followed closely by American Indian/Alaska Native women at 27.5%. Non-Hispanic Black women (21.2%) and non-Hispanic White women (20.5%) in the United States had nearly the same report of lifetime prevalence of rape. Hispanic women in the United States had the lowest reported lifetime prevalence of rape at 13.6% (Centers for Disease Control and Prevention [CDC], 2014a).

Human sex trafficking is a major domestic and international concern. Sex trafficking has come to the attention of authorities, human rights advocates, policymakers, and the public only in recent years. The Department of Justice’s Bureau of Justice Assistance (n.d.) reports that human trafficking is one of the most profitable organized crimes and is growing rapidly. The FBI (n.d.a) reports that over the past decade, they have arrested more than 2000 sex traffickers. The National Human Trafficking Resource Center (2016) reports that in the first quarter of 2016, there were 1654 human trafficking cases reported in the United States, with California reporting the highest occurrence with 305 cases.

Homicide

Homicide occurs when the unlawful acts of a perpetrator result in the death of a victim. In addition to caring for the victims of assault and attempted homicide, nurses may also be responsible for caring for the perpetrators. Nurses provide the same high quality of care for all patients regardless of the events that have led them to seek medical treatment.

SAFETY ALERT In situations where patients have the potential to become violent toward the healthcare professionals working to treat their injuries, nurses should take appropriate precautions. In the clinical setting, security personnel or police officers should be present when needed.

Prevalence

In the United States, trauma-related events are a widespread problem that affects people of all ages. More than 3 million suspected child maltreatment cases are reported to state and local agencies each year, with almost 700,000 cases of confirmed maltreatment (CDC, 2014b). In addition, almost 800,000 youth are hospitalized annually because of violence (CDC, 2016a). Data about maltreatment of older adults is harder to assess, largely because it is extremely underreported and often occurs at the hands of the person’s intended caregiver. A study conducted in 2011 reported that 7.6–10% of older adults had experienced abuse in the year prior to the study (National Center on Elder Abuse, n.d.b).

Emergency departments handle 42 million trauma-related visits each year in the United States. Each year, roughly 2 million people are admitted to hospitals because of trauma. Violence accounts for about 10% of all traumatic brain injuries, including shaken baby syndrome, gunshot wounds, intimate partner violence (IPV; also called domestic violence), and child maltreatment (National Trauma Institute, 2012).

Genetic Considerations and Risk Factors

To better understand the causes and risk factors of the occurrence of trauma, specifically related to violence, researchers have conducted studies about the influence that

genetic predisposition, age, and gender have on people who commit violent acts. Each of these lenses explores the scope of violent behavior.

Genetic Predispositions Toward Violence

Researchers continue to study whether a genetic predisposition toward violent behavior exists. They have found that although genetics may increase the risk that an individual will become violent, environment is often a cofactor in its manifestation. For example, prior abuse and exposure to violence increase an individual's risk of becoming violent (CDC, 2016b).

Genetic disorders that relate to social and mental health are often discussed in conjunction with studies that look at the genetic predisposition toward violence. Included in this discussion are bipolar disorder, paranoid schizophrenia, impulse control disorder, and depression. Mental illness alone is not a predictor of future violent behavior. However, studies have shown that individuals diagnosed with a mental illness that goes untreated can manifest violent behaviors (Treatment Advocacy Center, 2015).

Age

According to the CDC (2014a), many victims of sexual violence and IPV were first victimized at a young age, with 78.7% of rapes occurring before the age of 25 years. A number of behaviors displayed in youth are considered risk factors for becoming a violent perpetrator. These include a history of being a victim of violence, low IQ, substance use or abuse, history of early aggressive behaviors, deficits in social cognitive or information-processing abilities, and exposure to violence and conflict in the family (CDC, 2016b).

Gender

Gender has a strong influence on violence, according to statistics. Although individuals of any gender may become victims of violence, women are victims of IPV and sexual violence more frequently than men are. In recent studies, women accounted for four of every five victims of IPV. Although still prevalent in the United States, IPV has declined by over 60% for males and females in recent years. Severe physical violence at the hands of an intimate partner affected 24.3% of female intimate partner victims versus 13.8% of male victims (CDC, 2013a).

When it comes to IPV, several factors contribute to male aggression. Factors that relate to the family include having a criminal father figure, coming from a disrupted family, and having poor parental relationships. Individual risk predictors include impulsive behaviors and aggressiveness. Research has shown that these factors, when present in early childhood, can predict IPV in men. In addition, men who engaged in IPV often had struggles with employment, alcoholism, and drugs (CDC, 2015a).

SAFETY ALERT Nurses will encounter violent patients at times; therefore, it is important to monitor for and identify warning signs that a patient that may be escalating so that nurses and other staff can act to de-escalate the patient's behaviors. Some indications that a patient may become aggressive include pacing, loud voice, reddened face, clenched fists, and rigid posture.

Case Study » Part 1

A gunshot victim is en route to the emergency department (ED) by ambulance. You will be the patient's admitting nurse. At present, you have minimal information about the patient. The paramedics report that the bleeding is controlled and the patient is alert with temperature 97.0°F oral; pulse 92 bpm; respirations 22/min; and BP 105/75 mmHg. It is currently unclear how much blood loss the patient has sustained. The ambulance ETA (estimated time of arrival) is 5 minutes.

Clinical Reasoning Questions Level I

1. How would severe blood loss affect the patient's blood pressure?
2. What are the primary nursing considerations for this patient?

Clinical Reasoning Questions Level II

3. Consider your perceptions of this patient, knowing only that this individual is a gunshot victim. What is your initial response?
4. How would your perceptions change if the patient is a victim of IPV? A criminal assailant? Someone who was injured while protecting another individual from harm? Explain your perceptions for each category.
5. Describe the symptoms of severe blood loss and shock. Describe the nursing interventions for a patient who presents with severe blood loss.

Community and Systemic Violence

Although violence often occurs between two individuals, violence can also occur at a community level and within specific organizations such as the workplace or school. Community and systemic violence often involves multiple victims with varying degrees of trauma. This can put a strain on emergency department resources and healthcare workers because of the rapid influx of a large number of patients, some of whom will likely have life-threatening injuries.

Community Violence

The NCTSN (n.d.a) defines *community violence* as “predatory violence (such as robbery) and violence that comes from personal conflicts between people who are not family members. It may include brutal acts such as shootings, rapes, stabbings, and beatings. Children may experience trauma as victims, witnesses, or perpetrators.”

Hate crimes and gang-related violence also fall into the category of community violence. Hate crimes are crimes against a person or property with the underlying motivation of bias against a race, religion, disability, sexual orientation, ethnicity, gender, or gender identity (FBI, n.d.b). Of the 5922 single-bias hate crimes reported in 2013, 48.5% were racially motivated, 20.8% were due to sexual orientation, 17.4% were religiously motivated, 11.1% were associated with ethnicity, 1.4% were disability related, and 0.3% were against a gender (FBI, 2014). Gang violence includes approximately 33,000 street gangs, motorcycle gangs, and prison gangs, encompassing approximately 1.4 million criminally active members. These gangs operate by using violence for control of their community to increase their illegal money-making activities (FBI, n.d.c).

Focus on Diversity and Culture

Extremists and Hate Groups

Some cultures are more prone to assault and homicide than others due to circumstances and adherent belief systems. Religious and/or political extremists such as the Islamic State of Iraq and Syria (ISIS) and hate groups such as the Ku Klux Klan and Aryan Brotherhood are similarly known for their propensity for violent acts toward others. These groups often assault or even murder other individuals based on their religion, race, or sexual orientation. Religious and political extremists who seek to injure or kill others as an act of homage to their belief system or as an act of revenge against a political decision pose a threat to all who encounter them. The level of violence within these particular groups has increased during the past decade (Meadows, 2013). Nurses need to be aware that they may need to provide care to a member of an extremist or hate group who may react violently toward healthcare members from diverse backgrounds (Meadows, 2013).

Workplace Violence

Workplace violence is a widespread issue that has more recently come to the attention of authorities, health professionals, media, and the public, mostly due to mass fatality occurrences; however, most incidents do not result in mass fatalities or even a single homicide. The Bureau of Justice's (2011) Statistics Special Report indicated that 1.7 million workplace violence episodes occurred each year from 1993 to 1999. Aggravated assaults accounted for the majority of these reported incidents.

The National Safety Council (2014) reported that 15.1 of every 10,000 full-time healthcare and social assistance workers required time off from work for workplace violence-related injuries in 2012. This report further stated that contributing factors for violent episodes included long wait times, patients with psychiatric problems, patients under the influence of drugs or alcohol, and patients with a history of violent behaviors. States are now passing legislation to protect their healthcare workers; for example, Idaho passed a bill making it a felony to assault a healthcare worker, with a penalty of up to 3 years in prison.

Horizontal violence is also an issue in the workplace. The Crisis Prevention Institute (CPI) (2016) defines *horizontal violence*, also known as lateral violence, as "hostile or aggressive behavior by an individual or group toward other group members. It is usually nonviolent, but can cause psychological or emotional damage to employees." Behaviors may include sabotage, criticism, and harassment. Horizontal violence often results in nurse bullying, which has become so prevalent that The Joint Commission developed standards that went into effect in 2009 to address this issue (CPI, 2016). Novice nurses and seasoned nurses can both fall prey to nurse bullying.

Young nurses with less than 3 years of professional experience are more likely to receive negative criticism of their

Evidence-Based Practice

Nurses Assaulted in the Workplace

Problem

Emergency department and psychiatric unit nurses experience high levels of assault at the hands of patients. This problem has not been decreasing in recent years, with some wondering if the problem is actually increasing. Physical assaults on nurses by patients are overwhelmingly underreported.

Evidence

The National Advisory Council on Nurse Education and Practice (2007) has reported that "health care workers are more likely to be attacked than prison guards and police officers." A risk for assault from a patient is present for all nurses, but emergency department and psychiatric unit nurses carry the highest levels of risk. One study concluded that 76% of nurses surveyed experienced a form of violence within the past 12 months (Speroni et al., 2014). The types of violence reported included physical violence, verbal abuse, and verbal threats by both patients and visitors.

Implications

High incidences of assault in the workplace lead to low job satisfaction, low retention rates, difficult recruitment, and detrimental effects on patient care. According to a study performed by Roldan and colleagues (2013), physical violence encountered in the work environment is linked to anxiety, feelings of low personal accomplishment, and burnout.

Critical Thinking Application

Identify ways in which instances of violence in emergency departments and psychiatric units could be decreased. Consider how patient care is affected by violent behavior. Describe some collaborative efforts that could be taken within the hospital setting to decrease cases of assault.

work, are more isolated from institutional activities, and face more challenges in proving themselves (Ovayolu, Ovayolu, & Karadag, 2014). Effective functioning of the team requires that all nurses, both novice and experienced, respect each other, treat each other fairly, remain empathetic, and maintain focus as to why they are working as a nurse—to assist in achieving positive patient outcomes.

School Violence

The BJS (2016a) annual report on "Indicators of School Crime and Safety" presents 23 indicators of crime and safety from a number of sources, including the perspectives of students, teachers, and administrators in the school systems. The topics addressed are specific to the school environment and include victimization, injuries sustained by teachers, bullying and cyber-bullying, fights, availability of weapons, use of substances by students, and students' perceptions of safety and crime. This report indicates that in 2014, children between the ages of 12 and 18 years were victims of 486,400 nonfatal violent crimes. According to the CDC (2014c), only 1–2% of all homicides of school-age children happen on the grounds of

schools or on the way to or from a school-sponsored event; therefore, most students will never experience lethal violence at school. These findings minimize the importance of school-related violence prevention.

Bullying

Bullying occurs when the perpetrator perceives the victim as being weaker or more vulnerable than they are. Bullying can be overt, such as the perpetrator being physically aggressive toward the victim, taunting, calling the victim names, and teasing. However, more passive bullying methods are also prevalent, such as intentionally leaving the victim out of a group or activity, spreading malicious rumors, and encouraging other students to shun or alienate the victim.

According to the CDC (2014d), children who report both being bullied and participating in bullying are at high, long-term risk for suicide. Children involved in bullying in any way are at increased risk for an array of negative outcomes, including mental illness, poor school performance, and involvement in interpersonal or sexual violence. Children who are the frequent victims of bullies have an increased risk of suicidal behaviors as well as increased negative physical and emotional outcomes.

Although there is no way to validate that bullying directly causes suicide, there are enough data to support the potential correlation. As one example, Jessica Logan, an 18-year-old senior in an Ohio high school, sent a nude picture to her boyfriend in a text message. After they broke up, the ex-boyfriend shared the picture with other people, which is when the bullying, taunting, and cyber-bullying began. After attending a funeral of a boy who committed suicide, Jessica went home and hanged herself. Greater attention to cases such as Jessica's are leading to the development of preventive measures. For instance, Ohio passed the "Jessica Logan Act" in November 2012, which mandates that the State Board of Education establish and implement guidelines for defining and establishing policies related to cyber-bullying. Before this, school administrators had no ability to hold students accountable for bullying behaviors that occurred using technology (e.g., internet, texting, and social media). Continued efforts need to be made to address bullying behaviors, minimize the opportunities for bullying to occur, and increase accountability for bullying behaviors.

Mass Shooter Incidents

The FBI (2013b) states that mass shooting incidents involve an "active shooter," and has defined active shooter as "an individual actively engaged in killing or attempting to kill people in a confined and populated area." The FBI further reports that approximately 160 active shooter incidents occurred between 2000 and 2013. During the first 7 years of this period, there was an average of 6.4 shootings per year. This percentage drastically increased to 16.4 active shooter incidents in the next 7 years. These same incidents either killed or injured 1043 victims, a total that does not include the shooters. Mass shootings are defined as killing three or more people, and 40% of the active shooter incidents were deemed mass shootings. Of the total shooters in these active shooter incidents, 40% committed suicide. Of the 160 active shooter incidents, an alarming 24% occurred in the educational environment (preschool through institutions of higher learning). The most deadly

mass shooting in the United States occurred June 12, 2016, in an Orlando, Florida, nightclub, where the active shooter killed 50 people, with an additional 53 people injured (Alvarez & Pérez-Peña, 2016). The second and third most deadly mass shootings were both in educational environments, with 32 killed at Virginia Tech in 2007 and 27 killed at Sandy Hook Elementary School in 2012.

Systemic Violence

Systemic violence occurs when there is a deliberate attempt to cause social injustice or inequality that could result in injury or death. Several examples of systemic violence include racism, sexism, slavery, and genocide. Systemic violence resulting in injury, death, or violation of human rights that is committed in the United States is federally prosecuted.

Unintentional Trauma

Unintentional trauma is caused by unintentional action and is not associated with medical conditions. Trauma-related and stressor-related disorders may also be associated with a major accident, a medical incident that is sudden and catastrophic (e.g., waking during surgery or anaphylactic reaction), or continuous stressors such as a persistent, painful illness (American Psychiatric Association [APA], 2013). Physical and emotional trauma may coincide with each other; therefore, it is important for nurses to understand the impact of physical trauma on patients, including how the physical trauma may precipitate emotional trauma.

Major Illness or Injury

Serious accidents, injuries, persistent painful medical conditions, and sudden, catastrophic medical conditions have a major physical and emotional impact on patients. Multisystem trauma occurs when injury involves multiple body systems, such as to the cardiac, respiratory, integumentary, or musculoskeletal systems (frequently associated with motor vehicle crashes), and may be attributed to trauma and stressor-related disorders (see Exemplar 32.B on Multisystem Trauma). Trauma-related and stressor-related disorders associated with an injury or medical event include posttraumatic stress disorder and acute stress disorder. Major illnesses, especially those associated with pain, may be a precursor to an adjustment disorder, which is also classified as a trauma and stressor-related disorder (APA, 2013).

Natural Disasters

Natural disasters, such as earthquakes, floods, tornadoes, and hurricanes, affect thousands of people every year. All natural disasters have the ability to cause severe emotional and physical trauma, major destruction, and death. Survivors of natural disasters will exhibit a mild to moderate stress response during and immediately after the emergency due to recognizing the grave danger associated with the disaster. Generally, survivors show resiliency after disasters, and the stress responses do not become chronic or debilitating; however, some people may be more affected by the disaster and will require medical intervention. The likelihood of developing PTSD is multifactorial, including the amount and extent of exposure and the nature of the individual (U.S. Department of Veterans Affairs [VA], 2016a).

Alterations and Therapies

Trauma

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	MANIFESTATIONS	INTERVENTIONS AND THERAPIES
Complicated grief	<ul style="list-style-type: none"> Grief is a natural response to loss of a loved one. Generally, as time passes, the symptoms of grief diminish or resolve so that the survivor can accept and move forward For some people, the feelings of grief are so severe and debilitating that they do not improve with time (Mayo Clinic, 2014b) A risk factor associated with grief includes being the survivor of disaster. They may know that their loved one has died or their loved one may be missing and presumed dead A sudden loss of life due to unexpected illness or accident may be traumatic Suicide survivors also experience trauma-related grief. 	<ul style="list-style-type: none"> Intense sorrow Focus is on the death of the loved one Numbness or detachment Bitterness, agitation, and irritability Lack of trust in others Anhedonia and inability to think of positive experiences with the loved one 	<ul style="list-style-type: none"> Psychotherapy (similar to what is used for PTSD) CBT Pharmacologic treatments, which may include antidepressants

Concepts Related to Trauma

Trauma is related to various nursing practices, among them the concepts of communication, sexuality, and stress and coping. Communication is vital in all areas of nursing, especially when violence is a contributing factor. Patients who have been exposed to a traumatic situation are likely to be experiencing pain (both physical and emotional) and significant amounts of stress. Nurses need to employ therapeutic communication to help patients work through the stress and fear and ultimately accept that the situation they experienced cannot be reversed. If the patient has experienced any form of sexual trauma, the patient could also be experiencing fear regarding sexually transmitted infections as well as the possibility of unwanted pregnancy.

In addition, the concepts of comfort, development, grief, and ethics are associated with trauma. Comfort measures will need to be employed to address the physical discomfort and emotional trauma. If tragedy strikes a child, development could be altered. Traumatic events may cause such strong responses that they may impair normal emotional development. Grief is a normal response to death; however, experiencing the death of a loved one caused by a traumatic event is a risk factor associated with complicated grief. Ethical principles will guide practice related to trauma victims. Treatment requires informed consent; however, trauma victims are often unable to give consent, so the healthcare provider will need to obtain alternate consent, such as from a parent, caregiver, spouse, or designated healthcare advocate. Some, but not all, of the concepts related to trauma are outlined in the Concepts Related to Trauma feature. They are presented in alphabetical order.

Health Promotion

Trauma often results from a combination of predisposing, precipitating, and protective factors in several areas. **Predisposing factors** are those that increase an individual's risk of being a victim of a traumatic experience or causing a traumatic experience for others (i.e., perpetrating violence). Predisposing factors may be categorized as vulnerability factors or risk factors. In the context of violence, **vulnerability factors** increase an individual's risk of being a victim; **risk factors** increase the potential that someone will become a perpetrator. **Precipitating factors** are factors that give rise to a specific incident. **Protective factors**, on the other hand, decrease the risk of perpetration and victimization. For example, connectedness to school has been found to be a protective factor for youth violence (CDC, 2016b). Areas to be addressed in examining factors contributing to societal violence include biophysical, psychological, physical, environmental, sociocultural, behavioral, and healthcare system considerations.

Many factors influence an individual's response to traumatic events, in terms of both vulnerability factors and risk factors. Influencing factors do not cause destructive behavior, nor do they wholly determine that an individual will become a victim; rather, factors such as these can define trends and warning signs. For example, an individual may have a childhood history of being abused, reacting with anger, and experiencing academic failures from a young age. All of these elements are predisposing factors to violent behavior, but they are not determining factors (Office of Mental Health, 2012).

Concepts Related to Trauma

CONCEPT	RELATIONSHIP TO TRAUMA	NURSING IMPLICATIONS
Comfort	Physical needs will need to be met so that psychologic needs may be addressed. Pain will need to be assessed and controlled. There may be a need for providing basic needs such as food, shelter, and the ability to meet basic hygiene needs.	<ul style="list-style-type: none"> ■ Assess and monitor pain; administer analgesics as prescribed. ■ Employ comfort measures to decrease stress, such as warm blankets, relaxation techniques, and reassurance of safety. ■ Provide supplies and opportunity to tend to basic hygiene.
Communication	Clear and therapeutic communication with patients after a violent or traumatic experience can help alleviate stress and facilitate acceptance.	<ul style="list-style-type: none"> ■ Use therapeutic communication to facilitate healing and acceptance. ■ Encourage the patient to ask questions. ■ Explain any procedures or tests suggested to the patient. ■ Use appropriate nonverbal communication (body language) to encourage open communication.
Development	The neurobiological impact of a traumatic event is contingent on the developmental stage of a child having experienced a traumatic event, or a series of traumatic events.	<ul style="list-style-type: none"> ■ Use therapeutic communication to promote trust and feelings of safety; use age-appropriate terminology. ■ Provide reassurance. ■ Encourage child to ask questions. ■ Explain any procedures or tests suggested to the patient. ■ Maintain therapeutic environment with decreased stimulation to assist in feelings of safety.
Ethics	Traumatic situations require principles of ethical nursing care so that effective treatment may be obtained by the victims; this promotes the most positive outcomes possible.	<p>Promote principles of ethical nursing care:</p> <ul style="list-style-type: none"> ■ Autonomy—allow patients to make decisions for themselves; informed consent. ■ Beneficence—compassionate care such as administering analgesics to control physical pain. ■ Nonmaleficence—Follow institutional guidelines and established best practice while administering care. ■ Fidelity—Demonstrate truthfulness, loyalty, fairness, and advocacy for the patient. ■ Justice—Equal and fair treatment; prioritizing victims' injuries accurately. ■ Paternalism—Providing information based on patient's best interest. <p>(American Nurses Association, n.d.)</p>
Grief and Loss	Trauma-related incidents, especially related to disasters and sudden unexpected death of a loved one, are risk factors associated with complicated grief.	<ul style="list-style-type: none"> ■ Assess for safety. ■ Use therapeutic communication. ■ Promote trust. ■ Validate patient feelings. ■ Assess spiritual needs. ■ Assist with disaster registries to find missing loved ones.
Sexuality	Sexual trauma is a form of violence that can cause both psychologic and physical trauma. Sexual trauma can also result in diseases, infections, and unwanted pregnancy.	<ul style="list-style-type: none"> ■ For victims of sexual assault, assessment may include use of a sexual assault evidence collection kit (also known as a rape kit), if permitted by the patient. ■ Educate about options regarding the possibility of unwanted pregnancy (e.g., emergency contraception). ■ Educate about tests for sexually transmitted infections and diseases. ■ Facilitate referrals to resources such as support groups, therapy, and counseling.
Stress and Coping	All forms of trauma can cause stress, potentially leading to exacerbation of the injury and increased emotional strain.	<ul style="list-style-type: none"> ■ Communicate with the patient regarding needs and wants, especially those in relation to stress relief (e.g., the presence of a family member or friend). ■ Answer questions regarding treatment and injuries calmly and honestly.

Predisposing Factors

Predisposing factors for trauma include environmental, psychologic, cultural, and behavioral variables. Geographical and environmental factors can deeply affect other aspects of an individual's life. Living in an impoverished community, especially one with a strong presence of gangs and drugs, puts an individual at increased risk for witnessing, experiencing, or even committing acts of violence (CDC, 2016b; Office of Mental Health, 2012). These environmental situations can also become cyclical, with multiple generations feeling trapped in the same community with the same high levels of violence. Over time, the stress and constant danger become traumatic, often feeding into more violence within the community, as well as within individual families.

Families themselves can be a predisposing factor to violence, especially if there is a history of abuse and neglect within the family or if family members are involved in drug or alcohol abuse. Other influencing variables are individual or behavioral in nature, such as a preoccupation with danger or violence, a history of abusing or torturing animals, or a history of bullying (either as the bully or as the bullied). Psychologic factors should also be considered, including aggressive tendencies, uncontrolled anger, extreme emotional distress, emotional instability, and depression (CDC, 2016b; Office of Mental Health, 2012).

When a disaster occurs, stress reactions are typically the same reactions seen with any trauma. Predisposing factors may have an impact on a victim, making their stress reaction more intense and long-lasting. The amount of exposure that a victim experiences has a direct impact on future mental health disorders. For example, directly experiencing the threat of severe injury or death increases the risk for needing professional mental healthcare (VA, 2016b). Females are more likely than males to have extreme reactions, and extreme reactions are more prevalent in people age 40–60 years, which is attributed to having more responsibility related to family and jobs. Examples of factors that predict the worst outcomes include severe injury or death of a loved one, separation from family (especially children), extreme loss of property, and forced displacement (VA, 2016b).

Protective Factors

In opposition to predisposing factors to violence and trauma, protective factors reduce the risk of becoming a perpetrator or experiencing debilitating responses to traumatic situations. Many of these protective factors apply to adolescents. According to the CDC (2016b), some variables that decrease the risk associated with violence include:

- Determination and success in school
- Healthy and positive social relationships
- Parents who show interest in their child's experiences
- Involvement in the community
- Participation in family activities
- Participation in cultural or religious practices
- Strong emotional support from friends and family.

There are protective factors associated with victims of disastrous events as well. Over time, most people will recover and move forward with their lives without having severe, chronic mental health issues. Factors that can

increase resiliency include a strong, well-developed support system; effective coping skills and the positive belief that one can survive; and hope, including optimism, spiritual belief, and practical resources (VA, 2016b).

Promoting Safety

Anyone can become a perpetrator or victim of violence or abuse, and anyone can develop chronic mental health issues following traumatic situations. Knowing the warning signs of violent behavior can help promote safety. Warning signs of potentially violent behavior include uncontrolled anger, threatening language, and aggression. Similarly, recognizing the indicators of violence can help individuals avoid potentially dangerous situations by implementing protective measures. Protective measures include not walking or running alone in deserted areas, asking for help when being abused, and reporting violent behaviors or abusive situations.

Promoting a healthy community involves changing the roots of negative behavior in individual homes, in schools, and within the community. Community programs should focus on education regarding abuse, bullying, and neighborhood violence. Middle and high schools should include a curriculum about dating violence, bullying, and overall safety. Youth centers devoted to healthy recreational and educational activities can help prevent youth violence. According to the National Crime Prevention Council (2016), the incidence of personal violence has decreased over the past three decades; they attribute this decrease to vigilance and use of precautions.

Nurses can help promote safety by educating patients about high-risk situations, such as spouses who have been abusive in the past and the dangers of date rape and violence. Assessing the signs of abuse and offering interventions can also help establish safety. Nurses working in schools or other community settings can help dispel myths about aggression and abuse, assuring patients that it is never acceptable for someone to control or injure them. Assessing for inadequate coping mechanisms, signs of inadequate anger management, or inappropriate behavior can help identify risk factors and implement behavior therapy before someone is victimized.

Traumatic situations can occur at any time and to anyone; however, some traumatic situations can be prepared for because they are predictable. For example, earthquakes are more likely to occur on the West Coast, tropical storms and hurricanes are more likely on the coasts, and tornadoes are more common in the Midwest. People living in susceptible regions should be educated on how to prepare for potential disaster situations. Being prepared with supplies, communication plans, and family meeting places are protective measures to decrease long-lasting effects. Nurses must remain current with new, evidence-based practice initiatives to help promote safety for individuals, patients, facilities, and the community during and after traumatic events.

Modifiable Risk Factors

Abuse can be stopped, but many victims feel powerless against their abusers. By recognizing the signs of distress and injury that accompany abuse, nurses can assist victims in making their environment safer. Promoting safe behaviors and preparedness and identifying risk factors may decrease traumatic mental illnesses and trauma-related injuries and death.

Abuse Prevention

Nurses in all areas of practice need to take a proactive role in prevention, identification, and treatment of violence-related trauma. Early screening of vulnerable individuals and efforts to promote a change in attitudes and beliefs about family violence are essential. If they are to assist victims effectively, nurses must be aware of their own feelings about family violence. Nurses who are unclear about their own feelings about family violence may deny its existence, blame the victim in crisis, or minimize the effects of the violence. Nurses may be providing medical care to perpetrators and must perform self-reflection regarding their personal biases, allowing the nurse to maintain a nonjudgmental and unbiased attitude while providing medical care.

Nurses can be instrumental as advocates for developing policies and programs and providing in-service training and education to healthcare professionals and the public. Comprehensive violence prevention programs require a variety of disciplines and organizations working together, such as healthcare agencies, criminal justice agencies, and social service agencies.

Trauma Prevention

Areas of health promotion and trauma prevention interventions for individuals and communities include the following:

- **Motor vehicle safety:** Use seat belts and helmets as appropriate, have properly functioning air bags, avoid driving under the influence of alcohol or drugs, refrain from reckless driving, test for visual or cognitive deficits in older adults, avoid cell phone use while driving, avoid driving while fatigued, reduce distraction of young drivers by limiting the number of passengers
- **Relationships:** Teach communities how to recognize IPV, child abuse, elder abuse, abuse of developmentally delayed persons, or neglect
- **Communities:** Promote gun control, reduce participation in gangs, improve the condition of streets, promote neighborhood safety, review child abuse and fatalities for trends.

One example of a community trauma prevention strategy or intervention is the multidisciplinary child abuse or child fatality prevention team. Communities may develop teams such as these to review child abuse or child fatality cases to determine whether recommendations need to be made at the state level. Examples of recommendations include requirements for car seat or bicycle helmet use. Team members frequently include community health nurses, school nurses, preschool directors and school principals, members of law enforcement, and representatives of the district attorney's office.

Trauma-Informed Care

SAMHSA (2014) uses a trauma-informed approach that includes six key principles when addressing the needs of trauma victims. These principles are generalized for different settings, events, and areas:

1. Safety
2. Trustworthiness and Transparency
3. Peer Support
4. Collaboration and Mutuality
5. Empowerment, Voice and Choice
6. Cultural, Historical, and Gender Issues.

Trauma-specific interventions should meet the needs of the survivor, including treating the individual with respect and providing information, connectivity, and hope regarding recovery. Nurses should also understand the interrelation between trauma and substance abuse and mental health issues. Last, nurses need to work with the survivor, family and friends, and human service agencies to empower the survivor.

Nursing Assessment

Assessment of a trauma victim will depend on the nature and extent of the injuries. Because both acute trauma and chronic trauma can lead to long-standing mental health issues such as depression, anxiety, and posttraumatic stress disorder, the nurse not only must address the physical injuries identified, but also should perform a mental health assessment. During the assessment phase, it is imperative for nurses to consider the patient's cultural and spiritual practices, because these can have bearing on further treatment, interventions, and outcomes.

To begin the physical assessment, the priority when assessing any patient always begins with the **ABCs**:

- A**irway
- B**reathing
- C**irculation

For patients with severe physical injuries, the nurse may need to implement primary CAB (compressions, airway, breathing) protocols within the Basic Life Support guidelines and the ABC protocols within the Advanced Cardiac Life Support guidelines. Only when these priority needs have been met will the nurse go on to conduct a more complete assessment. Abuse and trauma assessments are the most common assessments for violence-related trauma. Nurses consider patients on a case-by-case basis; injuries from trauma manifest differently depending on the patient's overall disposition, experience, age, and history. Stereotypical mindsets regarding abuse victims have no place in nursing; all patients who present with signs of abuse should be assessed for abuse.

Abuse Assessment

Often the nurse is the first person to discover that the patient has been abused. Some victims may not disclose the abuse, may deny it despite obvious symptoms, or may minimize its impact. However, it is the nurse's responsibility to be alert for symptoms of abuse in all patients without allowing personal bias to influence assessments. During the assessment interview, the nurse must ensure privacy and safety from the perpetrator. The patient may be unwilling to admit to the reality of family violence until a trusting nurse-patient relationship evolves. The nurse should assure the patient of a genuine desire to help the entire family system. The nurse should approach this topic with a professional and calm demeanor, as if it were any other health risk. The nurse can also offer the option of answering questions about incidents of abuse with "sometimes" instead of "yes" or "no." This may encourage the patient to make a first step to acknowledge the abuse.

Victims of violence-related trauma or abuse require healthcare for a variety of conditions. Common physical complaints include chronic pelvic pain, headache, irritable bowel syndrome, arthritis, pelvic inflammatory disease, and

neurologic damage. Psychiatric illness (e.g., alcoholism) may be the result of sexual or physical abuse. Depression is also common. The assessment interview should include a detailed nursing history and a description of current symptoms.

Victims of physical abuse may sustain a variety of injuries. During a head-to-toe assessment, the nurse may observe for indications of abuse, such as the following:

- **Head:** bald patches on the scalp where hair has been pulled out; evidence of trauma from blows to the head, such as hematoma, facial bruises, facial fractures, bruised or swollen eyes, hemorrhages into the eyes; petechiae around the eyes from attempted strangulation
- **Skin:** swelling or tenderness, bruises, burns, or scars of past injuries on the skin, genitals, and rectal areas (these injuries could also be in various stages of healing)
- **Musculoskeletal system:** fractures or evidence of previous fractures, particularly of the face, arms/legs, and ribs; dislocated joints, especially in the shoulder when the victim is grabbed or pulled by the arm
- **Abdomen:** bruises, wounds, or intra-abdominal injuries, especially if the person is pregnant
- **Neurologic system:** hyperactive reflexes due to neurologic damage; paresthesias, numbness, or pain from old injuries.

If the nursing assessment reveals possible IPV, a team assessment needs to take place. The victim's medical condition and emotional state must be assessed. The severity and potential fatality of the situation must be considered as well as the legal ramifications and the needs of dependent children. The nurse must follow state regulations and institutional policies related to mandatory reporting.

Trauma Assessment

Violence or disaster-related events result in traumatic injury that may involve multiple systems. Because of the serious consequences of trauma, it is important to identify the patient's injuries and institute appropriate interventions immediately. When caring for the trauma victim, the nurse must always prioritize assessments with the **ABCDEs** as the highest priority concerns (American College of Surgeons Committee on Trauma [ACSCOT], 2017):

- A**irway maintenance with cervical spine protection
- B**reathing and ventilation
- C**irculation with hemorrhage control
- D**isability and neurologic assessment
- E**xposure and environmental control

Only after assessing the ABCDEs can the nurse go on to perform a detailed assessment of other systems or a focused assessment of the involved area of trauma.

Trauma usually occurs suddenly, leaving the patient and family with little time to prepare for its consequences. Nurses provide a vital link in both the physical and psychosocial care of an injured patient and family. In caring for the patient who has experienced trauma, nurses must consider not only the initial physical injury but also its

long-term consequences, including rehabilitation and (in cases of accidents, abuse, or assault) prevention. Trauma may alter the patient's previous way of life, potentially affecting independence, mobility, cognitive thinking, and appearance. Therefore, the nurse should assess the patient in each of these areas.

Death is a common result of serious traumatic injury and may be immediate, early, or late. Immediate death happens at the scene from such injuries as a torn thoracic aorta or decapitation. Early death occurs within several hours of the injury from, for example, shock or delay in recognizing injuries. Late death generally occurs one or more days after the injury and may result from multiple organ failure, sepsis, head trauma, or blood loss.

Trauma may result in death or cause injury serious enough to alter both the patient's and the family's lives. The suddenness and seriousness of the event are precipitating factors in the development of a psychologic crisis. Nurses working with the patient who has experienced trauma should assess the family for a variety of needs, including immediate social and spiritual support. For patients who will require long-term rehabilitation, nurses may provide family members with referrals for counseling or financial support services. Assessment of patients' religious preferences regarding treatment and rehabilitation is critical (see the Focus on Diversity and Culture feature).

Nurses may call on the hospital chaplain, foreign language interpreter, dietitian, social worker, victim's advocate, or other professional to assist a patient who is the victim of violence or trauma and/or the patient's family. Law enforcement officers are also integral to cases of trauma, but they are not a required healthcare provider; therefore, their investigation should occur once the patient is stable (unless questioning is critical for safety purposes). Although these officials are trained for investigations, officers may, on occasion, become an obstacle to providing effective care to a victim. They may also overstimulate the victim, causing emotional decompensation. The nurse will need to advocate for the victim and intervene following hospital protocol.

Focus on Diversity and Culture Religious Practice Considerations for Violence-Related Trauma

Cultural and spiritual considerations in treatments for violence-related trauma are numerous and will vary based on the incident (e.g., abuse vs. extensive trauma). For example, Christian Scientists believe that healing is a matter of faith and find that they can live happy and healthy lives without drugs and traditional medical interventions (Christian Science, 2016). Jehovah's Witnesses believe it is in defiance of their religious scripture to accept blood transfusions, even as a lifesaving procedure (Jehovah's Witnesses, 2016). If a patient participates in a religion that prohibits blood transfusions or any life saving procedure, nurses and physicians should explain the dangers and potential outcomes of not accepting the procedure, as well as educate the patient and family on alternative options, but ultimately the care team must honor the patient's decision (Chand, Subramanya, & Rao, 2014).

Numerous factors help healthcare providers determine the seriousness of a patient's injuries and the potential for survival when violence results in serious trauma. Scoring systems such as the Champion Revised Trauma Score system can be helpful. A rapid but comprehensive trauma assessment, completed on the scene, includes the following:

- **Airway and breathing assessments** to determine if the airway is patent, maintainable, or nonmaintainable and if ventilations are impeded in any way, such as by rib fractures or a pneumothorax
- **Circulation assessment** to palpate peripheral and central pulses; to assess capillary refill, skin color, and temperature; and to identify any external sources of bleeding
- **Level of consciousness** and *pupillary function assessments*
- **Assessment for any obvious injuries.**

The Glasgow Coma Scale is another scoring system that is used to quantify the level of consciousness following traumatic brain injury (TBI). For more information on the Glasgow Coma Scale, see the module on Intracranial Regulation.

Diagnostic Tests

The diagnostic tests ordered once the patient reaches the hospital depend on the type of injury the patient has sustained. Tests that may be ordered for victims of trauma include the following:

- **Blood type and crossmatch** involves typing the patient's blood for ABO antigens and Rh factor, screening the blood for antibodies, and crossmatching the patient's serum and donor red blood cells.
- **Blood alcohol level** measures the amount of alcohol in a patient's blood. Alcohol alters the patient's level of consciousness and response to pain.
- **Urine drug screen** may also be ordered. Like alcohol, drugs such as cocaine alter the patient's level of consciousness and overall response to the primary survey.
- **Pregnancy test** for any woman of childbearing age rules out the potential for pregnancy and fetal injury.
- **Focused assessment by sonography in trauma (FAST)** exam evaluates the presence of blood in body cavities. Primary focus is on the peritoneum. It is also helpful in identification of blood in the pleura and pericardium.
- **Diagnostic peritoneal lavage** determines the presence of blood in the peritoneal cavity, which may indicate abdominal injury. This test is generally done in the emergency department, but has been used less frequently since the inception of the FAST exam.
- **Computerized tomography (CT) scans** can reveal injuries to the brain, skull, spine, spinal cord, chest, and abdomen.
- **Magnetic resonance imaging (MRI) scans** can reveal injuries to the brain and spinal cord.
- **X-rays** can reveal bone fractures.

Case Study » Part 2

The ambulance arrives at the ED and paramedics emerge with the patient, Mark Alvarez, a 32-year-old police officer. Officer Alvarez was shot during a routine traffic stop, sustaining a bullet wound to his right shoulder. Upon arrival, the patient is awake and alert. His clear speech suggests a patent airway. His respirations are regular and non-labored. His skin is pink, warm, and dry. You obtain another set of vital signs, which include temperature 97.2°F oral; pulse 90 bpm; respirations 20/min; and BP 100/72 mmHg. Following a thorough medical assessment by the ED physician, Officer Alvarez is declared stable. He will require surgical intervention to explore and treat his shoulder injury. The ED physician orders laboratory diagnostics, including complete blood count (CBC), serum electrolytes, and type and cross-match for possible administration of blood products.

Following assessment and evaluation by the trauma surgeon, Officer Alvarez is scheduled for immediate surgical exploration of his right shoulder.

You remain with Officer Alvarez while he is waiting to be taken to surgery. The patient seems slightly anxious. When you ask if he has any questions about his surgery, Officer Alvarez responds by asking if his wife has arrived yet. You report that she has not. Officer Alvarez seems disappointed to hear this; he asks you to make sure she is told he is going to surgery and you assure him she will be informed as soon as she arrives. A nurse from the operating room arrives to transport Officer Alvarez to surgery.

Clinical Reasoning Questions Level I

1. Explain two possible reasons for Officer Alvarez's decrease in blood pressure.
2. Why do you think Officer Alvarez seems more concerned about his wife's absence than his impending surgery?
3. How would the case have changed if Officer Alvarez's airway had not been patent?

Clinical Reasoning Questions Level II

4. Would Officer Alvarez's injury have been worse had he been shot in the left shoulder? Explain your answer.
5. Describe three long-term interventions for Officer Alvarez's care after surgery.
6. Describe two possible complications that could arise during the patient's surgery.

Independent Interventions

Caring for patients who have experienced traumatic events may evoke strong emotional responses from the nurse. However challenging the situation, the nurse must maintain focus on the patient to provide effective, high-quality care. Interventions for all types of trauma-related care will be both independent and collaborative, but the nurse may have first contact with the patient, during which time several independent interventions can be employed.

Interventions for Victims of Abuse

In cases of abuse, the nurse may be the first professional to have contact with the patient, so it is essential for the nurse to (a) assess safety by determining the immediacy of danger, (b) convey that the patient is not to blame and has the right to be safe, (c) explore options for help, and (d) provide information regarding available services. The nurse must avoid a judgmental attitude and support the individual's choice about whether to leave the unsafe situation or return to the abusive relationship. Because severely battered women are

at risk for homicide, the nurse needs to inform the patient about associated risk factors and determine the immediacy of danger.

Nurses must familiarize themselves with agency protocols and resources available for victims of IPV. Most municipalities have crisis help lines and hotlines to assist victims of abuse. The nurse should also keep a record of telephone numbers for transition houses and rape crisis centers, alcohol and drug abuse information, support groups, religious organizations, and legal services. In addition, several national organizations offer toll-free contacts, such as the National Organization for Victim Assistance, the National Coalition Against Domestic Violence (in the United States), and the National Clearinghouse on Family Violence (in Canada).

The priority nursing consideration regarding the child who is abused is to ensure safety. Once the child's safety is ensured, developing a trusting relationship will allow the child to discuss his or her feelings and describe the abusive event(s). The child should not be required to repeat the story for multiple reports, because each retelling carries the possibility of creating trauma for the child. All hospitals and agencies working with children who are abused have standard protocols that provide a supportive environment and ensure that adequate information needed by law enforcement is obtained without further victimization of children through a repetitive or unfriendly process.

The nurse working with a child who is a victim of abuse needs to convey belief in the child's story; the nurse also must assure the child that he or she has done nothing wrong. The nurse should avoid making negative comments about the abuser and must follow established protocols for mandatory reporting, documentation, and use of available support services (e.g., the police department, social service agencies, and child welfare agency).

Short-term interventions for older adults the nurse suspects of being abused include developing a positive relationship with both the victim and the abuser, exploring ways for the older adult to maximize independence, and exploring the need for additional home care services or alternative living arrangements.

Interventions for Victims of Trauma

Victims of trauma often present in the emergency department with life-threatening injuries, including hypovolemia due to blood loss, organ damage, and multisystem complications. The patient will often be in both physical and psychologic shock. Medical care for the patient in shock focuses on treating the underlying cause, increasing arterial oxygenation, and improving tissue perfusion. Depending on the cause and type of shock, interventions include emergency care measures, oxygen therapy, fluid replacement, and medication administration.

The nurse's role in trauma care begins with **triage**, the process of determining which patient most urgently needs medical intervention. Triage is based on the ABCDEs of trauma care. The nurse begins the triage process by performing a rapid general assessment, including vital signs, level of consciousness, and a head-to-toe review looking for obvious physical alterations (ACSCOT, 2017).

When caring for a patient who has experienced trauma, maintaining a patent airway and monitoring breathing and

circulation are ongoing responsibilities. If the patient has experienced blood loss, is in shock, or is in unstable condition, the initiation of an IV line is often a high priority because it allows for administration of medications, fluid, and blood products. Changes in the patient's condition are often marked by subtle alterations, so the nurse's primary role is in performing ongoing assessments in order to correct problems before they become more acute.

Collaborative Therapies

Care of the trauma patient depends on a team approach. Providing trauma care with a team focus helps each team member know his or her role. Prompt delegation of tasks and responsibilities improves the patient's chances for survival and decreases the morbidity that may result from traumatic injuries. For more information on delegation, refer to the exemplar on Delegation in the module on Managing Care.

The initial focus of care for the patient with a traumatic injury is physiologic stabilization. During this time, physical injuries are identified and treated. From the psychosocial standpoint, the best treatment for families experiencing trauma or violence generally involves an interprofessional approach with nurses, physicians, social workers, spiritual leaders, law enforcement, protective services personnel, community resource organizations, and, often, lawyers. Most families are more open to accepting help during a time of crisis than at other times. Patients being treated for violence-related trauma will most likely be willing to develop new behavior patterns for a short time following a traumatic event. If families are not helped during that time, they will likely return to previous behavior patterns, including violence.

Nurses should know the laws associated with reporting abuse. In the United States and Canada, nurses are required to report any suspected child abuse. The courts and child protective agencies make decisions in the child's interest. They may allow a child to remain in the home but under court supervision; they may remove the child from the home; or, in instances of very severe abuse or repeated abuse despite intervention, they may terminate parental rights. Adult victims of IPV generally will make the decision whether they want to report the violent episode(s) to law enforcement. It is important that the nurse educate the victim on all options and resources available so that an informed decision can be made.

The nurse plays a critical role on a multidisciplinary team working with families involved in traumatic injuries. The nurse is often the healthcare worker who spends the most time with patients and forms a trusting nurse-patient relationship. As a result, the patient may feel most comfortable when talking with the nurse and be more likely to relate details of the traumatic event. The nurse's role may include teaching, support, or role modeling behavior. For example, if a child is transferred to foster care, the nurse may provide patient teaching to the foster family to provide for the child's healthcare needs.

Adults and older adults experiencing abuse or a traumatic event need similar collaborative interventions, including physicians, social workers, counselors, spiritual leaders, law enforcement, and lawyers. Nurses facilitate referrals and honestly answer any questions asked by the patient.

Medications

Trauma

CLASSIFICATION AND DRUG EXAMPLES	MECHANISMS OF ACTION	NURSING CONSIDERATIONS
Inotropic drugs Drug examples: Dopamine (Intropin) Dobutamine (Dobutrex) Isoproterenol (Isuprel)	Inotropic drugs (drugs that increase myocardial contractility) may be given to increase cardiac output and improve tissue perfusion.	<ul style="list-style-type: none"> Administer only after fluid volume restoration. Monitor for signs of extravasation, and stop infusion immediately if it occurs. Watch for any side effects such as pain, irregular heartbeat, or rise in diastolic pressure.
Vasopressors Drug examples: Dopamine Epinephrine Norepinephrine Phenylephrine	Vasopressors may be administered in conjunction with fluid replacement to treat neurogenic, septic, or anaphylactic shock.	<ul style="list-style-type: none"> Monitor cardiovascular response to medications, including heart rate and rhythm and blood pressure. Use cautiously in children, volume-depleted patients (e.g., severely dehydrated or those who have sustained significant blood loss), and older adults. Watch for signs of confusion and headache, which could be signs of water intoxication.
Opioid Analgesics Drug example: Morphine	Opioids are used to treat pain. However, the effects of the pain medications may alter patient responses to injury and mask potential injuries. For this reason, patient assessment generally is performed prior to administration of opioids or other medications that may produce sedative effects.	<ul style="list-style-type: none"> Monitor for respiratory depression and administer reversal agent (naloxone) if needed. Use cautiously in patients with head trauma.

Source: Based on Adams, M. P., Holland, L. N., & Urban, C. (2017). *Pharmacology for nurses: A pathophysiologic approach* (5th ed.). Hoboken, NJ: Pearson Education.

Surgery

Surgical intervention may be required to treat injuries related to trauma. Some injuries require emergency surgery to stop bleeding or repair organ damage. Nurses will work to keep patients stable while preparing them for surgery, diagnostic testing, or other treatments to repair their injuries. Whereas some injuries sustained from trauma will require basic surgical interventions, other injuries will require more complex surgery.

Pharmacologic Therapy

Pharmacologic treatment for trauma patients may include administering analgesics for pain; however, because analgesics may cause sedation, physical and neurologic assessments are usually conducted prior to administering these medications. Depending on the severity of the patient's injury, inotropic agents and vasopressors also may be indicated (see the Medications feature).

Nonpharmacologic Therapy

A common issue with physical trauma is pain control. A patient who does not have effective pain management may require longer hospitalization, experience additional complications, and have poor outcomes. Along with pharmacologic pain management, the nurse will also need to employ nonpharmacologic pain management techniques.

For more information on nonpharmacologic pain control, see the module on Comfort.

Complementary Health Approaches

Complementary health approaches may be added to the traditional treatment to assist in symptom management. Patients with a long treatment trajectory (for example, extensive physical therapy and rehabilitation) may benefit from complementary strategies such as stress reduction techniques or acupuncture to help alleviate pain. Patients who face long-term disability will benefit from referrals to organizations that provide education and support in obtaining assistive devices, including service animals. The nurse will need to educate the patient to inform all healthcare providers if using complementary health approaches, especially herbal remedies or supplements, because of the possibility that such approaches may be contraindicated with prescription medications.

Case Study » Part 3

One month following his right shoulder injury and surgery, Officer Alvarez presents to the clinic for his post-op visit. His surgery was successful; the bullet was excised, and damage to the surrounding tissues was minimal. Officer Alvarez has been attending physical therapy sessions, which he describes as "sort of helpful, but my shoulder swells a little bit after my therapy appointments." He reports that he is gaining range of motion in his right shoulder. On a

scale of 0 to 10 (with 10 being extreme pain), Officer Alvarez rates his pain as 2.

When asked about his anticipated return to work, Officer Alvarez becomes very quiet. After a pause, he tells you he is expected to return to work in 3 days. He explains that he will be on light duty, which entails working in an administrative role inside the police department until he has fully recovered. You notice that Officer Alvarez seems uncomfortable discussing his return to work, so you tactfully explore the topic. You begin by asking how he feels about returning to work. Officer Alvarez reports that he feels fine physically; however, he has been having nightmares about the shooting. When you ask if he has discussed his nightmares or the actual shooting with anyone, he replies, "It's not something I really want to talk about. I have an appointment with the department shrink tomorrow, though. They're making me see her before I can go back to work." When you ask if he would like to speak with a counselor outside his department, Officer Alvarez replies, "I really don't

want to talk about anything with anybody. I just want my shoulder to heal up."

Clinical Reasoning Questions Level I

1. What nursing interventions could you suggest to Officer Alvarez to promote comfort in his shoulder following therapy sessions?
2. What concerns might Officer Alvarez have with regard to his return to work, both in the psychosocial and physical realms?

Clinical Reasoning Questions Level II

3. Is Officer Alvarez at risk for developing posttraumatic stress disorder? Explain your answer.
4. In light of Officer Alvarez's statements, should the nurse proceed with exploring psychosocial considerations related to his injury? Why or why not?

REVIEW The Concept of Trauma

RELATE Link the Concepts

Linking the concept of trauma with the concept of cognition:

1. Describe how untreated schizophrenia could lead to instances of violence and/or violent behavior.
2. How would you assess and diagnose abuse in a patient with advanced Alzheimer disease? What signs and symptoms would you look for in particular?

Linking the concept of trauma with the concept of mood and affect:

3. What assessment questions would you want to ask the patient who was admitted after sustaining injuries from domestic violence whose mood appears sad with a tearful affect?
4. Could a woman experiencing postpartum depression be at increased risk for abusing her children or spouse? Explain your answer.

Linking the concept of trauma with the concept of clinical decision making:

5. You are working in the emergency department when several ambulances arrive simultaneously because of a nearby apartment fire. When triaging the patients, you find that there are patients with fractures, second- and third-degree burns, and respiratory distress. Another patient is unconscious. Which of the patients require priority care? Explain your answer.
6. A patient has been admitted to the emergency department following a motor vehicle crash. The patient has an open fracture of the femur, deep facial lacerations, and broken ribs coupled with a pneumothorax. What priority nursing interventions would you implement first? Explain your answer.

REFLECT Apply Your Knowledge

A family of four was vacationing on the West Coast when a major earthquake occurred. The destruction where their hotel was located was severe, and many buildings were damaged, including their hotel. The parents and 13-year-old daughter were unharmed; however, the 9-year-old son, James, sustained severe physical trauma with obvious open fractures and profuse bleeding from the head. James was unconscious when the rescue team found him. The disaster response team triaged James and immediately transported him, via ambulance, to Los Angeles, the nearest city that remained operational, for medical care. Upon arrival, James' respirations were 26 per minute, blood pressure was 68/40 mmHg, and pulse was 140 bpm. James has regained consciousness and is being sent for x-rays and a CT scan of the brain. Test results show fractures of the left femur and tibia, the left humerus, radius and ulna, and a skull fracture. The CT scan reports a contusion of the brain with no other anomalies. James will need to have surgery to correct placement of the open, complete fractures. After surgery, he will need to remain in the hospital for additional tests, stabilization, and monitoring. The parents and sister have arrived and are displaced. The entire family is traumatized (crying, confused, and in a state of disbelief) and the nurse noted that the mother was clenching her prayer beads.

1. What three priority nursing diagnoses would you select for James?
2. Whom should the nurse contact regarding arrangements that can be made for the family so that they can remain close to James during his stay in the hospital? What might these arrangements include?
3. What other healthcare professionals and ancillary staff members should the nurse involve in the care of James and his family?

Exemplar 32.A Abuse

Exemplar Learning Outcomes

32.A Analyze abuse as it relates to trauma.

- Describe the pathophysiology of abuse.
- Describe the etiology of abuse.
- Compare the risk factors and prevention of abuse.
- Outline the types of abuse perpetrated throughout the lifespan.
- Identify the clinical manifestations of abuse.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual who has been abused.
- Apply the nursing process in providing culturally competent care to an individual who has been abused.

Overview

Abuse can happen to individuals of any age and from any demographic or sociocultural background. Abuse does not only happen to those with supposedly *weak* personalities; individuals with strong or dominant personalities can fall victim to abuse as well. Predisposing risk factors to become an abuser exist for all forms of abuse; however, even if all identified factors are present, the person may not become an

abuser. Abuse is a growing concern in the United States, with many cases going unreported because of fear of or threats from the abuser.

Pathophysiology and Etiology

Abuse is often related to control (see **Figure 32-1** »). When one individual attempts to control another individual, a form of abuse must occur. The four types of abuse that most

Source: Potter, M. L., & Moller, M. D. (2016). *Psychiatric-mental health nursing: From suffering to hope*. Hoboken, NJ: Pearson Education. Reprinted and Electronically reproduced by permission of Pearson Education, Inc., New York, NY.

Figure 32-1 » The power and control wheel illustrates the strategies one partner may use to intimidate, control, and harm another.

states identify are **physical abuse**, **psychologic abuse**, **sexual abuse**, and **neglect** (see Table 32–1 for definitions). All of these can work to break down an individual's self-confidence and self-worth. Some common elements of abuse are humiliation, intimidation, and physical injury (Benedictis, Jaffe, & Segal, 2012). Each type of abuse has unique characteristics and requires individual approaches to diagnosis and management (Medscape, 2015). Abuse sometimes start as emotional abuse—such as telling the victim he is not smart enough, or that no one will ever love him—but over time, emotional abuse can escalate to physical abuse or even sexual abuse. Physical abuse is generally accompanied by psychologic abuse. In cases of sexual abuse, especially childhood sexual abuse, victims will often be exposed to forms of psychologic abuse whereby the perpetrator will use the child's need for love and approval against him in order to force the child to submit (American Psychological Association, 2013). Ultimately, cases of abuse involve both the use of control and manipulation.

Etiology

Many theories exist concerning the motivation for violent behavior and abuse within families. Some of those theories propose that individuals are genetically predisposed to violence, whereas other theories discuss the influences of society and family structure. No definite causes of family violence have ever been agreed on, but neurobiology, psychopathology theory, and social learning theory lead into one another to help highlight some contributing factors to abusive behavior.

Neurobiology

Genetics is believed to play a role in anger modulation and emotion control. Anger and its manifestations vary among individuals, with some having self-control and others expressing their anger by becoming abusers. Some studies have therefore suggested that genes can be linked to how the brain processes situations and emotions and then ultimately produces a reaction of anger. Gene studies show that individuals with low levels of the monoamine oxidase A (MAOA) genotype (often associated with antisocial behavior and aggression) are more prone to become aggressive in high-anxiety or emotional situations. MAOA breaks down the biogenic amines serotonin, dopamine, and norepinephrine, which influences behavior. One study found that the association between neglect and physical abuse and the short version of the MAOA gene was significantly associated with mental health problems, antisocial behavior, attentional problems, and hyperactivity in boys (De Bellis & Zisk, 2014).

Psychopathology Theory

The psychopathology theory suggests that some individuals who experience personality disorders and mental illnesses participate in family violence as a direct result of these illnesses. Although this is a popular theory, specific mental illnesses and personality disorders have never been indicated, and many individuals with these illnesses are not violent. Some personality disorders and emotional illnesses when left untreated can result in violent tendencies (e.g., bipolar disorder, schizophrenia, paranoid personality disorder)

(Treatment Advocacy Center, 2015); however, as with risk factors, having an untreated mental illness does not always result in abuse or violence.

Social Learning Theory

Social learning theory explains that individuals learn violent tendencies through association with others and a reinforcement of the abusive behavior. Children are especially susceptible to this form of learning, because they model the behaviors of those around them. Children often model the behaviors of parents, siblings, other adults, or actions they see on television. Therefore, children have a high likelihood of adopting abusive tendencies perpetrated by their parents or siblings, thus furthering a cycle of abuse within the family. Relationship factors, including a family environment characterized by physical violence and a childhood history of abuse or neglect, are risk factors for perpetration (CDC, 2016c).

Risk Factors

Risk factors associated with perpetration of abuse include individual (e.g., parents' history of child maltreatment), family (e.g., family disorganization, dissolution, and violence), and community. Risk factors associated with victimization include very young children, older adults, and individuals with special needs (CDC, 2016c).

Age

Some age groups, particularly younger children and older adults, are at increased risk for abuse because abusers consider these age groups to be more helpless than others. Research indicates that very young children (age 4 and younger) are the most frequent victims of child fatalities. Children younger than 1 year accounted for 46.5% of fatalities; children younger than 3 years accounted for almost three fourths (73.9%) of fatalities (USDHHS, 2013). In cases of elder abuse, it is virtually impossible to know the full extent of instances of abuse because many are not reported. However, it is known that as older adults age, the risk for abuse increases. Abuse in older adults is commonly in the form of neglect, but it can also be in terms of financial exploitation or physical, emotional, or sexual abuse (Anetzberger, 2012; DOJ, n.d.; National Center on Elder Abuse, n.d.b). The DOJ (n.d.) reports that between 30% and 40% of abused older adults experience more than one form of abuse by the same offender.

Gender

For some forms of abuse, gender can be a risk factor, whereas for other forms it does not play an active role. For example, in cases of child abuse, there is virtually no difference between the number of female victims and the number of male victims (USDHHS, 2012). IPV, however, does show a higher instance of women being abused (24.3% of the female population) than men (13.8% of the male population) (CDC, 2013a). Debates exist over reported numbers of IPV victims, with many claiming that the majority of male victims do not report being abused by their spouse. Trends in elder abuse, though, show a clear delineation of women being abused more often than men (National Center on Elder Abuse, n.d.b).

Testosterone has been correlated with higher aggression levels in humans, which helps explain why many offenders are young men with muscular physiques. These individuals typically have high levels of testosterone and low levels of serotonin, the neurotransmitter commonly associated with satisfaction.

Physiologic Development

Physiologic illnesses and disabilities may present one of the highest risk factors for all forms of abuse. Individuals with disabilities are more likely to be seen as easy targets for abuse, with perpetrators assuming that the victim will not, or cannot, report the crime. Some common reported disabilities associated with cases of abuse include intellectual disabilities, physical and learning disabilities, visual or hearing impairments, dementia, and Alzheimer disease (National Center on Elder Abuse, n.d.b; USDHHS, 2012). Approximately 11% of all child abuse victims had a physical or emotional disability of some kind. A study of women with disabilities found that 67% had been subjected to physical abuse and 53% had been sexually abused at some point in their lives. A similar study was conducted in men with disabilities and found that 55% had been physically abused at some time in their lives. It has also been discovered that IPV among individuals with disabilities is increasingly prevalent and even disproportionate (National Center on Elder Abuse, n.d.b).

Cultural Factors

An individual's culture can also be a risk factor for abuse, with some cultures condoning acts that Western culture considers to be abusive. For example, some Asian cultures use shame as a method of teaching children respect or for controlling individuals within the family unit. Shame in these instances could be considered a form of psychologic abuse, as the individual being shamed may be continually verbally confronted with his supposed shortcomings and mistakes. Parents from Asian cultures frequently practice the honor and shame practice even when they migrate to the United States, and this practice is passed down from generation to generation. This practice leaves some children needing mental health treatment for low self-esteem, depression, and anxiety; however, because of a perception that mental illness may tarnish the family reputation, many children go untreated (Louie, 2014). Physical abuse can also be a matter of cultural significance, with some cultures employing and condoning punishments of a physical nature toward their children or spouses.

Within cultures that are strictly patriarchal (or matriarchal), IPV may be more prevalent. In these situations, one member of the relationship has more power than the other, creating tension that could lead to physical or psychologic violence. In other cultures, the husband or male partner is strictly in control of the relationship and all members of the family, thus giving him the right to use punishments that he considers necessary. Stress is not a reason for violence. Abuse and violence are an explanation of the "privileges of men's experiences over women's" (Asian Pacific Institute on Gender-Based Violence [APIGBV], n.d.).

In rare but increasingly prevalent instances, some cultures may practice ritualistic forms of abuse. Many of these

cultures acknowledge a belief and worship of Satan or another devil-like deity. Within the practices of these cultures, children (or new inductees) are continuously terrorized and tortured as a mode of control. Physical, emotional, sexual, and spiritual abuse are all parts of ritualistic abuse. Examples of ritualistic physical abuse include beatings, torture, confinement, and forced ingestion. Methods of emotional abuse include manipulating, lying to, and blaming the victim. Sexual abuse may include forcing sex on children or nonconsenting adults, as well as forcing others to commit sex acts against children or nonconsenting adults. Spiritual abuse may present as reversal of good and evil and infringement on freedom of thought (Ritual Abuse, Ritual Crime and Healing, 2016). If a nurse suspects a patient is being abused, regardless of the source of the abuse, the nurse must follow state and agency reporting policies.

Socioeconomic Factors

Some researchers consider poverty to be the largest risk factor and predictor of child abuse and neglect. The stress and feelings of inevitability that come with poverty can lead to frustration, anger, and potentially physical and emotional abuse. Living in poverty or an economically depressed area contributes significantly to the probability of an individual engaging in or becoming the victim of an assault. However, individuals from high socioeconomic backgrounds can also become the victims and perpetrators of abuse.

Substance Abuse

Substance or alcohol abuse is not necessarily a predictor of abusive behavior, but the excessive use of any mind-altering substance can make abusive situations much worse. Alcohol can contribute to the aggressive behavior that leads to violent behaviors by reducing inhibitions and modifying the functioning of neurotransmitters, including a decrease in serotonin function (Ciccarelli & White, 2013). For example, if an individual is already being extremely emotionally abusive, the use of illegal substances or alcohol could push the perpetrator to physical or sexual abuse, or the emotional abuse could become intensified. Alcohol and other substances do not create an abusive situation; other factors also need to be considered, such as the personality of the individual using the substances. However, substance and/or alcohol abuse is one of the leading risk factors for perpetrators of all forms of abuse.

SAFETY ALERT A patient who is under the influence of an illegal substance and/or alcohol is highly unpredictable, which increases the risk for violent behavior. The nurse will need to monitor the patient at all times and assess for signs of escalating behavior. If there is potential for violence, it is important that the healthcare team and security be made aware for safety purposes.

Firearms in the Home

It is controversial and virtually impossible to assign statistics for an increased risk for mortality in cases of abuse when a gun is present in the house, because these statistics depend on too many reported variables such as the type of firearm, the storage of the firearm, and the location of the incident. However, according to the FBI (n.d.d), the following 2014

statistics were reported regarding intimate partner homicide, firearm violence, and related factors:

- 35.5% of female victims (for whom the murderer was known) were killed by a husband or boyfriend.
- 40.4% of all murder victims (for whom the circumstance was known) were killed during arguments—including romantic arguments.
- 68.5% of weapons used during all murders were handguns.

Prevention

The prevention of abuse must come from various levels, including individual, community, society, relationship, and parenting. In addition, the many factors that contribute to abusive relationships need to be addressed in order to stop abuse. Often, abuse is part of a familial or personal cycle that has been going on for years, and until the abuser acknowledges or realizes the cycle, it is likely to continue. Nurses can help prevent abuse by observing for the signs and symptoms of abuse and then working to address the situation. When children are involved, nurses must report the abuse per facility protocol and state regulations; but in cases of IPV, it is ultimately the individual's choice to seek help in stopping the situation. In cases in which the patient does desire help to stop a violent and abusive situation, nurses can work to facilitate referrals to shelters, other healthcare providers, law enforcement, and lawyers. For patients who want to leave an abusive home or relationship, nurses can provide patient teaching regarding the development of a safety plan (see the Patient Teaching feature).

SAFETY ALERT Sudden unemployment or other forms of financial stress can greatly increase an individual's stress and thus create a large risk factor for participating in abusive behavior toward another individual.

Patient Teaching

Developing a Safety Plan

Developing a safety plan will help an individual who lives in an abusive environment to plan an escape. Elements of a safety plan may include:

1. Practice how to get out safely. Know the easiest escape route from the current location (exiting through doors, windows, fire escapes).
2. Keep purse or wallet and keys easily accessible at all times.
3. Have a contact person(s) and number(s) available who can be notified to call police.
4. Teach children to call police or 911.
5. Have a code word to indicate a violent situation so that friends, family, or children know to call police.
6. Move to a low-risk area in the event of an argument (rooms with access to outside door and not in bathroom, kitchen, or room with weapons).
7. Use judgment. If the situation is serious, give the partner what is being demanded to calm them down.

Abuse Throughout the Lifespan

Categorizing abuse is often done in terms of the age of the victim or the form of abuse being perpetrated. Infant abuse, child abuse, bullying, youth violence, IPV, sexual abuse, and elder abuse are the main categories discussed in this section. Each type of mistreatment presents differently within the life of the victim and has a common perpetrator; for example, child abuse is commonly committed by parents or caregivers. The physical and emotional manifestations of these types of abuse are presented in detail later in the exemplar.

Infant Abuse

Infants are prone to abuse because they are completely dependent and vulnerable. Their needs sometimes outweigh the patience of a parent, especially if the pregnancy was unwanted or if the parent is young, has poor coping skills, or has a poor support system. Infants under 12 months of age had the highest prevalence of victimization in 2013 (USDHHS, 2013). Abusive head trauma (AHT), which includes shaken baby syndrome, is the leading cause of child abuse deaths in children under 5 years of age. Babies less than a year old are at greatest risk for AHT, which is likely because the most common trigger is inconsolable crying (CDC, 2016d). AHT often happens when the caregiver or parent becomes angry or frustrated, and then shakes the child or hits or slams child's head into something in order to stop the crying. Nearly all victims of AHT experience long-term physical consequences, and approximately 25% of all victims die from their injuries (CDC, 2016d).

Child Abuse

According to the Child Abuse Prevention and Treatment Act (CAPTA), **child abuse** and neglect are defined as "any recent act or failure to act on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation" of a child or "an act or failure to act which presents an imminent risk of serious harm" to a child (USDHHS, 2010). In 2013, approximately 3.5 million children (age newborn to 17) were reported to be victims of child abuse in the United States, with one fifth of reports being substantiated. Of the reports made, 61.6% were made by professionals (USDHHS, 2013). However, many cases of child abuse still go unnoticed and unreported.

Children of all races and ethnicities may be victims of child abuse. Child abuse is often defined as having three forms: neglect, physical abuse, or sexual abuse. In 2013, neglect accounted for the highest percentage of child mistreatment cases in the United States at 79.5%. Approximately 83% of the perpetrators were between the ages of 18 and 44 years, and 53.9% of perpetrators were women (USDHHS, 2013).

Bullying

School-age children frequently find themselves the victims of bullying. The CDC (2016e) defines **bullying** as "any unwanted aggressive behavior(s) by another youth or group of youths, who are not siblings or current dating partners, involving an observed or perceived power imbalance that is repeated multiple times or is highly likely to be repeated." Bullying may result in physical injuries and emotional

distress, and it may disturb academic progress. Bullying can occur in the presence of the victim as well as through the use of technology such as text messages, email, cell phone applications, chat rooms, and social media, which are all forms of **cyber-bullying**. Although electronic media are helpful in allowing youth to communicate with family and friends easily and regularly, youth can also use this technology to threaten, embarrass, and harass their peers. Technology has also made it possible for the bully to be anonymous, making it difficult for parents or authorities to confront this behavior. Bullying has been addressed by most states' boards of education by making bullying a punishable offense by school authorities; however, cyber-bullying has been challenging for school officials to address because the act often does not occur on school grounds. Regulations are beginning to catch up with technology with some states, such as Ohio's "Jessica Logan Act" (see Community and Systemic Violence—Bullying earlier in this module) putting mandates in place that require the state board of education to establish and implement policies related to cyber-bullying. Recent research suggests that youth who are victims of electronic aggression are more likely to experience victimization in person, including sexual harassment, psychological or emotional abuse by a caregiver, witnessing an assault with a weapon, and rape (CDC, 2016f).

Although there is not a direct link between being a bully or being bullied and suicidal behavior, there is a correlation between the two. One study indicates that 22% of bullies, 29% of victims of bullying, and 38% of bully victims reported suicidal thinking or a suicide attempt (Borowsky, Taliaferro, & McMorris, 2013).

SAFETY ALERT Screenings of all youth at school and health-care settings should include questions related to bullying, as the bully, the bullied, or both, for identification of these risk factors so that intervention can occur.

Youth Violence

Youth violence occurs in minors and may continue into young adulthood. Youth violence may include being a victim of violence, a violent offender, or a witness to violence. According to the CDC (2015b), in 2012, more than 599,000 youth, age 10–24 years, received medical treatment for injuries related to assault. Violence has a negative effect on communities, increases healthcare costs, decreases property values, and disrupts social services (CDC, 2015b). Violence perpetrated by youths is one of the most visible forms of violence in society. In the United States and around the world, violence by youths flourishes in gangs, schools, and public areas.

As with assault and homicide committed by individuals in any age demographic, the problem of youth violence cannot be viewed as isolated from other problem behaviors. Violent adolescents and young adults exhibit a range of problems, from truancy and dropping out of school to substance abuse, compulsive lying, reckless driving, and contraction of sexually transmitted diseases. The recklessness and instability of adolescence is partially responsible for high levels of youth violence, but there are close links between youth violence and experience in childhood. Witnessing violence in the family, being abused, and prolonged exposure to a community culture

of violence can all condition children and adolescents to view violence as an acceptable means of solving problems (WHO, 2013b). Adolescents and young adults are most likely to commit and be victimized by assault and homicide, but other groups are at risk as well.

Intimate Partner Violence

Intimate partner violence (IPV) is the act of inflicting sexual, emotional, or physical harm on a current or previous partner or spouse. IPV can occur in any couple, including same-sex couples, adolescent couples, and older adult couples. The four main forms include physical violence such as punching, kicking, or biting; sexual violence that includes forced sexual acts or physically violent sexual contact; threats of both physical and/or sexual violence; and emotional abuse such as humiliating the victim or controlling the victim by diminishing self-esteem. Stalking can also be a form of IPV and is defined by the CDC (2016g) as "a pattern of repeated, unwanted attention and contact that causes fear or concern for one's own safety or the safety of someone else (e.g., family member or friend)." Some examples of stalking include the stalker sending the target continuous unwanted gifts and the stalker watching from a distance or showing up at a place where the target does not want them to be. The stalker may also instill fear by threatening to harm the target's friends, family, or pet or damage property or by sneaking into the targeted individual's home.

Although IPV is commonly believed to be committed primarily by men, research does not support this perception. Approximately 27.3% of women and 11.5% of men in the United States have been victims of IPV. Furthermore, 22.3% of women and 14% of men age 18 and older reported being a victim of severe physical violence by an intimate partner (CDC, 2015c).

When assessing an individual for IPV, nurses must remain nonjudgmental regardless of gender, sexual orientation, culture, or the socioeconomic status of the patient. IPV can result in long-lasting physical and emotional complications, and if the individual feels helpless or as though she will not be believed, then the violence is likely to continue. Most cases of IPV begin as mild emotional or physical abuse, but they eventually escalate to more severe violence and can even end in death. Nurses can help prevent this form of violence by being observant for the manifestations of IPV (discussed later in this section) and helping to empower the victim.

» **Stay Current:** Jacquelyn C. Campbell, PhD, RN, FAAN, and Nancy Glass, PhD, MPH, RN, FAAN, have created an instrument that helps determine the level of risk an abused woman has of being killed by her intimate partner. Visit their website at <http://dangerassessment.org> to learn more about it.

Sexual Abuse

Sexual abuse is defined by the DOJ as "any type of sexual contact or behavior that occurs without the explicit consent of the recipient to include forced sexual intercourse, forcible sodomy, child molestation, incest, fondling, and attempted rape" (DOJ, 2016). Sexual assault falls under the category of "Sexual Violence," which includes the following types: "Completed or attempted forced penetration of a victim;

completed or attempted alcohol/drug-facilitated penetration of a victim; completed or attempted forced acts in which a victim is made to penetrate a perpetrator or someone else; completed or attempted alcohol/drug-facilitated acts in which a victim is made to penetrate a perpetrator or someone else; non-physically forced penetration, which occurs after a person is pressured verbally or through intimidation or misuse of authority to consent or acquiesce; unwanted sexual contact; and non-contact unwanted sexual experiences” (CDC, 2016h). All individuals can be at risk for sexual violence regardless of gender, age, education, IQ, or socioeconomic status. Sexual abuse is often perpetrated by an individual the victim knows, such as an acquaintance, family member, teacher, authority figure, parent, sibling, or spouse. The majority of offenders involved in child sexual abuse are family members or are known to the child in some manner (American Psychological Association, 2013).

Elder Abuse

Elder abuse is the intentional physical, emotional, or sexual mistreatment or neglect of an individual 65 years of age or older. Although other forms of abuse have been declining over recent years, elder abuse has been on the rise. It is believed that this upward trend is due to increased reporting of elder abuse as the problem receives more attention. Even so, recent studies estimate that only one in every 14 cases of elder abuse is actually reported. The reasons behind decreased reporting are numerous but are believed to be the result of an unwillingness to report family members—who are the primary perpetrators of elder abuse. Other reasons for low reporting involve the physical or mental inability to report the abuse, as well as a fear of retaliation from the abuser (National Center on Elder Abuse, n.d.b). The older adult may also fear that they will not have a place to live if they report the abuser. The abuser may have even threatened to place the patient in a residential nursing facility if they report the abuse. The nurse will need to assure the patient that they will be protected and that safety is a priority.

The abuse of older adults—whether it is physical, emotional, or sexual—results in numerous consequences, including decreased health, inability to heal from broken bones, and an increased risk for mortality. Studies have also shown that elder abuse that results in hospitalization for the victim often leads to the individual being discharged to a nursing home or long-term care facility as opposed to returning home (Anetzberger, 2012). Nursing homes and other facilities are also not immune to mistreatment. The National Institute of Justice (2015) reports that the most common form of abuse sustained by older adults in residential care facilities was verbal and psychologic abuse by staff, although they found these incidents to be relatively uncommon. Nurses need to be vigilant in assessing for cases of maltreatment in older adults.

Clinical Manifestations

The signs of abuse can vary based on the population being abused as well as the type of abuse. IPV, for example, will often manifest with signs of intense fear and control, such as the victim not having access to cash and losing all contact with friends and family. The signs of physical and emotional abuse will also vary among populations, with children

reacting to psychologic abuse differently than adults. In cases of sexual abuse, however, the signs are primarily consistent across age demographics. Nurses should be vigilant in assessing for signs of abuse in all patients.

Manifestations of Physical Abuse

Infants have the highest prevalence of fatality due to physical abuse, which is likely related to the infant’s small body and occurrences of AHT. “Shaken baby syndrome” occurs in as little as 5 seconds of violent shaking. This action causes the infant’s brain to bounce back and forth against the skull, leading to bruising, swelling, pressure, and bleeding in the brain, all of which may lead to permanent brain damage. Shaking an infant may also lead to other injuries such as damage to the neck, spine, and eyes (U.S. National Library of Medicine, 2016). Gentle bouncing, playing, swinging, and bouncing associated with jogging while holding the infant do not cause AHT. If an infant falls or is accidentally dropped, it will cause a different type of brain trauma than that associated with shaken baby syndrome.

Many of the manifestations of physical abuse of a child are apparent, such as broken or fractured bones in different stages of healing, AHT, excessive bruising, and burns or scars in specific shapes (**Figure 32-2** »). More of these physical indicators are outlined in the Clinical Manifestations and Therapies table. Signs of long-term traumatic physical abuse can be evidenced by poor language, cognitive, and emotional development, primarily caused by the stress of abuse as an infant or young child. Advanced visual and motor impairment—such as blindness and spinal cord injuries—can also be indicators of physical abuse at a young age. A child who is being abused may also present with

Figure 32-2 » Examples of child abuse. **A**, This child’s feet were burned when the parent held the feet against a heater. **B**, Battered child showing bruises and lacerations.

behavioral changes. Some common changes include trouble sleeping, changes in eating habits, wetting the bed, avoiding specific situations or individuals (e.g., family gatherings, a once-trusted friend or relative), and participation in high-risk behavior (drugs, alcohol, dangerous sports) (CDC, 2016i; Meadows, 2013).

Youth violence can also result in physical harm to a child. According to a survey by the CDC (2016a), in the 30 days preceding the survey, 7% of high school students reported not attending school on one or more days because of not feeling safe. Youth violence is a nationwide issue that causes injury and death to youth victims. This violence also causes issues within the community, such as decreased property values. There are potential warning signs of violent behavior that cannot be modified, such as being a victim of bullying, being young at the onset of the first violent episode, witnessing violence at home, or having a major mental illness (American Psychological Association, 2016). Additional factors that may precipitate violence include substance abuse, gang involvement, and feelings of rejection and disrespect. The American Psychological Association also reports that new or active signs associated with youth violence include increased drug or alcohol use, frequent physical altercations, declining school performance, and carrying a weapon (2016).

IPV presents with physical manifestations similar to those of other forms of violence, such as bruises, broken bones, knife wounds, head injuries, and headaches. Individuals experiencing this form of abuse may begin using alcohol and other substances to cope with the abuse. Depression, suicide attempts, fear, and avoidance of social situations are common. Victims of IPV are often cut off from any form of support by their abuser; they are generally not encouraged to have relationships with family members or friends, and their freedoms are limited. Interestingly, victims of IPV and their children are at increased risk for being victims of violence, including homicide, when they are leaving the perpetrator.

Manifestations of physical abuse in older adults include bruises, contusions, or broken bones; however, these symptoms can also be explained away by a simple fall. Therefore, all major injuries in older adults need to be investigated for the possibility of physical abuse.

Manifestations of Psychologic Abuse

Bullying can include either physical or psychologic abuse or both. It is not always obvious that a child is a victim of bullying. A child may fear telling parents or authorities about the attacks because of fear of retaliation from the bully. Most symptoms of bullying are passive and could be overlooked. A child may experience an acute change in behavior and may decline participating in activities they previously found enjoyable (if the bully is present at these functions). Also, the child may begin to dislike school, have increased absenteeism, or experience a decrease in academic performance. Other manifestations include low self-esteem, loneliness, anxiety, depression, and suicidal ideations. There may also be somatic complaints such as frequent headaches and stomachaches (CDC, 2016j).

IPV abusers will seek to control victims' finances and decision-making abilities in order to prevent them from

leaving the relationship. Some perpetrators will even work to get their partner (or themselves) pregnant and then threaten to keep the child if the victim leaves. Individuals involved in IPV are likely to be intimidated by their abuser and reluctant to seek or accept help. Controlling abusers will likely accompany the victim to the hospital or treatment center for treatment of their injuries to ensure that the patient does not ask for help, and, depending on the type of abuse, to demonstrate repentance for the injuries (Benedictis et al., 2012). In situations such as these, it may be very difficult or even impossible for the nurse to talk to the patient alone. Nurses could try to schedule a follow-up appointment or express a willingness to help the patient at a later date if the patient wishes to come back alone.

In addition to assessing for typical signs of abuse, psychologic, or emotional, abuse should be assessed. General symptoms may include acute changes of behavior or frequent arguments between the caregiver and patient. The nurse may witness threatening, controlling, or belittling behaviors of the caregiver toward the patient. Another manifestation is the patient exhibiting dementia-like symptoms such as rocking, sucking, or mumbling to self (HelpGuide.org, 2016).

Manifestations of Sexual Abuse

Victims of sexual abuse may be withdrawn or combative, acting out in various situations. Emotions such as guilt, anxiety, depression, suicidal thoughts, and fear are quite common. In children who have experienced sexual abuse, one of the most pronounced indicators is an early sexual knowledge or early interest in sexual acts. Other children may regress instead, demonstrating behavioral difficulties, bed-wetting, and insomnia. Physical manifestations of sexual abuse at any age include injuries to genitals or anus, swollen genitals, bladder or kidney infections, sexually transmitted infections or diseases, unintended pregnancies, and pelvic inflammatory disease (National Sex Offender Public Website [NSOPW], n.d.).

In addition, there are warning signs that may be suggestive of a perpetrator of sexual abuse. Some examples of these behaviors include ignoring social, emotional, or physical boundaries; oversharing adult issues with a child; being overly interested in the sexuality of a teen; frequently walking in on children/teens in the bathroom; and exposing a child to adult sexual interaction with lack of regard (NSOPW, n.d.). If the nurse observes any of these behaviors in an older teen or adult, the nurse should assess the situation further.

Manifestations of Neglect

Some signs of neglect of an infant may include uncared-for diaper rash, dirty diapers, poor hygiene, poor eye contact or detachment, failure to thrive, and skin sores, rashes, and flea bites (National Society for the Prevention of Cruelty to Children [NSPCC], 2016). Healthcare providers need to be mindful when assessing infants, as some of these conditions may develop unrelated to neglect; therefore, if neglect is suspected, a further, more in-depth assessment must occur.

Children may display signs of neglect in various ways. Neglect may include anything from leaving a child home alone to more critical situations such as malnutrition. Poor hygiene,

dirty clothing, clothing that is too small or inappropriate for weather conditions, and appearing hungry or presenting with no money for lunch at school are all signs of neglect. Health and developmental problems may present as untreated medical or dental issues, not reaching developmental milestones, and poor language development. Living conditions may indicate neglect of a child as well, such as living in an unsanitary environment that has animal feces or urine that is not cleaned up, infestations of bugs leaving bites on the child, or even having to care for other family members at a young age (NSPCC, 2016).

Neglect in an adult relationship may also occur. Generally, emotional neglect is difficult to determine, as the symptoms may not be present or overt and usually consists of omissions (failing to meet the needs of the partner). An example of emotional neglect may involve one partner spending more time at work or with others than the other partner. Another example is a partner consistently not providing the emotional support that the other needs (Cohen, 2013).

Neglect is the most common form of abuse of the older adult (Ayalon, 2015). Similar to that in children, neglect of an older adult comprises physical needs not being met or care being intentionally withheld. Neglect in older adults may be difficult to identify and is underreported because many victims are unable to report due to physical, cognitive, or mental deficits. Because family members frequently are caregivers, the victim may also be reluctant to tell because they don't want them to get into trouble. Manifestations of neglect of older adults may include unexplained weight loss, dehydration, poor hygiene, unsanitary conditions, untreated medical issues, decubiti, unsafe living conditions (no electricity, heat, or running water), or desertion of the older adult (HelpGuide.org, 2016).

SAFETY ALERT Older adults often go unheard when complaints of abuse occur; claims are often dismissed because the listener thinks the older adult is confused or disoriented. As a nurse, you must explore and report any complaint related to any form of abuse. It is not the job of the nurse to determine whether abuse is occurring, but rather to advocate for the patient by obtaining as much information as possible and reporting the potential abuse per institution protocol and state regulations.

Cultural Considerations

Cultural considerations in cases of abuse are twofold, with some acts or traditions presenting as signs of abuse (such as cupping or coin rubbing), and other cultures partaking in acts that Western culture considers abusive (hitting one's wife for disobedience or hitting children with objects as a form of punishment). In cases of suspected abuse due to marks on the patient's body, nurses must take cultural healing practices into consideration. The practices of cupping and coin rubbing—generally practiced by many Asian cultures, as well as individuals who participate in holistic healing—can both create marks on the body that could be misinterpreted as signs of abuse (**Figure 32-3** ») (Ward et al., 2013). Cupping is the act of placing a glass cup on the skin and then using heat to create suction; often this is performed to promote blood flow and overall healing. The

Figure 32-3 » It is important to differentiate cultural practices such as **A**, cupping, and **B**, coining, from signs of child abuse.

result of the procedure can be circular red welts or even dark bruising, which are often found along the individual's back. Coin rubbing is used to treat a multitude of ailments from headaches and fevers to minor illnesses, but it also leaves marks on the skin. In this treatment, warm oil is rubbed on the skin and then a coin is rubbed in a diagonal line until long marks appear. If these marks are seen without knowledge of their origin, they may look almost like marks from a whip. Neither of these treatments are abusive in nature but are instead a form of healing.

Some cultural conceptions of punishment can be considered child abuse. Physical punishment of a child varies among cultures from spanking or hitting their hand, to burning the child, to even hitting the child with a cord to leave cuts (see the Focus on Diversity and Culture feature). Many of these practices may not seem acceptable from a Western perspective, but in some areas of Trinidad and

Focus on Diversity and Culture

Cultural Interpretations of Abuse

- Some Latin American cultures discipline children by having them kneel on uncooked rice for a short period of time. Practices similar to this are common in many cultures and are not considered to be harmful (Pennsylvania Family Support Alliance, 2016).
- Elder abuse is a growing problem around the world, and it is overlooked and ignored in numerous cultures (WHO, 2013c).
- Certain interpretations of holy scripture and teachings by different religions allow for women to be hit by their husbands. Women of those belief systems may be reluctant to report their abuse based on religious grounds.
- Many victims of IPV from other countries who live in the United States do not report abuse because of a fear of deportation for themselves or their families.
- Some individuals do not report IPV because it would dishonor or shame their families. Individuals who reported this custom were originally from South Asia, Bangladesh, China, Japan, Jordan, Latin America, and Vietnam (Montalvo-Liendo, 2009).

Nigeria, hitting a child with a cord is a common form of punishment. Similarly, in many cultures—particularly Chinese and Vietnamese—it is acceptable to discipline a child with the use of sticks. Burning a child, particularly with a shaped object, could be a tradition of punishment passed down within an individual family, whereby the mother was burned as a child so she deems it acceptable to do the same to her child. In cases of suspected culturally influenced abuse, nurses recognize that parents may not see the injuries to their child as inappropriate or even abusive but rather as an unfortunate result of the child's behavior. It is not a nurse's place to judge; however, nurses are mandated reporters of child abuse and should follow the state regulations and facility protocol on reporting, even if it is a cultural form of discipline.

Collaboration

Usually, the best way to treat abusive families is to use an interprofessional approach involving nurses, physicians, social workers, protective services personnel, law enforcement, and, often, lawyers. Most families are more open to accepting help and may be willing to develop new behavior patterns for a short time following a crisis, but changing behaviors over time requires more work and support. It is common for family members to return to previous, unhealthy behavior patterns, including those that condone or promote abuse.

The nurse plays an important role in the interprofessional team providing treatment to the child who is the victim of abuse. The nurse should ensure that the team creates a safe environment in which the child feels supported at home, at school, and in the therapeutic environment. Children of abuse are often deprived of control, so it is important to shift control back to the child while helping the child feel empowered. Building trust is also imperative, because it will help

the nurse develop a rapport with the young patient. Building trust with a child should never involve lying or making false promises; for example, do not promise that the child's parent(s) will not *get in trouble*—that is for Child Protective Services and the courts to decide. Nurses are also “mandatory reporters,” so if a child discloses information about abuse, the nurse must report the situation; therefore, it would also be a false promise to say, or imply, that information will be kept between the nurse and the child. For more information, see the exemplar on Mandatory Reporting in the module on Legal Issues.

As part of the interprofessional team, the nurse should plan interventions that will encourage affective release in a supportive environment. Play therapy helps these children explore traumatic themes, fears, and distorted beliefs. It is a nonthreatening way to process thoughts and feelings associated with abuse. Art therapy provides an opportunity to express feelings for which the children have no words. Therapeutic stories can be used to present the traumatic issues of abuse, link victims' feelings to their behaviors, and describe new coping methods. Journal writing can help older children cope with intrusive thoughts and feelings. They often choose to bring their journal into therapy sessions.

Diagnostic Tests

Diagnostic tests cannot prove that an individual is being abused, but some tests, such as x-rays, MRIs, and CT scans, can show indicators of possible abuse. In most cases, tests are used to diagnose the full extent of the damage in order to properly treat the patient. In cases of physical abuse, an ultrasound or a CT scan of the abdomen can check for abdominal or organ injuries, CT scans of the head will show hemorrhage or skull fractures, and an MRI of the spine will show any spinal injuries. For sexual abuse, swabs for DNA are needed to provide the abuser's identity, and urine samples will show bladder or kidney infections. Tests for sexually transmitted infection should be conducted. Pregnancy tests should be administered to females of childbearing age who are victims of sexual abuse. The range of testing to be conducted will depend on the type of abuse, injuries, and consent of the victim.

Pharmacologic Therapy

Because injuries associated with abuse vary greatly depending on the situation and type of abuse, pharmacologic therapies also vary. Physical injuries such as broken bones and dislocations will require pain medication, sedatives, and anti-inflammatories while setting the injury and for resultant pain. Stabbings, gunshot wounds, or other penetrating injuries will require medications to prevent or heal infections as well as fluids to correct fluid volume deficit. Tetanus boosters or vaccines will be needed for most deep penetrating wounds. In cases of physical and emotional abuse, the patient may experience posttraumatic stress disorder (PTSD), which could require medication in addition to therapy interventions (see Exemplar 32.C on PTSD).

Nonpharmacologic Therapy

The physical effects of abuse will often heal long before the emotional effects have even begun to fade; therefore,

Clinical Manifestations and Therapies

Abuse

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Infant abuse	<ul style="list-style-type: none"> Untreated diaper rash; lengthy time spent in soiled diapers; poor hygiene Poor eye contact; detachment Frequent ear infections (from bottle propping) Failure to thrive Sores; rashes; flea bites Fractures (multiple or in various stages of healing, inconsistent with explanations of injury); bruises; welts AHT; shaken baby syndrome 	<ul style="list-style-type: none"> Treat physical injuries. Give antibiotics for any infections as prescribed. Reporting of the abuse is mandatory. Ensure the safety and security of the child.
Child abuse and youth violence	<ul style="list-style-type: none"> Bruises or welts in unusual places or in several stages of healing; distinctive shapes Wary of physical contact with adults Behavioral extremes of withdrawal or aggression Burns (especially cigarette burns; immersion burns of hands, feet, or buttocks; rope burns; or distinctively shaped burns) Apprehensive when other children cry Fractures (multiple or in various stages of healing, inconsistent with explanations of injury) Joint swelling or limited mobility Long-bone deformities Lacerations and abrasions to the mouth, lip, gums, eye, genitalia Human bite marks Signs of AHT Deformed or displaced nasal septum Bleeding or fluid drainage from the ears or ruptured eardrums Broken, loose, or missing teeth Difficulty in respirations, tenderness or crepitus over ribs Abdominal pain or tenderness Recurrent urinary tract infection Emotional and/or behavioral problems Increased absenteeism from school Severe injuries such as penetrating wounds or gunshot wounds 	<ul style="list-style-type: none"> Treat physical injuries. Give antibiotics for any infections as prescribed. Therapy may be behavioral, cognitive, group, or play therapy depending on developmental stage. Reporting of the abuse is mandatory. Ensure the safety and security of the child.
Bullying	<ul style="list-style-type: none"> Acute change in behavior Decreased participation in previously enjoyed activities Disliking school; increased absenteeism; decrease in academic performance Low self-esteem; loneliness; anxiety Depression; thoughts or plans for suicide Frequent somatic complaints 	<ul style="list-style-type: none"> Allow child to express feelings; give validation of concerns. Notify proper authorities (teacher, school administrators) so that adequate supervision may occur. Therapy for depression; may be behavioral, cognitive, group, or play therapy depending on developmental stage. Ensure the safety and security of the child.
Sexual Abuse	<ul style="list-style-type: none"> Torn, stained, or bloody underwear Pain or itching in genital areas Bruises or bleeding from external genitalia, vagina, rectum Poor peer relationships Withdrawal Sexually transmitted disease Unwilling to participate in physical activities Swollen or red cervix, vulva, or perineum Wears long sleeves and several layers of clothing even in hot weather Semen around the mouth or genitalia or on clothing Pregnancy Delinquency or running away Inappropriate sexual behavior or mannerisms Regressive behaviors 	<ul style="list-style-type: none"> Treat physical injuries. Test for sexually transmitted diseases and infections. Administer pregnancy test. Take DNA swabs for identification of the perpetrator. Treat for depression and/or suicidal behavior. Therapy may be behavioral, cognitive, group, or play, depending on developmental stage. Educate on rights and ability to report to authorities. Consider behavioral therapy for perpetrators.

Clinical Manifestations and Therapies *(continued)*

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Intimate partner violence (IPV)	<ul style="list-style-type: none"> Chronic fatigue Casual response to serious pain Vague complaints, aches, and injury or excessively emotional response to a relatively minor injury Frequent injuries Recurrent sexually transmitted diseases Frequent ambulatory or emergency department visits Muscle tension Nightmares Facial lacerations Depression Injuries to chest, breasts, back, abdomen, or genitalia Anorexia or other eating disorder Bilateral injuries of arms or legs Anxiety Symmetric injuries Drug or alcohol abuse Obvious patterns of belt buckles, bite marks, fist or hand marks Suicide attempts Poor self-esteem Burns of hands, feet, buttocks, or with distinctive patterns Headaches Gastrointestinal or stress ulcers 	<ul style="list-style-type: none"> Treat physical injuries and physiologic conditions. Treat psychologic effects such as depression with medication or therapy. Suggest substance abuse counseling for perpetrator and victim, as needed. Provide referrals for community services, support groups, and shelters.
Elder abuse	<ul style="list-style-type: none"> Constant hunger or malnutrition Listlessness Poor hygiene Social isolation Inappropriate dress for the weather Chronic fatigue Unattended medical needs Poor skin integrity or decubiti Contractures Urine burns/excoriation Dehydration Fecal impaction Bruises and welts Withdrawal Burns Confusion Fractures Fear or suspicion of caretaker, family members, healthcare providers Sprains or dislocations Lacerations or abrasions Evidence of oversedation Failure to meet financial obligations 	<ul style="list-style-type: none"> Treat physical injuries. Treat dehydration and malnutrition with increased fluids and food intake. Treat psychologic effects such as depression with medication or therapy. Arrange for respite services. Consider adult day care. Reporting of the abuse is mandatory. Ensure the safety and security of the older adult. Refer perpetrators to treatment or therapy. Arrange transfer of legal authority.

nonpharmacologic therapies used with victims of abuse are numerous and important for the patient. Therapy, counseling, and support groups are the most commonly prescribed forms of treatment in cases of abuse. The type of therapy will depend on the personality, needs, and desires of the patient.

Domestic Violence Shelters

Domestic violence shelters offer a broad array of services for patients of all ages, including immediate shelter for

victims and their children and referrals to agencies that provide group therapy for parents and children, advocacy, and parent training. Some shelters may be gender specific, but most offer shelter regardless of gender. Many shelters offer lists of attorneys and other professionals who offer services with sliding-scale fees. Many programs offer outreach services, including education and training on workplace violence and elder abuse. Nurses working in all settings should have contact information available for community domestic violence shelters.

NURSING PROCESS

Care of an individual who has been abused will vary depending on the type of abuse and the age of the individual. A patient's reaction to the abuse will also affect care, especially if fear, shame, and/or self-blaming are present. Nurses treat individuals on a patient-by-patient basis, assessing the need of a specific individual rather than the needs of a supposedly *typical* abuse victim.

Assessment

The nurse's assessment in cases of abuse will be in order of the severity of the injuries. Life-threatening injuries will be assessed first, and other injuries will be assessed after the patient's safety is ensured. A complete medical history will be performed to determine if the patient has a history of injuries that could be the result of abuse. Nurses need to consider the patient's emotional state; victims of abuse could be scared of their abuser or of being blamed for the abuse. Similarly, some patients may be more nervous around staff of the same gender as the abuser; if possible, make adjustments to the staff directly caring for that patient. Some hospitals now assess victims of violence on locked units to minimize exposure of victims and hospital staff to perpetrators.

Diagnosis

Nursing diagnoses are dependent on the patient's current physical and psychosocial status. Patients who have experienced abuse could have a range of diagnoses, depending on the mode of abuse. Diagnoses relevant to actual or suspected victims of child abuse, elder abuse, or interpersonal violence may include, but are not limited to, the following:

- *Pain, Acute*
- *Powerlessness*
- *Post-Trauma Syndrome*
- *Sexual Dysfunction*
- *Social Isolation.*

(NANDA-I © 2014)

Planning

Goals for a patient who has experienced abuse will change according to the nursing diagnoses and the individual. The age of the patient will also affect how an individual reacts to having been injured as the result of abuse. Examples of goals for the patient who has experienced abuse are as follows:

- The patient will be safe and free from harm.
- The patient will report mild to no pain.
- The patient will ask for help in safely resolving the abusive situation.
- The patient will honestly convey feelings of fear, helplessness, anger, or depression.
- The patient will report any suicidal ideation.
- The patient will acknowledge that she is not responsible for the abuse.
- The patient will practice healthy coping mechanisms.

Implementation

The nurse's ability to implement care measures will depend on the patient's willingness to accept help in leaving or reconciling the abusive situation. In most states, some forms of abuse, such as child abuse and elder abuse, must be reported to the proper authorities. However, reporting other forms of abuse—including IPV and certain instances of sexual abuse—is often left to the discretion of the victim.

Promote Safety

In cases of abuse, the patient's safety is the primary concern. Because of mandatory reporting laws, nurses must report all suspected cases of child abuse. In some states, it is also legally mandated for nurses to report the abuse or neglect of an older adult. Cases of IPV are often left to the victim to report, but some areas have laws concerning mandatory reporting of IPV. The use of specific weapons and the nature of the injuries are often factors for mandatory reporting of IPV in states with those laws. Nurses must be aware of regulations within the state where they are practicing and abide by those laws. When abuse is suspected, the nurse should follow institutional policies and guidelines for reporting. In the clinical setting, the nurse usually is required to notify a supervisor to begin the reporting process.

When mandatory reporting is not indicated, it is imperative for nurses to provide the patient with information about resources for seeking help. Adults who have experienced a form of abuse can be gently encouraged to seek assistance in promoting their own safety. If the patient chooses not to seek assistance, then information should be provided in case assistance is ever needed. Resources can be in the form of the patient's friends and family members or community liaisons who can work to help the individual find a secure living environment. Other resources can be offered, such as police, lawyers, and agencies that can provide ongoing assistance for the victim. Nurses encourage the patient to accept help in seeking an abuse-free living situation, but the decision ultimately lies with the patient. Some individuals will not be ready to seek help, and while the nurse may disagree with this decision, he must refrain from judgment and be respectful of the patient's decision. All nurses can do in these situations is offer assistance and resources; this lets the victim know that help is available if it is needed in the future.

Establish a Therapeutic Relationship

Establishing appropriate modes of interaction with a patient who has been abused is vital. A large factor in establishing a therapeutic relationship is establishing trust. Many cases of physical abuse involve psychologic abuse, which often belittles an individual's sense of self-worth and self-love, sometimes to the point that they feel it is impossible for them to do anything correctly. A healthcare worker who appears to be angry or disappointed in a patient for not choosing to seek assistance in leaving an abusive situation will shatter all forms of trust that had been established with that patient. Nurses need to work to establish a trusting relationship with adults who have been abused, assuring them that they are in a judgment-free and safe setting.

When nurses suspect child abuse, age-specific considerations must be employed. The child needs to feel safe and secure, particularly from the potential abuser. All early conclusions about the situation should be dismissed, because it is unwise to assume knowledge of a situation until all the details are presented. Child abuse is a very serious situation and should never be taken lightly; however, nurses should be aware that cases of false reporting do exist. The majority of these cases are not malicious on the part of the child but are rather the result of a misunderstanding or a leading question on the part of the healthcare professional. All forms of leading questions should be avoided when talking to children about abuse. It is appropriate to ask a child how she hit her head; it is inappropriate to ask a child if her mother slammed her head into a kitchen counter. Children in high-stress situations will sometimes work to tell an adult what they think that adult wants to hear. With this in mind, nurses should ask open-ended questions with no indication of the answer they expect to receive. It is imperative for nurses to follow organizational protocols with regard to suspected child abuse interviews.

Facilitate Communication

Accepting help after having experienced abuse for weeks, months, or years is sometimes exceptionally difficult for victims. Elements of fear of their abuser, lack of social support, decreased financial resources, and a sense of hopelessness all contribute to an apparent disinclination to accept assistance. Nurses need to understand these fears to better assist patients in this difficult situation. Many resources can be offered to help combat these individual reservations. For example, the patient can be put in contact with local law enforcement agencies to file an order of protection against the abuser to ensure some degree of safety from retaliation. Connections can also be fostered with social workers, counselors, and community liaisons to find safe housing and assist with social and financial support. Nurses reassure patients that options and resources are available to help them move away from the abusive situation being experienced.

Promote Empowerment

Helping patients achieve a sense of control within the situation is one of the first steps in helping them accept assistance. All forms of abuse include an element of control on the part of the perpetrator and generally result in taking control away from the victim. In working to help patients regain that sense of control, nurses can help empower them

to leave the situation. Support groups and individual therapy are recommended to help the patient talk about the abuse and potentially connect with others who have experienced similar situations. Education should occur to ensure that the patient is aware of community services, support groups, and law enforcement numbers. Ensuring that a safety plan is developed will also aid in empowering the patient (see Patient Teaching: Developing a Safety Plan). Interventions vary depending on the individual's age and circumstances, so referrals are made on a case-by-case basis.

Evaluation

All forms and cases of abuse are different depending on the age of the victim and the circumstances of the abuse; therefore, the outcomes in these cases will vary. It is important to set realistic goals for patients. Some desired outcomes include the following:

- The patient remains free from injury or harm.
- The patient has a safety plan in place.
- The patient seeks assistance when needed.
- The patient demonstrates knowledge of the resources available to individuals in abusive situations.
- The patient verbalizes awareness that she is not responsible for or deserving of abuse.
- The patient openly communicates her fears with regard to the abusive situation.

Individuals with severe injuries related to abuse may need additional evaluation and follow-up, including potential surgical interventions. The nurse should treat these patients like other patients undergoing surgery, including prepping the patient for surgery and providing aseptic care of the surgical wound. In addition, nurses may need to continue to suggest counseling or group therapy or other types of emotional support to individuals who seem reluctant to get help for emotional trauma. When a nurse sees a patient repeatedly because of injuries from abuse, the nurse should continue to advocate for patient safety and encourage the patient to seek help. The patient may not be receptive to help after a first or second instance of abuse, but the patient may be more likely to want help if the abuse has happened repeatedly. Continued evaluation and support of the patient sustaining abuse is necessary to promote the most positive outcome possible.

REVIEW Abuse

RELATE Link the Concepts and Exemplars

Linking the exemplar of abuse with the concept of development:

1. What protective factors would indicate a child probably has not experienced abuse? At age 3? At age 15?
2. What factors would put a child at risk for abuse?

Linking the exemplar of abuse with the concept of mood and affect:

3. What mood and affect would you anticipate a victim of abuse might display?

4. What nursing assessment regarding mood and affect would be a priority when admitting a patient who was abused by a family member?

REFLECT Apply Your Knowledge

Lucy Barnes, a 30-year-old woman who is 25 weeks pregnant, comes to the emergency department of Parkfield Community Hospi-

tal. She says she fell and hit her head at home and is having headaches. During the assessment, the nurse notices multiple bruises in various stages of healing over her body and asks Lucy how she got them. Lucy says that she is just clumsy and falls a lot. While the nurse is assessing Lucy, another nurse enters the room to tell Lucy that her boyfriend is there to take her back home. At that point, Lucy becomes frightened and tells the nurse that her boyfriend has hit her many times before and had knocked her down today. She says he

has threatened to kill her if she tells anyone, and she does not want to leave with him.

1. Identify questions that the nurse could use in continuing her assessment and in documenting the discussion with Lucy.
2. What other people should be involved in Lucy's care in the emergency department?
3. Who should make the decision about where Lucy should go?

Exemplar 32.B Multisystem Trauma

Exemplar Learning Outcomes

32.B Analyze multisystem trauma as it relates to trauma.

- Describe the etiology of multisystem trauma.
- Compare the risk factors and prevention of multisystem trauma.
- Identify the clinical manifestations of multisystem trauma.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual with multisystem trauma.

Overview

Multisystem trauma refers to injuries affecting multiple body systems such as the neurologic, respiratory, and circulatory systems. There are many causes of multisystem trauma, such as abuse, motor vehicle crashes, poisonings, drownings, falls, natural disasters, human-caused disasters, homicide, and suicide. Nearly 80% of pediatric multisystem trauma victims include head trauma. The CDC (2015d) further reports unintentional injuries as the leading cause of death in the United States for people age 1–44 years. According to the CDC (2016k), unintentional poisonings are the leading cause of injury-related deaths, followed by **motor vehicle crashes (MVCs)**.

Etiology

Poisonings are the leading cause of injury death in the United States, with 47,055 people losing their lives to drug poisoning in 2014 (CDC, 2016l) (see **Figure 32–4** »). Prescription and illicit drugs cause the majority of these poisonings. MVCs are a major concern because of the significance of injuries sustained. The leading causes of death related to MVCs include teenage drivers, distracted driving, and alcohol- or drug-impaired driving (CDC, 2015e, 2016m). Note that the leading causes of death in the United States also indicate the prevalence of nonfatal injuries related to the same cause. In addition, all causes of fatal injuries are also causes of multisystem trauma.

Risk Factors

Although there is no way to fully cover all risk factors associated with multisystem trauma, some of the major causes of injury and death are discussed in this section.

The CDC (2016l) indicates that 1.6 times more males died from poisonings than females, with the highest death rate

- Differentiate care of patients with multisystem trauma across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with multisystem trauma.

Exemplar Key Terms

Motor vehicle crash (MVC), 2136

Traumatic brain injury (TBI), 2139

Whiplash, 2139

being between the ages of 45 and 54 years. Opioid analgesics accounted for 40% of all drug-related poisonings.

While some MVCs are influenced by forces of nature, such as a deer or other forms of wildlife running across the road or a sudden ice or rain storm, the primary cause of accidents is human error. Some of the main risk factors for motor vehicle incidents include age, speeding, distraction, aggressive driving, and impaired driving.

Both young and older drivers are at particular risk for motor vehicle crashes. Beginning drivers age 16–19 are still gaining experience with a variety of driving conditions and situations (**Figure 32–5** »). They are also more likely to take risks while driving. Individuals in this age group are three

Figure 32-5 » Beginning drivers take more risks and are three times more likely to be involved in a crash.

times more likely to be involved in a crash than drivers age 20 and older (CDC, 2015e). Older adult drivers (age 65 and older) are at risk for MVCs because of preexisting health conditions that can flare up while driving (such as heart or respiratory problems) and decreases in sensory perception (reduced eyesight and hearing).

Unsafe driving practices are a risk within every age group. Speeding and impaired driving in particular contribute to the majority of MVCs. When a motor vehicle is moving too quickly, it is impossible to stop effectively if there is a sudden incident on the road—such as a car stopping suddenly, an animal walking across the road, or a pedestrian unexpectedly crossing the street. Impaired driving limits the individual's ability to react quickly, potentially leading to an accident due to delayed response time. Other driving traits that represent a risk for MVCs are driver distraction and aggressive driving. Distraction can result from using a phone, dropping a beverage or food item while driving, or even having talking or crying children in the car. Aggressive driving leads to tailgating and other dangerous driving habits that increase the risk for accidents.

Refer to the following sections in this module for additional information related to risk factors for multisystem trauma related to these etiologies: Interpersonal Violence, Community and Systemic Violence, and Accidental/Incidental Trauma.

Prevention

Knowledge of the causes and at-risk groups directs prevention efforts. Trauma-related injuries and deaths are preventable. Injury is the greatest health hazard for most age groups; therefore, injury prevention must be integrated into every health contact with all patients.

Poisonings can be prevented by following the prescription and by not taking too much or not taking it too frequently. Make sure that all medications are kept in a protected area and, if children are in the home, that child-proof lids are used. Turn on the light when taking medications and keep medication in the original container. Medications for children, teenagers, and older adults should be monitored to ensure that no errors occur during administration. Substance abuse may also lead to poisoning;

therefore, it is important to encourage the abuser to obtain substance abuse treatment and not enable the abuse by providing the drug or money for the drug.

Many teens learn to drive and have a license by 16 years of age. They often transport friends, get distracted by social interactions in the car, have little experience with actions to take if a car slides or has mechanical problems, may drink and drive, and are often tired when driving. Several states have instituted graduated driver licensing to help decrease some risks. Graduated driver licensing is an approach used to decrease MVCs among novice teen drivers. Common approaches are to increase the period required for a learner's permit, decrease driving after dark, and limit passengers in the car. Another method that has been suggested to improve safety records is to involve parents in practice driving times. Driving should always be presented as a privilege and a responsibility. Serious consequences such as losing the ability to drive for a time after any infraction can be suggested to parents. Because of the great risk of injury and death from MVCs, ask at each health visit if the teen drives or rides with other teens, what rules parents have established about driving, and whether the teen ever drinks and drives or rides with someone who does. Reinforce the need to wear a safety belt at all times and to never drink and drive. Many injuries can be prevented by using protective gear and following safety guidelines.

Prevention efforts among older adults can be in the form of regular eye and hearing examinations as well as considerations of side effects of any medications being taken. Various injury prevention efforts for all ages are listed in **Table 32-2** ».

SAFETY ALERT Older adults are frequently on multiple medications that may cause vertigo, drowsiness, or orthostatic hypotension. The patient should be educated on the side effects of the medications and be advised of the dangers of driving while taking the medication.

Patient Teaching

Pool Safety for Children

Parents of children who have easy access to a swimming pool or body of water should be educated on water safety:

1. Never leave children unattended around water. Provide constant, undistracted supervision.
2. Ensure that all children know how to swim (enroll in swim lessons).
3. Have inexperienced swimmers wear Coast Guard-approved life jackets.
4. Prevent unsupervised access to pools (install locks, alarms, monitoring system and fencing).
5. Learn first aid and CPR.
6. Educate children to not play around drains or suction devices.
7. If a child is missing, check the water first.

TABLE 32–2 Strategies for Preventing Injuries Based on Top Three Causes of Death per Age Group

At-Risk Group or Behavior and Top Three Causes of Death	Injury Prevention Strategy
Newborns/infants: 0–12 months: Unintentional suffocation Homicide (unspecified) Homicide (other specified)	<ul style="list-style-type: none"> ■ Never place a newborn or infant face down on soft surfaces. ■ Do not use soft bedding, pillows, or crib bumpers, and ensure the mattress is the correct size and not covered in plastic and that no plastic bags are accessible. ■ Broken balloons are a choke hazard, so it is important to make sure that infants are unable to reach a balloon or any broken pieces. ■ Choose an infant-only car seat or a convertible seat suitable for an infant. Always have infant ride in a rear-facing car seat. Never place a rear-facing car safety seat in the front seat with an active passenger air bag. ■ Ensure that parents and caregivers have necessary resources to properly care for an infant. Make sure that they have adequate assistance in caring for the child to prevent exhaustion, frustrations, and resentment. ■ If a parent has a mental illness, make sure that the mental illness is effectively treated and the parent is stable, especially while taking care of infants and young children. ■ Report any suspected abuse of a newborn or infant to the proper authorities.
Toddlers and preschoolers: 1–4 years: Unintentional drowning MVC Homicide (unspecified)	<ul style="list-style-type: none"> ■ Monitor toddlers at all times, especially during bath time or around any water. Toddlers can drown in as little as 1 inch of water. ■ If there is a swimming pool accessible, it is important to have a protective gate around the pool and to have pool alarms indicating unexpected motion in the water. If the toddler or preschooler's home is near a body of water such as a pond or a lake, a protective barrier (such as a fence) should be installed. The toddler/preschooler should be attended at all times while outside. See the Patient Teaching feature for more information on pool safety. ■ Enroll toddlers and preschoolers in swimming lessons. They will be taught safety around water as well as basic life-saving techniques such as floating. ■ Insist on safety seat use for all trips. Use an approved safety seat only. Know the laws in your state. Some states now require children up to age 2 to be in rear-facing car seats (Pennsylvania Department of Transportation, 2016). Toddlers and preschoolers are not large enough to use car seat belts. ■ Report any suspected abuse of toddlers or preschoolers to the proper authorities.
School-age: 5–9 years: MVC Unintentional drowning Unintentional fire/burn 10–14 years: MVC Suicide (suffocation) Suicide (firearm)	<ul style="list-style-type: none"> ■ Verify that the school-age child is belted in properly before starting car. Forward-facing car seats and booster seats are used in the backseat. These child restraint systems must be used until the child is 57 inches tall (or 8–12 years of age) and can safely use regular car safety belts. The backseat is preferred for all children and should be the only location used for children 12 years and younger. ■ Always use both lap and shoulder belts. Make sure the lap belt fits low and tight across the lap/upper thigh area and the shoulder belt is snug across the chest and shoulder to avoid abdominal injuries. ■ Use locking mechanisms on hot tubs. Install fencing or a barrier to prevent children from gaining access to a pool or body of water. ■ Do not allow children to dive into pools less than 9 feet deep, and teach them to not play around drains. ■ Always supervise children, even if a lifeguard is present. At large bodies of water (e.g., ocean or lake) make sure that the child wears an approved flotation device. ■ Fire detectors should be working in all homes regardless of age group. The detector should be tested monthly. ■ Have a developed fire escape plan and test it routinely. Have an identified meeting place outside the home. Teach children to stay low when smoke is present. ■ Maintain the home's water heater at 120 degrees to prevent scalding. ■ Use the back burner on the stove, keeping pan handles facing back so that children cannot reach. Monitor stove and oven at all times while in use. ■ Educate children that steam can also cause burns. Microwaves easily cause food to heat quickly and let off steam; therefore, a child needs to understand microwave safety as well as being careful with microwave-prepared foods.
Adolescents and young adults: 15–24 years: MVC Homicide (firearm) Unintentional poisoning	<ul style="list-style-type: none"> ■ Promote school-based education programs. ■ Enforce rules about safe driving, including use of seat belts for every trip. ■ Discourage drug and alcohol use. ■ The best way to protect adolescents from gun violence is to remove all guns from the home. If there are guns in the home, they should be stored in a securely locked container, with the ammunition stored in a separate locked container. ■ Monitor for warning signs of suicide such as behavioral changes, low self-esteem, and hopelessness. Obtain professional assistance if warning signs are present. ■ Parents should maintain involvement with their teens and provide a safe, stable home. Maintain a supportive yet non-intrusive relationship. ■ Teens should be encouraged to be involved in extracurricular activities.
Adults: 25–34 years: Unintentional poisoning MVC Homicide (firearm) 35–64 years: Unintentional poisoning MVC Suicide (firearm)	<ul style="list-style-type: none"> ■ Take prescription medications as directed. ■ If substance abuse is present, encourage treatment. ■ Use seat belts for every trip. Drive following all laws such as speed limit, stopping at all stops signs/lights, and so forth. ■ Do not drive under the influence of prescription medication, illicit drugs, or alcohol. Maintain focus and do not use cell phone while driving to eliminate being a distracted driver. ■ Monitor for warning signs of depression (see the module on Mood and Affect). Intervention should immediately occur if suicidal ideation is present. ■ Monitor for warning signs of aggression (see the Concept section of this module).

TABLE 32–2 Strategies for Preventing Injuries Based on Top Three Causes of Death per Age Group (continued)

At-Risk Group or Behavior and Top Three Causes of Death	Injury Prevention Strategy
Older adults: 65+ years: Unintentional fall MVC Suicide (firearm)	<ul style="list-style-type: none"> ■ Encourage regular vision exams, driving ability screenings, and community programs. ■ Evaluate potential effects of medications for both driving purposes and determining fall risk potential. ■ Encourage exercise to maintain strength and endurance while ambulating. ■ Eliminate trip hazards such as rugs and items placed in walkways or on stairwells, and keep walkways illuminated at night. ■ Monitor for warning signs of depression (see the module on Mood and Affect). Intervention should immediately occur if suicidal ideation is present.

Clinical Manifestations

MVCs, violence, abuse, and disaster-related events often result in a combination of physical and emotional injuries. Physical injuries can range from mild (minor scrapes and contusions) to severe (broken bones, head injuries, and even fatal injuries). When emotional injuries are present, they are often in the form of acute trauma syndrome (especially if other victims were severely or fatally injured) or a fear of exposure to the same event. Nurses will see a wide range of injuries as the result of trauma-related events.

Common Injuries

Injuries are very common as the result of trauma, with some of the more prevalent injuries being whiplash, **traumatic brain injury (TBI)**, spinal cord injuries, facial injuries, internal organ damage, and fractures. **Whiplash** results when a sudden impact to a motor vehicle causes an individual's head and neck to be forcibly contorted, resulting in injury to the spine. Spinal injuries are common in trauma and can result in partial or complete paralysis. Facial injuries and *traumatic brain injuries* (brain trauma that occurs after a sudden blow to the head) often occur in trauma-related events due to the individual's head hitting the dashboard, steering wheel, or air bag; blunt trauma from a violent assault; or objects falling on the victim's head.

Although wearing a seat belt can save a life, seat belts also can cause injuries during a crash. Common injuries from a seat belt are fractured ribs, fractured collarbone, internal injuries, and organ damage, as well as the potential for a punctured lung secondary to broken ribs.

Collaboration

Collaborative care of the patient who has sustained multisystem traumatic injury depends on a team approach (**Figure 32–6** ►). The team includes health personnel on site and the nurses, physicians, and surgeons at the hospital. Providing trauma care with a team focus helps each team member know his or her role. Prompt delegation of tasks and responsibilities improves the patient's chances for survival and decreases the morbidity that may result from traumatic injuries.

► **Stay Current:** Many organizations such as the Society of Trauma Nurses and the American College of Surgeons offer courses in trauma care for nurses. For more information, visit the Advanced Trauma Care for Nurses page at <http://www.traumanurses.org/atcn> and the Advanced Trauma Life Support page at www.facs.org/trauma/atls/about.html.

Community awareness and health promotion efforts require collaboration as well. Healthcare institutions along with local fire departments, law enforcement, and health departments will often combine to offer awareness campaigns regarding issues related to motor vehicle crashes, violence prevention, and disaster readiness. Communities have disaster readiness plans and train healthcare professionals and volunteers on emergency readiness and response.

Diagnostic Tests

Because trauma-related injuries vary widely, so do the diagnostic tests used to assess the severity of those injuries. Common diagnostic procedures include MRIs, CT scans, x-rays, and ultrasounds. These procedures can help determine the severity of head, neck, and back injuries and to identify internal bleeding, broken bones, or torn muscles. An EEG can be used to diagnose changes in brain activity.

Surgery

The life-threatening nature of traumatic incidents will often lead to a patient needing surgery to repair damage and/or stop internal bleeding. If internal organ damage is indicated—due either to organ rupture or to a foreign object puncturing the abdominal cavity—emergency surgery will be needed to

Clinical Manifestations and Therapies

Multisystem Trauma

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Mild head injury	<ul style="list-style-type: none"> Headache Sensitivity to light, blurred vision Nausea, dizziness, balance problems Changes in memory 	<ul style="list-style-type: none"> CT, MRI, and/or electroencephalogram (EEG) to determine the extent of the injury. Application of ice. Stitches for open wounds. Elevation of head of bed to 30 degrees.
Traumatic brain injury (TBI)	<ul style="list-style-type: none"> Loss of consciousness Headache; repeated nausea and vomiting Dilation of one or both pupils Confusion Seizures and coma Possible death 	<ul style="list-style-type: none"> Same clinical therapies as for mild head injury. Pharmacologic therapies such as diuretics and anticonvulsant medications. Surgery to remove hematomas, repair skull fractures, or remove skull fragments from the brain, and cutting out a section of skull to allow for swelling of brain, which diminishes the pressure on the brain. Physical and/or speech therapy depending on the severity of the injury.
Whiplash	<ul style="list-style-type: none"> Neck stiffness and pain Dizziness, blurred vision, headaches, ringing in the ears Concentration and memory problems 	<ul style="list-style-type: none"> Prescription pain relievers such as hydrocodone or oxycodone. Muscle relaxants to relieve muscle spasms. Lidocaine injections into the affected muscle to relieve pain and muscle spasms. Ice and heat therapy. Physical therapy. Immobilization collar to promote proper healing.
Spinal cord injury, either incomplete or complete	<ul style="list-style-type: none"> Loss of sensation and movement below affected area Pain if nerve damage is present Breathing difficulty Loss of bladder and bowel control Numbness and tingling in extremities 	<ul style="list-style-type: none"> Immobilization of the spine with a neck collar. Sedation to prevent further damage to the spine, if necessary. Methylprednisolone (Medrol) to decrease inflammation and nerve damage. Surgery if possible. Physical therapy and rehabilitation. Pain medications.

repair the damage or stabilize the patient until a transplantation can be performed.

Injuries involving severe head or spinal trauma may require surgery depending on the circumstances. Head injuries will not always need surgery; however, if an intracranial hemorrhage (ICH) is present and the bleeding does not stop on its own, surgery may be the only solution. Intracranial pressure (ICP) will be monitored when a head injury is present, and if the pressure rises to dangerous levels, surgery will be performed to release some of the pressure. Spinal injuries are often irreversible once they have occurred, but in most cases surgery will be needed to remove bone fragments and stabilize the spine.

Pharmacologic Therapy

The majority of injuries sustained will be painful to patients and will require pain management. Less severe injuries involving sprains, minor cuts, and mild concussions do not require strong pain medicines but rather a form of ibuprofen. Deep cuts requiring sutures usually will be treated with

lidocaine as a numbing agent. In cases of more severe injuries, particularly those that require surgery, stronger pain medications—most often opioids—are administered. Sedation may be necessary if the patient's reaction to the injuries or the pain puts her in danger of further injury. Nurses will follow proper sedation protocols, ensuring that the patient is not oversedated.

Nonpharmacologic Therapy

Physical therapy and rehabilitation are often required for severe injuries, including broken bones (especially compound fractures), spinal injuries, and some traumatic brain injuries. If the patient falls into a coma or is put into a drug-induced coma, physical therapy and rehabilitation will be needed if muscle tone decreased significantly while the patient was unconscious. Patients with impairments in neurologic, motor, speech, and/or language functioning may require speech therapy. Patients with TBI or another injury that impairs self-care and other abilities may work with an occupational therapist to relearn some of those activities.

Individuals will be provided with a referral and resources for therapy and counseling to help with emotional trauma resulting from the accident.

Complementary Health Approaches

Complementary health approaches are normally not recommended for anything other than mild injuries, although some pain reduction strategies, such as mindfulness meditation, may be used in conjunction with pharmacologic therapy with provider approval. For patients requiring rehabilitation, therapists may use integrative therapy that is tailored to the patient's specific needs. Thorough assessment of patient preferences regarding the use of complementary health approaches is necessary at each stage of assessment and treatment for patients with multisystem trauma.

Lifespan Considerations

Infants and Toddlers with Multisystem Trauma

Traffic accidents are the leading cause for multisystem trauma in infants and toddlers (**Figure 32-7** »). Infants and children are more susceptible to multisystem trauma than adults because of their small body size and, with infants, open cranial sutures and fontanelles; however, they recover better than adults, especially from head trauma (Children's Health, 2016). The open fontanelles allow for increased intracranial mass or brain swelling, which may mask symptoms of injury until a rapid decompensation occurs; therefore, bulging fontanelles indicate a severe injury and should be treated as such. The nurse needs to be alert for signs of child abuse. Injuries such as fractured ribs, multicolored bruises, evidence of previous, healed injuries,

Source: Kari Rene Hall/Los Angeles Times/Getty Images.

Figure 32-7 » Motor vehicle crashes are the leading cause of multisystem trauma in infants and toddlers. This 2-year-old girl was trapped under a tractor-trailer and had to be extricated using the Jaws of Life. She was in a car seat strapped in the backseat of her mother's car, and she sustained moderate injuries.

fractures of long bones in children younger than 3 years, and retinal hemorrhages may indicate maltreatment and warrant an intensive investigation.

Children and Adolescents with Multisystem Trauma

Assessment priorities for a child are the same as for an adult; however, there may be even more serious effects of trauma in the pediatric patient because of the anatomical and physical characteristics of the younger patient (ACSCOT, 2017). Children are still growing, which means that after a traumatic injury, their body must not only heal from the injury, but also continue to develop.

Children are more likely to experience seizures after head trauma. These seizures usually resolve, but they require diagnostic testing with a CT scan. Injuries to the pancreas, small bowel perforations, and bladder ruptures are more common in children. These injuries are generally from blunt impact such as from bicycle handlebars and seat belts from a motor vehicle crash.

When a child has a fractured bone, the bone will heal, but the bone's growth plate may be affected, causing that affected bone to quit growing. Children are at high risk for tension pneumothorax secondary to mobility of the mediastinal structures. If a pneumothorax is identified, treatment is the same as for adults. The nurse also needs to be alert for signs of maltreatment.

Pregnant Women with Multisystem Trauma

There are two patients when a pregnant woman sustains multisystem trauma—the mother and the fetus; however, treatment priorities are the same for a pregnant woman as for a nonpregnant woman (ACSCOT, 2017). The best treatment for the fetus is resuscitation of the mother. The mother should be assessed, followed by an assessment of the fetus, and then the secondary assessment of the mother.

An increase in blood volume occurs in the pregnant woman. In cases of severe blood loss, the fetus may be in distress and the placenta deprived of oxygen before symptoms (tachycardia, hypotension, and other signs of hypovolemia) occur in the mother. The mother's condition and vital signs may appear stable initially with hypovolemia. It is also important to keep uterine compression of the vena cava from occurring. This can be completed by manually displacing the uterus to the left side, which relieves pressure on the inferior vena cava.

The main cause of fetal demise is maternal shock or death. Abdominal examination is also a priority. In 30% of trauma cases, placenta abruption occurs, which is the second leading cause of fetal death. Fetal heart rate should be monitored closely. A normal fetal heart rate is 120–160 beats/min. It is important to note that abruption of the placenta or other fetal demise does not always cause vaginal bleeding.

Older Adults with Multisystem Trauma

Older adults are less likely to be injured than younger adults; however, they are more likely to have a fatal outcome (ACSCOT, 2017). Falls are the most common cause of

multisystem trauma resulting in death (CDC, 2016k). Older adults may be wearing dentures, which could interfere with maintaining airway. Broken dentures should be removed while leaving well-fitted dentures in place. Monitoring the respiratory system closely is critical secondary to the decreased respiratory reserve due to the aging process. A blood pressure reading that is within normal limits may be misleading. Blood pressure generally increases with age; therefore, a systolic reading of 120 mmHg may actually be indicative of hypovolemia. Another consideration regarding the older adult includes obtaining a medication history, as the patient may be on multiple medications. The nurse should always be alert to the increased risk of abuse for this vulnerable population.

NURSING PROCESS

Nursing care of the patient who has been injured begins with a primary assessment and the initiation of collaborative interventions for any life-threatening injuries. Nursing care is directed toward the patient's specific responses to trauma.

Assessment

For the patient who has sustained a traumatic injury, primary consideration should be given to the airway: Assess if the airway is patent, maintainable, or nonmaintainable. Assess for manifestations of airway obstruction: stridor, tachypnea, bradypnea, cough, cyanosis, dyspnea, decreased or absent breath sounds, changes in oxygen levels, and changes in level of consciousness. Assessing the airway and initiating interventions are the first steps in managing the patient with multiple injuries. Cervical and spinal immobilization should be maintained to reduce risk of spinal cord injury. Cervical and spinal immobilization should be discontinued only by physician's order after determining that the patient has not sustained a spinal injury. Although not always needed, this determination may require evaluation of the patient's spine using CT scanning.

Diagnosis

The trauma patient has many complex and interrelated actual or potential alterations in health. The nursing care in this section focuses on patient and family problems with respirations, infection, immobility, spirituality, and stress. Potential nursing diagnoses, which are numerous, may include the following:

- *Airway Clearance, Ineffective*
- *Breathing Pattern, Ineffective*
- *Tissue Perfusion, Risk for Decreased Cardiac*
- *Tissue Perfusion, Risk for Ineffective Peripheral*
- *Fluid Volume, Risk for Deficient*
- *Infection, Risk for*
- *Mobility: Physical, Impaired*
- *Spiritual Distress*
- *Post-Trauma Syndrome.*

(NANDA-I © 2014)

Planning

Goals are based on individualized patient needs and the type and amount of trauma sustained. Goals may include the following:

- The patient's airway will remain patent.
- The patient will demonstrate regular, non-labored respirations and oxygen saturation levels of 95% or greater.
- The patient's blood pressure will be maintained within normal limits.
- The patient will not develop cardiac dysrhythmias.
- The patient will remain free of signs or symptoms of infection.
- The patient will remain free of sensory deficits.
- The patient will retain or regain mobility.

Implementation

As with any traumatic injury, nursing interventions begin with the ABCDEs. Only after ensuring an intact airway, appropriate breathing, and adequate circulation are other issues addressed.

Maintain Airway Patency and Ventilation

The patient with multiple injuries is at great risk for developing airway obstruction and apnea. Facial injuries, loose teeth, blood, and vomitus increase the risk for aspiration and obstruction. Neurologic injuries and cerebral edema alter the patient's respiratory drive and ability to keep the airway clear.

- For patients who do not require tracheal intubation and controlled or assisted ventilation, administer supplemental oxygen per hospital protocols by way of face mask or nasal cannula.
- Monitor oxygen saturation by applying a pulse oximeter. Adjust oxygen flow to maintain oxygen saturation from 95 to 100%. Decreased oxygen saturation readings despite a patent airway may indicate inadequate ventilation or ineffective oxygen exchange.

SAFETY ALERT Pulse oximetry in patients who have been exposed to carbon monoxide (i.e., house fires) is unreliable because it cannot differentiate carboxyhemoglobin from oxyhemoglobin.

- Monitor level of consciousness. An early sign of an ineffective airway is change in the patient's behavior. If the patient becomes restless, anxious, combative, or unresponsive, the effectiveness of the airway needs to be evaluated immediately and appropriate interventions initiated.

Assess for Neurologic Deficits and Expose Obscured Areas

For a trauma assessment, neurologic status and exposure are also assessed.

- Neurologic assessment includes identifying altered level of consciousness, abnormal pupillary response to light, impaired or diminished mobility, and decreased or absent sensation.

- Exposure requires removal of the patient's clothing to allow for identification of injuries that may be obscured. Expose the patient only as needed for assessment and treatment.
- Full assessment requires that the patient be rolled to one side for inspection of the back and posterior of the body. When rolling the patient to one side, the trauma team will use a technique known as "logrolling," which allows for maintenance of neutral alignment of the spine.
- To prevent hypothermia, warm blankets may be used to cover the patient, and the room temperature may be increased during periods for which exposure is required.

Promote Fluid Volume Balance

Both blood loss and the shifting of fluid from the intravascular space can lead to hypovolemia, which, if left untreated, may progress to cardiovascular shock. Therefore, the plan of care for patients who sustain significant traumatic injuries includes:

- Insertion of a large-bore IV catheter (at minimum, 18-gauge or larger in diameter) for administration of fluids, medications, and blood products.
- Administration of IV fluid and blood products as per the physician's orders.
- Insertion of a Foley catheter for continued assessment of urine production, which is an indirect reflection of the patient's kidney function and fluid volume status.

Prevent Infection

Traumatic injuries are considered dirty wounds. Projectiles enter the body through dirty surfaces and clothing, carrying dirt and debris into the wound. Open fractures provide a portal for the entry of bacteria and dirt. Even with surgical intervention, the wounds often remain contaminated. Risk factors for wound infection include contamination, inadequate wound care, and the condition of the wound at the time of closure. Aseptic techniques used in applying and changing dressings reduce the entry of organisms:

- Use careful hand hygiene practices. Hand hygiene remains the single most important factor in preventing the spread of infection.
- Use strict standard precautions and aseptic technique when caring for wounds. Standard precautions are essential to protect the patient and the nurse from infection. In addition, perform the following:
 - a. Monitor wounds for odor, redness, heat, swelling, and copious or purulent drainage.
 - b. Monitor hidden wounds, such as those under casts, by asking the patient whether the pain has increased and observing for increased drainage and heat over the area of the wound.
 - c. Ensure that cross-contamination between wounds does not occur. Collect drainage in ostomy bags if it is copious.
- Take and record vital signs, including temperature, every 2–4 hours. Abnormal vital signs, particularly an elevated body temperature, indicate the presence of an infection.
- Provide adequate fluids and nutrition. Adequate fluids, calories, and protein are essential to wound healing.

- Assess for manifestations of gas gangrene: fever, pain, and swelling in traumatized tissues and drainage with a foul odor. Gas gangrene is usually caused by the organism *Clostridium perfringens*. This bacterium is found in the soil and can be introduced into the body during a traumatic injury. The organism grows in the tissues, causing necrosis; hydrogen and carbon dioxide are released, with resultant swelling of tissues. If the infection continues, tissues are progressively destroyed, and sepsis and death may result.
- Assess status of tetanus immunization and administer tetanus toxoid or human toxin-antitoxin as prescribed.
- Use strict aseptic technique when inserting catheters, suctioning, administering parenteral medications, or performing any other invasive procedure. Using aseptic technique during invasive procedures reduces the chances of infection.

Promote Mobility

The patient with trauma injuries is often unable to change positions independently and is at risk for complications of the integumentary, cardiovascular, gastrointestinal, respiratory, musculoskeletal, and renal systems. Patients at greatest risk are those who have multiple injuries, spinal cord injuries, peripheral nerve injuries, or traumatic amputations. Collaborate with the physical therapist and occupational therapist (if available) to determine the most effective types and schedule of exercises and assistive devices:

- If active bleeding or edema is not present, provide active or passive exercises to affected and unaffected extremities at least once every 8 hours. Exercise improves muscle tone, maintains joint mobility, improves circulation, and prevents contractures.
- Help the patient turn, cough, and breathe deeply, and use the incentive spirometer at least every 2 hours. Changing positions, coughing, deep breathing, and incentive spirometry reduce the risk of integumentary and respiratory complications.
- If the patient is unable to be moved and positioned, consider a specialty bed, such as the kinetic continuous rotation bed. The kinetic continuous rotation bed allows continuous turning of the patient; the motion decreases pulmonary complications, venous stasis, postural hypotension, urinary stasis, muscle wasting, development of decubiti, and bone demineralization.
- Monitor the lower extremities each day for manifestations of deep venous thrombosis: heat, swelling, and pain. Measure and record the circumference of the thigh and calf each day. If anti-embolic stockings or intermittent compression stockings are used, remove them for 1 hour during each shift and assess the skin. Venous stasis results when surrounding muscles are unable to contract and help move the blood through the veins. Thrombus (clot) formation in deep veins is a major risk for pulmonary embolism.

Offer Spiritual Comfort Measures

Trauma generally strikes without warning and carries potentially devastating consequences, including death or

severe alterations in the lives of the victim and family. The traumatic death of a loved one may be the most difficult event a family will ever experience. The decision to cease life support systems or to donate organs challenges the family's belief systems and psychologic stability. Nursing care of the family (or patient) experiencing spiritual distress includes:

- Give the family information about the option to donate the patient's organs. The decision to donate organs needs to be based on information about the patient's condition, prognosis, and criteria by which brain death is determined. It is important to convey to family members that organ donation is only an option and that the choice is up to them.
- Encourage the family members to ask questions and express their feelings about the traumatic event and/or organ donation. Allowing families to express their feelings may help prevent long-term consequences such as guilt.
- Refer the family for follow-up care. Long-term follow-up is important for the family facing the sudden death of a loved one. Grieving is not an overnight process, and providing the family with resources that may be used in the future may prevent future crises and dysfunction.
- Provide the family of the dying or deceased patient a place and time to pray or observe faith rituals together. Provide the family the opportunity to call for the family minister or spiritual leader. Praying or observing faith rituals helps the family begin a healthy process of grieving.
- Be present for the family. By providing presence, the nurse provides a level of support and assures the family that they and their loved one are valued and respected. More information about providing spiritual support can be found in the module on Spirituality.

Promote Psychosocial Well-Being

Acute stress disorder is an immediate, intense, sustained emotional response to a disastrous event. It is characterized by emotions that range from anger to fear and by flashbacks or psychic numbing. The patient may be calm or may express feelings of anger, disbelief, terror, and shock, which may last from 3 days up to 1 month. Some individuals who witness or experience a traumatic event may develop PTSD, characterized by flashbacks and nightmares of the traumatic event (see the exemplar that follows). The patient may use ineffective coping mechanisms, such as alcohol or drugs, and withdraw from relationships. Appropriate interventions may include the following:

- Assess emotional responses while providing physical care. Observe for crying, sleep problems, suspiciousness, and fear during the initial phase of treatment. If the patient is unconscious, encourage family members and friends to express their feelings. These assessments provide valuable information about the patient's ability to cope with the trauma.
- Be available if the patient wishes to talk about the trauma, and encourage expression of feelings. The patient may initially deny negative feelings; this denial is a coping mechanism in the initial phase of recovery.

- Teach relaxation techniques, such as deep breathing, progressive muscle relaxation, or imagery. These techniques are often useful in coping when thoughts of the trauma recur.
- Refer the patient and family members for counseling, psychotherapy, or support groups as appropriate. Continued therapy may be necessary to assist the patient and family to resolve the acute and long-term effects of trauma.

Facilitate Community-Based Care

Address the following topics to prepare the patient and family for home care:

- The type of home environment to which the patient will be returning, including any changes that will be required to let the patient function in that environment
- Medications, dressings, wound care, equipment, and supplies
- Special diet, if needed
- Rehabilitation plan and its effect on the patient's family
- Follow-up appointments with the provider or at the trauma clinic
- Emotional changes that the patient may undergo as a result of the trauma
- Helpful resources include home healthcare, community support groups, and the National Institute of Neurological Disorders and Stroke.

Evaluation

The reaction and future care of each patient will vary based on the type and severity of injuries. In some cases, the patient will be discharged the same day as the injury, whereas other patients will need treatment for a longer period. Some desired outcomes for patients include the following:

- The patient's airway remains free of obstruction.
- The patient's respiratory rate remains within normal limits.
- The patient's oxygen saturation is maintained at 95% or greater.
- The patient develops no cardiac dysrhythmias.
- The patient's blood pressure is maintained within normal limits.
- The patient remains free of signs or symptoms of infection.
- The patient develops no neurovascular deficits.
- The patient retains mobility.
- The patient verbally expresses emotions and concerns.

If outcomes are not met, another evaluation will need to occur to determine what is preventing the patient from meeting established goals. For example, if the patient is not able to bear weight in the set amount of time, there may be an unidentified injury or complications related to a post-surgical procedure. Another example would be that the patient's vital signs do not stabilize after surgery. An assessment will need to occur to determine the cause of the decompensation, which may be an unidentified internal hemorrhage.

Nursing Care Plan

A Patient with Multiple Injuries

Jane Souza is a 25-year-old married woman with two children who provides day care for preschool children in her home. As she is driving the interstate at 65 miles per hour, a car crosses the median and strikes her vehicle head-on. Ms. Souza, who is not wearing a seat belt, is thrown forward against the steering wheel. The front of her car is pushed up against her by the car that struck her, entrapping her

lower extremities. After extensive efforts to extricate her from the car, Ms. Souza is transported to the local trauma center. She is still conscious, is receiving high-flow oxygen by mask, and has one intravenous line in place. Her vital signs are a palpable systolic blood pressure of 80 mmHg, a pulse rate of 120 bpm, and a respiratory rate of 36/min. On arrival, she states that she is having difficulty breathing.

ASSESSMENT	DIAGNOSES	PLANNING
<ul style="list-style-type: none">■ <i>Airway</i>: Maintainable with high-flow oxygen in place.■ <i>Breathing</i>: Respiratory rate of 36/min, multiple bruising and abrasions on right side of her chest, decreased breath sounds on the right side.■ <i>Circulation</i>: No palpable radial pulses; palpable brachial pulses. Monitor shows sinus tachycardia. No active external bleeding noted. Skin color pale, cool to the touch, and diaphoretic.■ <i>Neurologic</i>: Moved her fingers when asked; complains of difficulty breathing; denies that she is hurt. Pupils 4 mm, equal, and react to light. Has a broken right arm and an open fracture of the left ankle; because of these injuries, extremity movement is limited. <p>Because of Ms. Souza’s respiratory distress, she is intubated and ventilated with 100% oxygen. Another intravenous line is inserted and O-negative blood administered.</p>	<ul style="list-style-type: none">■ <i>Ineffective Breathing Pattern</i> related to multiple bruises and abrasions on the right side of the chest, and respiratory difficulty■ <i>Deficient Fluid Volume</i> related to acute internal blood loss (presumed because no active bleeding can be found)■ <i>Risk for Injury</i> related to trauma resuscitation <p>(NANDA-I © 2014)</p>	<p>Patient goals include:</p> <ul style="list-style-type: none">■ The patient will maintain adequate oxygenation.■ The patient will maintain adequate circulating blood volume.
IMPLEMENTATION		
<ul style="list-style-type: none">■ Monitor airway and assist in any needed airway management.■ Explain all procedures.■ Monitor the effects of fluid and blood administration, including any changes in blood pressure and pulse.	<ul style="list-style-type: none">■ Prepare for transfer to the operating room for emergency surgery.■ Keep family informed about her condition.	
EVALUATION		
Ms. Souza is transferred to the operating room, where it is determined that she has a ruptured spleen and a serious pelvic fracture.	Ms. Souza’s treatment continues in the operating room.	
CRITICAL THINKING		
<div><div><div>1. Is the nursing diagnosis of Deficient Fluid Volume appropriate for Ms. Souza? Why or why not?</div><div>2. The assessment of a patient who has experienced trauma is ABCDE. What is the rationale for this sequence?</div><div>3. Following surgery, Ms. Souza is moved to the surgical intensive care unit. She is very anxious and restless. What assessments would you make to identify the cause of her restlessness?</div></div><div><div>4. Infection is a common complication for the trauma patient. Describe five risks for infection that are present from the time of injury to the time of hospital discharge.</div></div></div>		

REVIEW Multisystem Trauma

RELATE Link the Concepts and Exemplars

Linking the exemplar of multisystem trauma with the concept of intracranial regulation:

- What is the priority of care when your patient who experienced a head injury in a car crash has a blood pressure of 90/60 mmHg and a heart rate of 51 bpm?
- What nursing interventions would be appropriate for inclusion in the plan of care for the patient who has a head injury from a car crash to prevent the rise of intracranial pressure?

Linking the exemplar of multisystem trauma with the concept of perfusion:

- Describe potential threats to a patient's perfusion as a result of a motor vehicle crash. How would perfusion be impacted if the patient's mobility was altered because of traction or other immobilizing treatments?
- How can you promote mobility for a patient involved in a motor vehicle crash who has a casted left leg and right arm? How would this plan change if the patient were an older adult with diminished mobility prior to the trauma?

REFLECT Apply Your Knowledge

Lilia Hoffman, age 25, was the driver of a vehicle that was struck by another vehicle at an intersection. The driver of the car that hit her ran a red light. Ms. Hoffman was extracted from her car using the Jaws of Life and was moaning when initially removed but did not respond to verbal commands. Her pupils were pinpoint and reactive to light. The paramedics at the scene provided initial emergent care. Her vital signs included temperature 96.2°F oral; pulse 110 bpm; respirations 12/min; and BP 90/50 mmHg. She had bleeding from facial and scalp lacerations as well as suspected rib fractures. Her lung sounds were clear and equal bilaterally, and her oxygen saturation was 97%. Ms. Hoffman's airway was determined to be patent and oxygen was administered via face mask at 10 liters per minute.

The air bag in Ms. Hoffman's car deployed. It was unknown whether she sustained a head or neck injury. One of the paramedics immediately administered manual stabilization of Ms. Hoffman's cervical spine until a cervical collar (c-collar) was applied. In addition to c-spine immobilization, Ms. Hoffman was placed on a long spinal board to prepare for transport to the local emergency department. Circulatory status was assessed and an 18-gauge intravenous catheter was inserted in her left forearm, followed by intravenous administration of 0.9% normal saline at a rate of 150 mL/hr.

In the emergency department, Ms. Hoffman's vital signs were temperature 98°F oral; pulse 118 bpm; respirations 14/min; and BP 98/50 mmHg. An IV bolus of 250 mL of normal saline was administered and a Foley catheter inserted. Her airway remained patent and oxygen was continued.

1. What are three priority nursing diagnoses for Ms. Hoffman?
2. What laboratory and diagnostic tests should the nurse anticipate being ordered?
3. Under what circumstances can Ms. Hoffman's spinal precautions (cervical collar and longboard spinal immobilization) be discontinued?

Exemplar 32.C Posttraumatic Stress Disorder

Exemplar Learning Outcomes

32.C Analyze PTSD as it relates to trauma.

- Describe the pathophysiology of PTSD.
- Describe the etiology of PTSD.
- Compare the risk factors and prevention of PTSD.
- Identify the clinical manifestations of PTSD.
- Summarize therapies used by interprofessional teams in the collaborative care of an individual with PTSD.

Overview

Each individual responds to traumatic events differently based on their own personal history, coping mechanisms, and the exact circumstances surrounding the nature of the traumatic event. For an individual to be diagnosed with a trauma or stressor-related disorder (e.g., acute stress disorder or PTSD), the individual must meet specific criteria for diagnosis, of which the first is exposure to a traumatic or stressful event. There is a close relationship between trauma-related disorders and anxiety, obsessive-compulsive, and dissociative disorders. Depending on the individual, emotional symptoms of trauma or stressor-related disorders can vary greatly from fear and anxiety to agitation and dysphoria. **Posttraumatic stress disorder (PTSD)** is commonly associated with military personnel, specifically those returning from war; however, PTSD can affect any individual from any background across the lifespan.

The APA (2013) characterizes PTSD as a disorder in which an individual who is exposed to a traumatic event develops intrusive symptoms, such as recurrent nightmares; patterns of persistent efforts to avoid stimuli associated with

or reminiscent of the traumatic event; negative changes in cognition or mood; and marked changes in reactivity or arousal, such as hypervigilance or impaired concentration. For an individual to be diagnosed, these symptoms must occur for more than 1 month beyond the precipitating event.

Along with PTSD, this class of disorders also includes (APA, 2013):

- Reactive attachment disorder, which is a rare disorder in young children that is often associated with neglect; manifests as an apparent aversion to engaging in interaction with adults.
- Disinhibited social engagement disorder, which is most commonly diagnosed in young children and is associated with neglect. Manifestations include an abnormal propensity for the child to interact with unfamiliar adults.
- Acute stress disorder, which is similar to PTSD, but the symptoms only last from 3 days to 1 month following exposure to one or more traumatic events such as war, experiencing assault, being kidnapped, or natural or human-caused disasters.

- Differentiate care of patients with PTSD across the lifespan.
- Apply the nursing process in providing culturally competent care to an individual with PTSD.

Exemplar Key Terms

Acute stress disorder, 2147

Depersonalization, 2148

Eye movement desensitization and reprocessing (EMDR), 2149

Flashbacks, 2147

Posttraumatic stress disorder (PTSD), 2146

- Adjustment disorders, which are characterized according to the patient's manifestations (e.g., depressed mood, anxiety, disturbance of conduct), begin approximately 3 months after a stressor, and resolve within 6 months.

Pathophysiology and Etiology

Pathophysiology

In the United States, recent events have brought discussion of PTSD to the forefront. For example, some of those who experienced, witnessed, or attended to survivors of the World Trade Center attacks on September 11, 2001, have spoken publicly about their personal experiences with PTSD. Recent wars and conflicts, particularly in the Middle East, have resulted in a significant rise in PTSD in military and civilian personnel (**Figure 32-8** »). Natural disasters, such as hurricanes and fires, also provide sources of trauma, as do the increasing incidences of mass shootings such as the 2012 shootings in a theater in Aurora, Colorado, and an elementary school in Newtown, Connecticut; and more recently, a night club shooting in Orlando, Florida, in 2016.

Traumatic events that may trigger PTSD include violent personal assaults, natural or human-caused disasters, motor vehicle crashes, military combat, being taken hostage or being tortured, imprisonment, dismemberment, incest, and child abuse. PTSD also can stem from sexual assault or being subjected to sexual experiences during childhood (APA, 2013). Even threats of violence or injury may prompt the development of PTSD. However, intentional infliction of harm or violence, such as torture or rape, is associated with a higher incidence of this disorder (APA, 2013).

PTSD may manifest through numerous signs and symptoms, including fear-based reexperiencing of the event; alterations in emotional and behavioral states; dysphoric mood and negative cognitive states; and alterations in arousal and reactivity (APA, 2013). Some patients will experience manifestations that predominantly reflect one

Figure 32-8 » Many military personnel in or returning from the wars in Iraq and Afghanistan experience PTSD.

Box 32-1

Overview of Acute Stress Disorder

Although there are similarities between **acute stress disorder** and PTSD, the two disorders are separate and distinct from one another. The individual with acute stress disorder experiences symptoms for 3 days to 1 month immediately after exposure to a traumatic event. In contrast, patients with PTSD experience symptoms for more than 1 month, with the onset of symptoms usually occurring 3 months or more after exposure to the trauma (APA, 2013).

Acute stress disorder stems from an individual experiencing, learning of, or witnessing an extremely stressful event that involves the threat of death, actual or threatened serious injury, or actual physical or sexual violation. The individual is said to be experiencing acute stress disorder if he experiences nine (or more) symptoms from any of five categories—intrusion (intrusive distressing memories), negative mood, dissociation (an altered sense of reality or dissociative amnesia), avoidance, and arousal (such as sleep disturbances, irritability, or poor concentration)—that begin or get worse after the traumatic event (APA, 2013).

category of alterations, whereas others will experience a combination of manifestations (APA, 2013).

When reexperiencing the traumatic event, the individual with PTSD may experience **flashbacks**, the recurrence of images, sounds, smells, or feelings from the traumatic event. Flashbacks are often triggered by daily events, such as a car backfiring on the street or the smell of a perpetrator's cologne. In the affected individual's mind, flashbacks may be so lifelike that they appear to be happening in reality. Frequently, the individual experiences recurrent nightmares or intrusive memories related to the traumatic event.

Some individuals who experience trauma may experience acute stress during the immediate aftermath of the trauma. An acute stress or anxiety response sufficient to impair functioning may result in acute stress disorder, discussed in **Box 32-1** ». Acute stress disorder shares several factors with PTSD, but is of a much shorter duration.

Etiology

Exposure to an overwhelming stressor can occur at any age. Childhood trauma, abuse, and molestation can create enduring effects and clinical symptoms that last into adulthood. Additional factors that contribute to the development of PTSD are an individual history of a psychiatric disorder or a lack of emotional support or resources during the trauma. Among adults in the United States, the prevalence of PTSD is about 3.5% (NIMH, n.d.), with women being more susceptible to its development (APA, 2013). Incidence among veterans is particularly high: One report documents that, of military personnel who had been deployed in overseas combat presenting for treatment at VA healthcare centers, 21% were treated for PTSD. Incidence increases when TBI is present: 75% of combat personnel who experienced TBI had a concurrent diagnosis of PTSD (Congressional Budget Office, 2012).

Focus on Diversity and Culture

Refugee Trauma

In 2013, a total of 69,909 refugees were admitted into the United States (Homeland Security, Office of Immigration Statistics, 2014). Refugee trauma is a form of PTSD that is specific to the traumatic events experienced by individuals during war or persecution that may have lifelong effects. Child refugees may exhibit symptoms such as nightmares, anxiety, psychosomatic symptoms, hopelessness, and disrupted sleep patterns (NCTSN, n.d.c). Adult refugees frequently experience negative manifestations of PTSD and depression (Harvard Program in Refugee Trauma, n.d.). The refugees will also need to be assessed for physical trauma secondary to possible torture and other forms of violence endured (see **Figure 32-9** »).

Source: Christophe Calais/Corbis Historical/Getty Images.

Figure 32-9 » This family, originally from the Democratic Republic of Congo, was living in a refugee camp in Burundi called Gatumba in 2004. One night, armed factions attacked the refugee camp, killed 166 people, and injured another 116. The oldest boy in this family had a leg amputated. Since that night, 525 Gatumba survivors have been relocated to North America. This family lives in Boise, Idaho, where the mother works as a chambermaid.

Risk Factors

Individuals of any age and any cultural group may develop PTSD. In the United States, the incidence of this disorder is higher among military veterans, law enforcement officers, firefighters, and emergency medical personnel (APA, 2013). Risk factors for PTSD include the following:

- The severity of the event itself, including whether or not the individual was harmed or watched others be harmed or killed
- Little or no social or psychologic support following the trauma
- Additional stressors immediately following the event, such as loss of a spouse or family member or loss of employment
- Presence of preexisting mental illness.

Prevention

The most effective way to prevent the development of PTSD is for the individual to use their support system after exposure to a traumatic event. This may mean reaching out to family and friends or seeking professional help. Obtaining help and support as soon as possible after exposure is integral in preventing normal stress reactions from developing into acute stress disorder or longer term PTSD. Obtaining support will aid the individual in using positive, effective coping skills and prevent her from succumbing to ineffective coping skills such as self-medicating with drugs and alcohol (Mayo Clinic, 2014c).

Clinical Manifestations

Patients who experience flashbacks may lose touch with reality and may cognitively return to the traumatic incident as if it is happening again. Some may experience **depersonalization**, an emotional numbing and a loss of their sense of reality, feelings, and sense of self in relation to others. Patients who experience depersonalization may have difficulty in interpersonal relationships and with trusting or being affectionate. Things they formerly enjoyed may not provide pleasure for them anymore. Individuals may express uncharacteristic irritability, aggression, and violence.

Hyperarousal and hypervigilance are associated with PTSD, rendering the affected individual in a near-constant state of “high alert.” The individual may experience sleep disturbances and become restless. He may also feel a strong sense of agitation and have poor concentration. Dissociation, in which the individual blocks emotions related to the traumatic event, or dissociative amnesia, in which certain elements of the traumatic event are blocked altogether, may occur. The emotional numbness that can occur leads to impairment in establishing and maintaining social relationships. As with other anxiety disorders, depression may accompany PTSD. Likewise, individuals with PTSD may abuse alcohol or other substances to alleviate their symptoms.

Although manifestations of PTSD usually emerge within 3 months following exposure to the traumatic event, years may pass before the individual’s signs and symptoms meet the criteria needed for an official diagnosis of PTSD (APA, 2013).

Collaboration

Caring for the patient with PTSD requires the skillful ability to assess and facilitate the care of patients, families, and communities. As a patient advocate, the nurse must effectively connect individuals with the resources they need to recover successfully from trauma. These resources may include financial resources, such as social services; medical resources, such as free clinics and mental health providers who treat uninsured patients on a sliding-scale basis; and agencies that provide food and shelter. If support from a spiritual leader is requested, it should be provided.

Because of the all-encompassing impact of trauma on an individual’s life, a holistic approach to treatment may be most effective, combining pharmacologic and alternative therapies, such as relaxation techniques, CBT, eye movement

Clinical Manifestations and Therapies

Acute and Posttraumatic Stress Disorders

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Acute Stress Disorder Anxiety disorder that evolves from exposure to actual trauma or threat of physical harm. Recovery varies from 3 days to 1 month.	<ul style="list-style-type: none"> ■ Intrusive distressing memories ■ Negative mood ■ Dissociation ■ Avoidance ■ Arousal problems 	<ul style="list-style-type: none"> ■ Ensure the safety of the patient and provide basic needs. ■ Promote support by family and friends. ■ Provide patient teaching related to coping mechanisms. ■ Provide emotional support. ■ Administer medications as prescribed to decrease arousal. ■ Holistic approach to treatment includes CBT.
PTSD Anxiety disorder that evolves from exposure to actual trauma or threat of physical harm. Recovery varies from 1 month to several years. Comorbidity may include depression, substance abuse, or other anxiety disorders.	<ul style="list-style-type: none"> ■ Persistent frightening thoughts and memories or flashbacks of the event: images, sounds, smells, or feelings ■ Emotional numbing ■ Sleep disorders ■ Hypervigilance and exaggerated startle response ■ Reexperiencing the event ■ Trouble with affection ■ Irritability, aggressiveness, or violence ■ Avoidance of trauma-related situations or general social contacts ■ Drug and alcohol abuse ■ Depression ■ Suicidal thoughts or violence 	<ul style="list-style-type: none"> ■ Holistic approach to treatment includes CBT. ■ Eye movement desensitization and reprocessing. ■ Supportive therapy. ■ Group therapy. ■ Pharmacologic therapy, including benzodiazepines, SSRIs, and antipsychotic agents. ■ Prazosin, which is an antihypertensive medication that also inhibits the brain's response to norepinephrine, may be prescribed for treatment and prevention of nightmares (Mayo Clinic, 2014a).

desensitization and response therapy (discussed below), and support from a multiagency team of providers.

Pharmacologic Therapy

Depending on the severity and nature of a patient's PTSD manifestations, SSRIs are often used in conjunction with psychotherapy as a treatment. The only two SSRIs approved by the U.S. Food and Drug Administration (FDA) for the treatment of PTSD are sertraline (Zoloft) and paroxetine (Paxil). Prazosin, which is an antihypertensive medication, is effective in the reduction of nightmares associated with PTSD (Mayo Clinic, 2014a).

SAFETY ALERT SSRI medications may produce undesirable side effects; therefore, it is important to educate the patient that most side effects will diminish after the first few weeks. If the patient does not understand this, the risk of nonadherence to the medication regimen increases, leaving the patient untreated and susceptible to decompensation of illness.

Nonpharmacologic Therapy

Eye movement desensitization and reprocessing (EMDR) is a form of psychotherapy that contains elements of several

types of therapy, including CBT and body-centered therapy. It is so named because one of the elements involves dual attention stimulus using eye movements, taps, or tones. *Dual attention stimulus* allows the patient to reprocess or reappraise the trauma by focusing internally on the traumatic event or another stressor while simultaneously focusing on a different external stimulus (EMDR Institute, n.d.).

Exposure therapy assists the patient by gradually exposing them to elements of the traumatic event, which enables them to face their fears. This form of treatment uses writing, pictures, and possibly visiting the place where the traumatic event occurred (NIMH, 2016). This form of therapy allows the patient to develop effective coping skills in a safe, controlled environment. The use of virtual reality also assists the patient in revisiting the site where the traumatic event occurred without having to go back to the real site (Mayo Clinic, 2014a).

Preliminary research indicates that acupuncture may be effective in treating patients with PTSD. Patients may need to participate in acupuncture on a regular basis for a period of 3 months or more (National Center for Complementary and Integrative Health [NCCIH], 2014). Nurses working with patients who are interested in trying acupuncture as a treatment for PTSD should encourage the patients to add

Focus on Integrative Health

PTSD

The U.S. Department of Veterans Affairs and Department of Defense identify psychopharmacology, stress inoculation, exposure, and/or CBT as the front-line, best standard approach to PTSD (International Society for Traumatic Stress Studies, 2016). Complementary integrative health (CIH) approaches, such as yoga and meditation, can also be taught to the patient. Stress inoculation is a form of psychotherapy in which the therapist educates the patient on the stress that they may endure, including the negative outcomes. This enables the patient to have an effective plan to address the negative obstacles he may encounter (Mills, Reiss, & Dombeck, n.d.). Prolonged exposure therapy (PE) is a type of exposure therapy that has four components to assist the patient in working through the feelings associated with the traumatic event. The first component is educating the patient on PTSD, including responses and symptoms. Breathing retraining is another component that teaches the patient how to control breathing while experiencing the stressful feelings. Real-world training is another part of PE that helps by having the patient practice situations that they may have been avoiding (e.g., a veteran who may fear driving because of hitting a roadside bomb while at war). Last, talking through the trauma assists the patient in not being fearful of his memories (VA, 2015).

acupuncture as an adjunctive therapy and not to abandon CBT and more traditional therapies.

Lifespan Considerations

PTSD in Children

Manifestations of PTSD in young children vary significantly from those demonstrated by adult patients. For example, children with PTSD who are under the age of 6 years may reexperience the trauma through play in such a way as to overtly or indirectly recreate the traumatic event. Some children may reexperience trauma by drawing pictures that symbolize the trauma. Children with PTSD may also behave recklessly or aggressively, or they may withdraw from interacting with others. Because of their undeveloped ability to express thoughts or identify emotions, expressions of PTSD in very young children often occur through changes in mood (APA, 2013).

Additional symptoms that may be seen in children under the age of 6 years may include nocturnal enuresis after the child has already been toilet trained, forgetting how to talk or not talking at all, acting out the traumatic event during activities with other children, and being exceptionally needy or clingy.

PTSD in Adolescents

Older children and adolescents have manifestations similar to those that the adult experiences; however, they may also demonstrate disruptive, disrespectful, or destructive behaviors (NIMH, 2016). Adolescents may engage in traumatic reenactment where the traumatic event(s) have been injected into their daily life. Impulsive and aggressive behaviors are

more typical of this age group as well (VA, 2016c). Furthermore, there is an increased risk of suicide, substance abuse, poor social support, poor concentration, academic problems, and poor physical health with adolescents diagnosed with PTSD (Nooner et al., 2012).

PTSD in Older Adults

PTSD in older adults is not limited to veterans, although it is often associated with the experiences of a soldier. According to the VA, 70–90% of adults age 65 and older have experienced at least one traumatic event during their lifetime (VA, 2016d). Older veterans may report more somatic complaints, fewer typical PTSD general symptoms, and less depression, hostility, and guilt than younger veterans (VA, 2016d).

A complete mental status exam, including cognitive screening, is recommended when assessing the older adult. Assessment of the history of trauma and symptomatology should be performed routinely, as these patients may minimize the significance of this history or not report it at all, as it likely occurred a long time ago. Note that older patients may report somatic symptoms as opposed to emotional symptoms. The older adult who may be experiencing PTSD symptoms should be assessed using a valid PTSD measuring tool and be assessed for suicidal thoughts and behaviors, because they are at increased risk of suicide compared with middle-aged adults (VA, 2016e).

NURSING PROCESS

Patients with PTSD experiencing hyperarousal and vigilance may exhibit unpredictable, aggressive, or bizarre behavior. The nursing priorities for these patients are ensuring the safety of the patient and others while quickly lowering patient anxiety levels. The patient with PTSD exhibiting extreme anxiety needs immediate pharmacologic intervention, a quiet and calm environment, and reassurance that he or she is safe. Once anxiety levels are reduced, the healthcare team can help the patient learn a new process of appraisal and coping mechanisms.

Because of the complexity of trauma, families may also experience PTSD and require the nurse's assistance and support. Evaluation of the impact on the family must also be included in the assessment, evaluation, and decision-making process. Families play a key role in the support of the individual. In the case of national disasters, entire communities may be involved in the trauma.

Assessment

Assessing a patient for PTSD will involve both physical and psychological approaches. Identify risk and protective factors and assess immediate and long-term safety concerns. Multiple tools are available for use in screening for PTSD; some have been developed for use with children. Specific interview questions to ascertain the diagnosis of PTSD are aimed at the following clinical manifestations: reexperiencing or flashbacks, hyperarousal and vigilance, an exaggerated startle response, and sleep disturbances. For example,

an interview question might be: “Have you experienced painful images or memories of combat or other trauma which you couldn’t get out of your mind, even though you may have wanted to? Have these been recurrent?” (VA, 2016e). Identification of PTSD in children is improved when they are questioned directly about their experiences. Assessment of younger children involves questioning the child and/or the parents about significant changes in behavior and sleeping patterns. For children and vulnerable patients who are believed to be victims of abuse, the nurse should follow organizational protocols for reporting these situations. Questions may include:

- How would you describe your mood?
- When do you feel most content? When do you feel least content?
- What are your favorite activities?
- What activities help you relax?
- How often do you socialize or participate in activities with others?
- Describe your sleep habits. Do you sleep soundly through the night? Do you feel rested when you awaken?
- Do you have friends or other individuals with whom you can be open and honest about your thoughts and emotions?
- How important is being able to share your thoughts and feelings?
- Are you currently working? If so, what type of work are you engaged in?

Because of the traumatization experienced by these patients, as well as the subsequent potential for emotional and physical isolation, establishment of trust can be especially challenging. For example, many military personnel and veterans are resistant to openly sharing their thoughts and emotions even with their colleagues and fellow veterans. During the assessment and throughout the care of all patients with PTSD, the nurse should be aware that direct questioning of the patient with regard to traumatic experiences may inhibit establishment of a trusting relationship and can even provoke frustration and anger in the patient. The nursing assessment should include interview questions that allow for patient assessment without pressuring the patient to reveal information he is not ready or able to share. Through the inclusion of open-ended questions, the nurse affords the patient the opportunity to express himself to the degree with which he is comfortable while demonstrating respect for the patient’s personal boundaries.

SAFETY ALERT Safety is always a priority. The nurse must remember that a patient diagnosed with PTSD may demonstrate agitation, aggressiveness, and even violence. The nurse will need to educate the family on the need for a safety plan in the event that the patient becomes violent.

Diagnosis

Evaluating assessment data for an individual with PTSD can be challenging. For some patients with PTSD, mani-

festations of the disorder can be compounded by substance abuse, depression, and insomnia. Appropriate diagnoses for the patient with PTSD may include any of the following:

- *Violence: Self-Directed, Risk for*
- *Violence: Other Directed, Risk for*
- *Post-Trauma Syndrome*
- *Anxiety*
- *Fear*
- *Coping, Ineffective*
- *Coping: Family, Compromised*
- *Sleep Pattern, Disturbed.*

(NANDA-I © 2014)

The nurse must explore the specific assessment questions directed at PTSD in order not to overlook the possibility of this diagnosis. It is important for the healthcare provider to involve the individual in the decision-making process and to facilitate the individual’s preferences.

Planning

Planning includes identification of measurable, realistic patient goals that are relevant to the selected nursing diagnoses. Examples of patient goals that may be relevant to the care of the patient with PTSD include the following:

- The patient will remain free from injury or harm.
- The patient will report a decreased perception of anxiety.
- The patient will report a reduction or cessation of nightmares.
- The patient will discuss emotions related to traumatic experiences with at least one trusted mental health specialist or counseling professional.
- The patient will verbalize awareness of nonpharmacologic stress reduction techniques.

Implementation

The presence of PTSD is not an inevitable outcome of a traumatic event. Some individuals may require only limited interventions. Clinically significant indicators are the severity of the event itself and the severity of the individual’s initial response. For patients who develop this disorder, in addition to the interventions described previously, it is important to recognize the profound impact PTSD exerts on components related to multiple aspects of daily life, including an impact on the social, interpersonal, and occupational domains. These patients may benefit from being connected with organizations and community resources that can facilitate long-term assistance and that can offer sensitive guidance to the process for building trusting relationships with others. The nurse should also reinforce understanding of effective coping strategies and encourage their use, which may assist in decreasing anxiety (see the module on Stress and Coping).

Patient Teaching

Typical Human Responses to Traumatic Events

Patients with PTSD should be given ample information about the typical human responses to traumatic events. Education about the process helps patients normalize the experience and gain information for reappraisal. Information and resources can lead to adaptive coping; conversely, a lack of resources may induce maladaptive coping. It is the nurse's responsibility to provide information about the treatments available and support resources for PTSD to help the individual and family make informed choices.

SAFETY ALERT Compassion fatigue (CF) often occurs in healthcare providers who perform caregiving work on a regular basis. Relating to people who are helpless, suffering, or traumatized can precipitate CF. Symptoms of CF include excessive blaming, isolation from others, receiving an unusual amount of complaints, self-medicating with drugs or alcohol, poor concentration, and apathy (Compassion Fatigue Awareness Project, 2013). Once CF is identi-

fied, the nurse has already made the first step in overcoming the issue. Actions such as taking care of oneself, expressing needs, and clarifying boundaries will assist in eliminating these negative emotions.

Evaluation

The nurse evaluates the patient's response to treatment using these suggested expected outcomes:

- The patient uses self-calming techniques.
- The patient experiences fewer cognitive distortions and fewer repetitive thoughts (ruminations) or obsessions.
- The patient decreases time spent ruminating over worries, verbalizing more accurate predictions of future events.

If patient outcomes are not met, additional measures should be taken, including evaluation of medication efficacy and adherence to treatment regimen. The patient may need to journal daily events in order to identify triggers, allowing effective coping skills to be incorporated. The patient may need to be encouraged to avoid triggers while learning coping strategies.

Nursing Care Plan

A Patient with Posttraumatic Stress Disorder

Sarah Green is a 44-year-old nurse whose 14-year-old son was killed in a motor vehicle crash (MVC) just over 6 months ago. At the time of the MVC, Ms. Green was driving her son to soccer practice when another vehicle crossed the interstate median and struck her

vehicle. Her son died at the scene, and Ms. Green sustained serious injuries. Ms. Green also has a 17-year-old daughter and a 19-year-old son.

ASSESSMENT	DIAGNOSES	PLANNING
<p>At present, Ms. Green attends a support group for grieving parents, which she finds to be therapeutic. However, she has been having flashbacks about the night of the accident and can barely control herself when she knows one of her children is driving or riding in a car. Usually, when one of the children asks to borrow the car she just says "no" to avoid having to worry about them. Ms. Green knows she needs to see someone. She talks to a friend who is also a coworker, who recommends that she talk with an occupational health counselor at work. Ms. Green does not want anyone at work to know she is having trouble, but she agrees to see a mental health nurse that her friend recommends.</p> <p>At her initial appointment, Ms. Green freely shares her experiences with the flashbacks, which happen two or three times a week, usually at night. She says that when she knows her children are going anywhere, she can feel her heart racing, her breathing speeding up, and her palms getting sweaty. She tells the mental health nurse that she gets through these episodes by lying down and saying the Lord's Prayer out loud.</p>	<p>The mental health nurse develops the following nursing diagnoses:</p> <ul style="list-style-type: none"> ■ <i>Post-Trauma Syndrome</i> ■ <i>Anxiety</i> ■ <i>Fear</i> <p>(NANDA-I © 2014)</p>	<p>Goals for Ms. Green's care include the following:</p> <ul style="list-style-type: none"> ■ The patient will use deep breathing to control escalating anxiety. ■ The patient will express fears clearly. ■ The patient will describe the symptoms associated with the various levels of anxiety. ■ The patient will demonstrate breathing exercises to reduce anxiety.

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Teach Ms. Green how to monitor her physiologic level of arousal.
- Teach use of abdominal breathing at first sign of anxiety.
- Help patient to express fears that interfere with her life.
- Encourage patient to search for, confront, and relieve the source of the original anxiety.
- Teach distraction techniques that can control moderate levels of anxiety.
- Teach the use of positive imagery.
- Teach calming techniques such as muscle relaxation.
- Teach positive affirmations such as “I am calm and happy” or “I am very relaxed.”
- Identify safe physical outlets for negative feelings, such as exercise.

EVALUATION

- The patient expresses feelings appropriately.
- The patient spends less time thinking about the accident and instead turns thoughts to more positive memories.
- The patient allows her adolescent children to borrow the car, setting reasonable limits to reduce her anxiety.

CRITICAL THINKING

1. What impact does Ms. Green’s PTSD have on her children’s development?
2. How would you teach Ms. Green relaxation techniques?

REVIEW Posttraumatic Stress Disorder

RELATE Link the Concepts and Exemplars

Linking the exemplar of posttraumatic stress disorder with the concept of development:

Explore the incidence of childhood abuse, molestation, and incest in the United States.

1. What impact does childhood abuse, molestation, and incest have on the growth and development of a child?
2. Childhood abuse, molestation, and incest can negatively affect the physical, emotional, spiritual, and cognitive processes of individuals. What alterations in health are associated with abuse later in life?

Linking the exemplar of posttraumatic stress disorder with the concept of mood and affect:

3. What questions should be asked of a patient who is experiencing manifestations of PTSD and expresses hopelessness?
4. What nursing interventions should be employed if the patient with PTSD is expressing suicidal ideation?

REFLECT Apply Your Knowledge

Melinda Burns lives in Manhattan. She is engaged to be married to a man she says she loves very much, and although this should be the happiest time of her life, she is feeling very anxious and stressed.

She was 12 years old on September 11, 2001, when terrorists attacked the United States. She was in school when the planes hit

the World Trade Center. They had to evacuate the school after the collapse of the buildings because the ash was so thick it made breathing difficult. Her father picked her up, and they went to a hotel room in New Jersey because their apartment was also covered in ash. They weren’t allowed to go home until several weeks later. Ms. Burns’ grandmother stayed with her in the hotel room while her father tried to find her mother, who worked on the 92nd floor of the North Tower. Her dad never found her mother, and she never came home. Ms. Burns says the worst part is that her mother’s body was never identified from the wreckage, so she feels like she has no closure or confirmation that her mother is really dead. One of the New York firemen came to their home almost a year later to return a necklace that was found, and the engraving helped them identify it as her mom’s. Ms. Burns treasures the necklace even though it is badly damaged and burned.

Ms. Burns is seeking care because she is having trouble functioning and difficulty performing ADLs. She reports severe anxiety whenever she hears a siren, she has been waking from nightmares related to the World Trade Center several times a week, and she can’t bring herself to watch any television programs or movies about the terrorist attack because they always make her cry. She has turned down a number of jobs because she can’t bring herself to work on the upper levels of tall buildings. She says lately she has been having trouble concentrating, even when planning her wedding, because she can’t seem to think about anything other than the World Trade Center and what her mother’s final minutes must have been like.

1. What nursing diagnoses are appropriate for Ms. Burns?
2. What collaborative actions can the healthcare team take to help Ms. Burns?
3. What independent nursing interventions would you initiate if Ms. Burns was your patient?

Exemplar 32.D

Rape and Rape-Trauma Syndrome

Exemplar Learning Outcomes

32.D Analyze rape and rape-trauma syndrome as they relate to trauma.

- Describe the pathophysiology of rape and rape-trauma syndrome.
- Describe the etiology of rape and rape-trauma syndrome.
- Compare the risk factors and prevention of rape and rape-trauma syndrome.
- Identify the clinical manifestations of rape and rape-trauma syndrome.
- Summarize diagnostic tests and therapies used by interprofessional teams in the collaborative care of an individual who has been raped.

Overview

Rape is one form of sexual violence. According to the FBI (2012c), **rape** is “penetration, no matter how slight, of the vagina or anus with any body part or object, or oral penetration by a sex organ of another person, without the consent of the victim.” Because rape occurs at the hands of another and involves loss of control, individuals who are raped are often referred to as “victims” by law enforcement, as seen in the definition provided by the FBI. However, healthcare and mental health professionals working with individuals who have been raped commonly use the term “survivor” for empowerment purposes.

Each individual who is raped will have a unique reaction to the incident. Variations in reactions can be due to the individual’s past history, personality, the circumstances of the event, whether infection or pregnancy occurs, and many other factors. For decades, clinicians working with rape survivors have recognized **rape-trauma syndrome (RTS)**, a series of psychologic sequelae that many individuals experience following rape in addition to physiologic sequelae. Although symptoms and reactions vary widely, most survivors of rape experience great emotional and physical impact. Many initially exhibit shock and disbelief, followed by fear, humiliation, shame, self-blame, and distrust in others (CDC, 2016n). Emotional detachment, sleep disturbances, flashbacks, and mental replay of the rape are common. Physical symptoms may include gastrointestinal disorders, chronic pain, sexually transmitted infections, cervical cancer, and genital injury. Another major health issue is that more than 32,000 pregnancies per year result from rape (CDC, 2016n). Some survivors of rape may go on to experience emotional symptoms so severe that they impact functioning to the extent that the survivor may develop PTSD (APA, 2013).

Pathophysiology and Etiology

Rape can occur under a number of circumstances and can include physically violent elements (such as being

- Differentiate care of patients across the lifespan who have been raped.
- Apply the nursing process in providing culturally competent care to an individual who has been raped.

Exemplar Key Terms

Acquaintance rape, 2155

Marital rape, 2155

Rape, 2154

Rape-trauma syndrome (RTS), 2154

threatened with a weapon or tortured) as well as psychologic elements (such as survivors being told the rape was their own fault, being called berating names, or being threatened with harm to their loved ones if they report the rape to authorities). Regardless of the circumstances of the rape, survivors will need to heal emotionally and physically. After being raped, survivors may feel as though they have little to no control over what happens to them and as though they have lost a part of themselves. Elements of fear, guilt, and anxiety will also often be present (CDC, 2016n).

Influencing Factors

Those who commit rape will often know their victim, who is often a spouse, an ex-spouse, an acquaintance, a friend, or a relative. A majority of individuals who have experienced rape knew their attacker, with only 13.8% of women and 15.1% of men reporting a stranger as their attacker (CDC, 2012). Some factors influencing those who commit rape are environmental or social in nature, while others pertain to the individual’s psychologic well-being. It is imperative to remember that both men and women can commit rape and be raped.

Intrapersonal and Interpersonal Factors

Multiple types of rapists exist, including those who know the victim and those who are strangers. To become a rapist, an individual needs to overcome the moral and ethical dilemma of taking away another individual’s right to say no. Often this decision comes about through the use of drugs or alcohol; through powerful emotions such as anger, revenge, or a sense of entitlement; or through the use of self-delusion, convincing themselves that their victim actually wants to go through with the act despite protests. Depending on the rapist’s own justifications, the act will either be physically violent with a result of profuse injuries to the victim, or emotionally violent with the perpetrator using verbal coercion and only enough physical force to complete the rape.

No one form of rape is easier than another; however, different types of rapists cause varied reactions in their targets.

For example, if the rapist was someone the individual knows on a personal level (e.g., a friend, relative, or spouse), the survivor is likely to have serious trust issues as a result of the experience. Individuals who had a prior romantic relationship with the rapist are also prone to developing low self-esteem and higher levels of guilt, believing that their supposed poor character judgment led to the event (DeAngelis, 2013).

Sociocultural Factors

For an individual to commit rape, a precipitating force needs to be present. This force could be emotional or substance based, or it could even be biological or environmental. Biological factors would include psychologic disorders that cause impaired decision making or deficient impulse control. Environmental factors that could influence an individual's decision to commit rape include growing up in a setting where physical, emotional, or sexual violence was common and perhaps even accepted. Similarly, being raised in a culture where women or men are seen as possessions rather than individuals could cause individuals to believe they have the right to take what they would like from others despite objections from the victim. Areas that have high crime rates and a seemingly increased tolerance for violence are also more prone to having a higher percentage of rape cases (CDC, 2016o).

Etiology

Approximately 79,770 girls and women were forcibly raped in 2013 in the United States (FBI, 2013c); overall, the incidents of rape have been decreasing steadily during the past 20 years. A national survey of adults has shown that approximately 1 in 5 women and 1 in 71 men have reported being raped at some point in their lives. Of female victims, 42.2% were first raped before age 18, and 37.4% were first raped between ages 18 and 24. Of male victims, 27.8% reported being raped before the age of 11 (CDC, 2012).

Marital rape occurs when one spouse forces the other to have sex against his or her will. Marital rape is considered a crime in all 50 states and can occur with both physical and emotional abuse. **Acquaintance rape** is a rather broad term used to describe a rape committed by an acquaintance or other familiar individual. The largest percentage of acquaintance rape cases occurs on college campuses, with many of them including factors such as the consumption of alcohol and illegal substances (by the perpetrator, the victim, or both) (Meadows, 2013).

Acquaintance rape can involve the use of "date rape" drugs or "club drugs." The three most common date rape drugs are gamma-hydroxybutyric acid (GHB), flunitrazepam (Rohypnol—slang "roofie"), and ketamine hydrochloride (ketamine). These three drugs are odorless and tasteless and thus can be easily added to a victim's drink without detection. After consuming the drugs, the victim will feel mildly euphoric and sedated and will often experience memory loss (Meadows, 2013). It is important to remember that even if the victim drank alcohol or consumed drugs willingly, he or she is *not* at fault for being assaulted.

Focus on Diversity and Culture

Rape of Vulnerable Populations

The homeless population, an identified vulnerable population, has an increased prevalence of sexual violence compared to women nationally. One study indicates that 13% of homeless women admitted to being raped in the past year, with half of those same women stating that they were raped at least twice (The White House Council on Women and Girls, 2014). This same report also indicates that homeless women are at increased risk of human sex trafficking as well.

The disabled population is also at higher risk for sexual violence. The White House Council on Women and Girls (2014) reports that women who have a disability are three times more likely to experience sexual violence than those without a disability.

The intense trauma associated with rape can lead to physical injuries as well as intense emotional injuries such as RTS. Individuals who have had a traumatic experience may display signs of shock and denial shortly after the experience.

Risk Factors

Individuals can be at a higher risk for rape if they are under the influence of drugs and/or alcohol, but these factors do not cause rape to occur. Similarly, being young could be considered a risk factor for rape, but only because a large percentage of survivors report having been raped before they were 18 years old.

The risk factors for committing a rape are also difficult to determine. Even if an individual has all of the risk factors, it does not necessarily mean that individual will become a rapist. Protective factors may lessen the risk of becoming a sexually violent perpetrator and may occur at the individual, relationship, community, or societal level. Risk and protective factors for sexual violence perpetration are listed in **Table 32-3** >>.

Prevention

The majority of preventive programs involving rape focus on stopping the perpetrator from committing the act. Programs such as these are often aimed at those who have committed sexual assault in the past, and they try to help the individual accept responsibility for the crime. Preventive measures for victims include knowledge and awareness about situations that could foster those looking to commit rape, such as crowded bars, parties, raves, and fraternity or sorority parties on college campuses. Paying attention to surroundings and traveling in pairs or groups can also deter an individual looking to rape a single unsuspecting victim. Self-defense classes and training aid in fighting off an individual attempting to commit sexual assault, which could give the victim a better chance of escaping (CDC, 2013b). For tips on avoiding date rape drugs, see the Patient Teaching feature.

TABLE 32–3 Risk and Protective Factors for Perpetration of Sexual Violence

Risk Factors for Perpetration			
Individual	Relationship	Community	Societal
<ul style="list-style-type: none"> Alcohol and drug use Delinquency Empathic deficits General aggressiveness and acceptance of violence Early sexual initiation Coercive sexual fantasies Preference for impersonal sex and sexual risk taking Exposure to sexually explicit media Hostility toward women Adherence to traditional gender role norms Hyper-masculinity Suicidal behavior Prior sexual victimization or perpetration 	<ul style="list-style-type: none"> Family environment characterized by physical violence and conflict Childhood history of physical, sexual, or emotional abuse Emotionally unsupportive family environment Poor parent–child relationships, particularly with fathers Association with sexually aggressive, hypermasculine, and delinquent peers Involvement in a violent or abusive intimate relationship 	<ul style="list-style-type: none"> Poverty Lack of employment opportunities Lack of institutional support from police and judicial system General tolerance of sexual violence within the community Weak community sanctions against sexual violence perpetrators 	<ul style="list-style-type: none"> Societal norms that support sexual violence Societal norms that support male superiority and sexual entitlement Societal norms that maintain women's inferiority and sexual submissiveness Weak laws and policies related to sexual violence and gender equity High levels of crime and other forms of violence
Protective Factors for Perpetration			
<ul style="list-style-type: none"> Parental use of reasoning to resolve family conflict Emotional health and connectedness Academic achievement Empathy and concern for how one's actions affect others

Clinical Manifestations

The clinical manifestations of rape vary depending on the genders of the assailant and the victim, the physical violence involved in the rape, and the type of rape. Common manifestations include oral, vaginal, or anal injuries and/or physical injuries with the presence of semen not belonging to the victim. Individuals who have been raped will also demonstrate psychologic symptoms such as shock, denial, and confusion directly following the event.

Physical Injuries

Common physical injuries in rape victims include swelling, redness, and lacerations around the vagina or anus; injuries to the throat from forced oral sex or restraint; bruises; broken bones; and knife and gunshot wounds. Defensive and restraint injuries will present as wounds to the hands, arms, feet, and legs, often in the form of bruises, lacerations, and/or fractured bones. If the victim was restrained (often with rope, handcuffs, or plastic zip ties), additional injuries will

Patient Teaching

Date Rape Drugs

Date rape drugs are being used to make a person vulnerable to being raped. The nurse should teach the patient methods of prevention and what to do if they suspect they have been drugged:

1. Always keep your drink with you; never leave it unattended.
2. Do not accept premade or open drinks from someone you don't know.
3. Watch your drink being made by the bartender.
4. Inspect drinks (Rohypnol now releases a blue dye when mixed in light-colored drinks; however, it is important to know that other drugs, including generic versions of Rohypnol, may not be detectable) (National Institute on Drug Abuse [NIDA] for Teens, 2015).
5. Do not leave a location if you are alone or with someone that you do not know or explicitly trust.

Symptoms of being drugged include:

1. Becoming sleepy or confused; feeling more drunk than warranted by the amount of alcohol consumed.
2. Feelings of weakness or loss of coordination.
3. Nausea, vomiting, headaches (National Crime Prevention Council, n.d.).

If you feel that you have been drugged, get help immediately. Seek out a friend, security, or even the bartender. Do not leave with the person you suspect may have drugged you, and seek medical attention immediately (Crime Prevention Tips, 2013).

be found around the wrists, ankles, and possibly the neck. Internal injuries and bleeding could be present if the patient was beaten before or after the rape, or raped with an object such as a bottle.

Long-term physical complications often present as pelvic pain, back pain, frequent headaches, gastrointestinal disorders, and potential pregnancy complications in women. Some of these long-term symptoms—such as headaches, gastrointestinal upset, and even back pain—can be caused by a mix of intense stress and injuries from the rape (CDC, 2016n). Other long-term effects could be the result of sexually transmitted diseases or infections, such as herpes or HIV.

Immediate Response

Initial responses to rape generally include feelings of shock, denial, and disbelief. Other early responses involve fear, anger, guilt, embarrassment, helplessness, loss of control, confusion, anxiety, and nervousness (CDC, 2016n; Meadows, 2013). The survivor will likely be hesitant to trust others, especially those of the same gender as the attacker. Nurses understand this fear and work to reassure patients of their safety. If a woman has been raped by a male attacker, it may be necessary to have primarily female healthcare professionals working with her. If a male staff member is needed, a female nurse should accompany him to provide reassurance to the patient.

An individual's first response after a rape is often to shower in an attempt to wash away the incident as well as what is left of the attacker's physical presence (such as the individual's body odor and fluids). If consulted, nurses advise patients not to shower before being examined because this will remove potential evidence that could be collected and used to identify the attacker. Nurses should recognize that this request is difficult for the patient and provide reassurance that a shower will be provided as soon as the examination is complete.

Some patients will present themselves as though nothing has happened while acting unfazed by the situation. Nurses realize that this reaction is often an effect of shock and denial. Patients who react in this manner should be treated as sensitively as other patients who outwardly display their emotions. All procedures, tests, and examinations should be explained to the patient in detail, and the patient should be asked to give consent before any test or examination is performed. Nurses should work to empower the patient's decision-making process. The staff involved in the care of a rape victim needs training on giving physical and emotional support to rape victims.

Long-term Response

After the initial shock of the incident subsides, patients will begin to accept that the rape has occurred. In the weeks following the incident, a variety of emotional responses will be present, and these responses will differ depending on the personality of the patient. Common responses include anger, flashbacks of the incident, avoidance of previously enjoyed activities, avoidance of the setting where the rape occurred, insomnia, eating disturbances, sexual dysfunction, and depression (Meadows, 2013). Some individuals will cut all emotional ties to

friends and family members, whereas others will seek the comfort of familiarity and respond very negatively to being alone. The emotional distress of the incident can trigger the use of unhealthy coping mechanisms such as using drugs and alcohol or participating in high-risk sexual behavior. Pregnancy is also a concern for those who have been raped; more than 32,000 pregnancies occur each year as the result of forced sexual encounters (CDC, 2016n). How the patient responds to the pregnancy depends on the emotional trauma associated with the incident as well as the personality of the individual. Emotional difficulties will likely coincide with the progression of the pregnancy.

Depression and suicidal thoughts or actions are common after rape. Nurses should be mindful of the warning signs of suicide (see the module on Mood and Affect) and employ appropriate interventions. All individuals who have experienced rape should be provided with resources for therapy, support groups, and counseling. Whether patients choose to use these resources is their decision, but the nurse is responsible to provide patients with the means to seek help.

SAFETY ALERT Rape survivors are at a high risk for developing an eating disorder, including anorexia, bulimia, or a crossover between the two. Eating disorders do not always develop out of an individual's desire to lose weight; often they come from an emotional disturbance. One of the main components of both anorexia and bulimia is control over what the individual is consuming and over the nutrients that stay in the body or are forcefully discarded. In a rape situation, anger and stress can lead to eating disorders (CDC, 2016p).

Cultural Considerations

The cultural considerations in rape often involve the culture's dominant definition of rape and what that act entails. Not all members of a culture will have the same beliefs about one particular topic. Cultures that demonstrate male superiority and devalue the thoughts and rights of women will likely not consider the forcible rape of a woman or girl a matter of great importance. Conversely, feminist cultures will view the rape of a woman or girl as an injustice (Kalra & Buhgra, 2013).

Marital rape is not acknowledged in many cultures around the world. If two individuals are married, then any sexual contact is considered legal and warranted. Individuals from these cultures would be hesitant to seek help if they were raped by their spouse; it could even be considered dishonorable to the victim's family to imply that a crime was committed. Marital rapes often go unreported; however, 9% of all rapes reported are perpetrated by a husband or ex-husband (Health Research Funding, 2014).

Individuals in the sex industry (e.g., prostitutes or exotic dancers) can also be raped. Regardless of whether an individual's job includes having sexual relations with others, if someone states an unwillingness to continue and the other person does not stop, then the act becomes rape. Nurses do not judge patients who say they have been raped; they provide quality care to all individuals.

Clinical Manifestations and Therapies

Rape-Trauma Syndrome

ETIOLOGY	CLINICAL MANIFESTATIONS	CLINICAL THERAPIES
Acute phase of RTS	Expressive styles vary: <ul style="list-style-type: none"> Open expression of feelings—confusion, fear, crying, sobbing, pacing, hostility, inappropriate laughter Controlled style—numbness, shock, disbelief, withdrawal Compound reaction—reactivated symptoms of previous conditions, for example, psychotic behavior, depression, suicidal behavior, substance abuse Somatic reactions—tension headache, fatigue, increased startle reaction, nausea, gagging Outward appearance of adjustment with an attempt to restore equilibrium Life activities are renewed, but superficially and mechanically Periods of anxiety, fear, nightmares, depression, guilt, shame, vulnerability, helplessness, isolation, sexual dysfunctions 	<ul style="list-style-type: none"> Counseling Therapy Follow-up care for emotional and physical trauma Medication
Reorganization phase of RTS	<ul style="list-style-type: none"> Anger at the assailant, at society, and at the judicial system The need to talk to resolve feelings The survivor seeks family and professional support 	<ul style="list-style-type: none"> Therapy Support groups
PTSD (if unable to recover)	<ul style="list-style-type: none"> Anxiety Flashbacks Depression Nightmares Withdrawal 	<ul style="list-style-type: none"> CBT Support groups Antidepressants

SAFETY ALERT Rape survivors may experience long-term effects that include depression and suicidal ideations. The nurse should provide referrals for support groups and other community services, including crisis hotline numbers, which may assist the patient in coping effectively with the traumatic event.

Collaboration

An interprofessional team caring for patients who have been raped includes law enforcement personnel immediately after the rape and nurses, physicians, and mental health professionals for ongoing treatment. Sexual Assault Nurse Examiners (SANE) often participate in the assessment process. Many communities have victims' advocates who are available to guide rape victims through the process of prosecuting their attacker. These are sometimes volunteers trained by local health departments and district attorneys' offices. Some law enforcement agencies or district attorneys' offices employ trained staff to serve as victim's advocates. It is important that the nurse validate that all policies and procedures are followed with precision and that meticulous documentation is completed, as the information may be presented in legal proceedings.

» **Stay Current:** Visit the website of the International Association of Forensic Nurses (IAFN) at www.iafn.org to learn more about becoming a Sexual Assault Nursing Examiner.

Diagnostic Tests

Although not diagnostic in nature, a rape kit will likely be completed for the purpose of convicting the rapist, if caught. As a result, chain-of-custody laws must be followed, and these vary within jurisdictions. The rape kit may take several hours to complete, and the healthcare provider cannot leave the rape kit at any time during the process. The rape kit has a special number assigned to it and contains 16 separate steps in collecting evidence. Each evidence envelope or bag has the same rape kit number. The victim will be given the number to this rape kit, but it will only be processed if the victim makes a report to the police. Specimens will include the following:

- Vaginal, oral, and anal swabs for DNA material (it is important that the victim be asked whether they have had any consensual sexual relations in the last 5 days so that the consensual partner and perpetrator can be differentiated) (Forensics for Survivors, 2015)
- Scrapings from under the patient's fingernails for skin samples if the patient scratched the rapist
- Combing of pubic hair for rapist's DNA
- Clothing worn by the victim (if the individual is brought directly to the ED following the rape).

In addition to the specimens collected for legal purposes, the victim is tested for sexually transmitted infections and

potential pregnancy. Baseline testing is performed at the time of the initial examination, and follow-up HIV testing is done at 3, 6, and 12 months. Pregnancy testing related to the rape cannot be accurately performed until the woman has missed her first menstrual period; however, emergency contraception is available to prevent pregnancy.

Pharmacologic Therapy

Women who have been raped can be offered emergency contraception in order to prevent unwanted pregnancy. The contraceptive is more likely to be successful if taken within 3 days of the attack. Some individuals will be opposed to using contraception; the nurse will explain the patient's options and then be respectful of whatever decision the patient makes.

Numerous sexually transmitted diseases and infections can be contracted during a rape—regardless of whether the attacker used a condom or not. The most common and treatable infections are listed below, along with their prescribed pharmacologic treatment:

- Syphilis, treated with penicillin (CDC, 2015f)
- Chlamydia, treated with a dose of azithromycin or a week of doxycycline (CDC, 2015g)
- Gonorrhea, treated with a combination of ceftriaxone and azithromycin (CDC, 2015h)
- Trichomoniasis, treated with metronidazole or tinidazole (CDC, 2015i).

Nonpharmacologic Therapy

Support groups, therapy, and counseling are recommended to patients who have experienced a forced sexual encounter or are experiencing RTS. Some patients will be more receptive to support groups where others who have had similar experiences come together to discuss the aftermath of the event and how they are working to heal from the experience. Other patients will prefer a more private setting and choose to work individually with a therapist to process their own personal experiences. While attending therapy, patients will develop healthy coping mechanisms to process their emotions and will work to release feelings of self-blame.

Lifespan Considerations

Treatment will predominantly be the same for victims of rape, regardless of gender or age; however, there may be slight variances in care. For instance, a young child, a postmenopausal woman, or a male victim will need physical treatment and emotional support, but they will not need emergency contraception. Younger and older individuals who are living with a caregiver may need help creating a post-discharge safety plan, especially if the perpetrator was the caregiver. The approach in explaining the rape kit, treatment, and follow-up will vary; age-appropriate terminology will need to be used.

NURSING PROCESS

Nursing care for a patient who has been raped depends on a number of factors, including the physical violence inflicted during the incident, the patient's emotional state, and the

patient's willingness to allow an examination. Nurses know that this is an extremely difficult situation for the patient, so they must be both patient and understanding.

Assessment

When conducting a nursing assessment for a patient who has been raped, nurses first need to ensure the patient's safety. If knife or gunshot wounds, organ damage, and/or severe head trauma are present, those injuries need to be assessed and treated first before any minor physical injuries or psychologic injuries are assessed. Injuries to the vagina, anus, and throat are likely to be present and should be assessed. The patient may be in shock or outwardly emotionally distraught. Nurses should be aware that patients' reactions to rape vary greatly in accordance with the situation and the developmental age and personality of the patient.

Once the physical safety of the patient is ensured, nurses work to comfort and empower the patient by explaining the patient's choices for examination and providing information about resources. Individuals who have been raped do not have to allow the nurse to complete a rape kit, nor do they have to talk to a counselor; however, nurses should encourage both of these. If the patient agrees to an examination and the collection of evidence, nurses will explain every step of the process and ask permission during the examination itself. Although the patient may be willing to allow evidence collection and DNA swabbing, she may not want any pictures taken of the injuries. Nurses need to remain supportive of the patient's decisions. Disease, infection, and pregnancy testing and treatment should be discussed with the patient, and interventions should be planned accordingly.

The nurse assesses the patient's emotional needs, asking if the person would like a parent, friend, or rape advocate present during the examination. Police involvement is also offered if the patient chooses to file a statement about the incident.

Diagnosis

The patient's diagnosis is contingent on the injuries and emotional state of the individual. Some potential nursing diagnoses include:

- *Infection, Risk for*
- *Rape-Trauma Syndrome*
- *Fear*
- *Pain, Acute*
- *Powerlessness*
- *Coping, Ineffective*
- *Self-Esteem, Situational Low*

(NANDA-I © 2014)

Planning

It is critical for the patient who is the victim of rape to have control over the planning process. The patient's input regarding short-term and long-term goals is essential to

prevent revictimization and to help the patient regain control over self and environment. Appropriate short-term goals include:

- The patient will receive treatment for physical injuries sustained during the rape.
- The patient will participate in follow-up care for physical injuries.
- The patient will follow a safety plan following release from medical care.

It may be more than the patient can manage to think beyond the first few days following the rape. The nurse can provide follow-up care to determine when the patient is ready to engage in further planning. This follow-up care also allows the nurse to reassess how the patient is meeting short-term goals. Appropriate long-term goals may include the following:

- The patient will gain control over remembering—experiencing decreased flashbacks and nightmares.
- The patient will work toward affect tolerance—ability to name feelings, feel them, and endure them without overwhelming arousal or numbing.
- The patient will gain mastery over symptoms—anxiety, fear, depression, and sexual problems will decrease or become more tolerable.
- The patient will reconnect—increasing his or her ability to trust and attach to others.
- The patient will discover or attach some kind of meaning to the event, finding empowerment.

Implementation

Patients who are victims of rape will require extensive nursing care. First, nurses must provide comfort for the patient, including providing privacy and ensuring the patient's safety. The nurse will also help facilitate evidence collection and help treat physical trauma. The nurse also can also help empower the patient to recover emotionally and psychologically from the event.

Provide Comfort

Upon admission, individuals who have been raped are placed in a private room. Access to the patient is restricted to only necessary personnel, and a family member or friend can be present to provide emotional support at the patient's request. Patients are assured of their safety and privacy, and nurses do not judge or make assumptions about the individual who has been raped or their decisions involving treatment and evaluation. Patients should be given emotional support, and pain medication can be administered as needed once appropriate assessments are completed.

Facilitate Evidence Collection

Nurses determine if the patient has taken a shower or changed clothing. The nurse works with the patient to relay

the details of the incident, including whether a condom was used and the type(s) of rape. If the patient chooses to have evidence collected, nurses explain every step of the process as it is being performed. Individuals are informed that they can ask to stop at any point in the process. Typically, a Sexual Assault Nurse Examiner (SANE) nurse will be involved with the forensic process of evidence collection. DNA swabs and hair and skin samples are taken in an effort to identify the attacker.

Treat Physical Injuries

All physical injuries, including broken bones, lacerations, bruises, and other wounds, are treated in order of severity. Tests for sexually transmitted diseases and infections are performed, and patients are informed about appropriate treatments. Emergency contraception for cases of potential pregnancy is explained to the patient and offered. The need for continued HIV testing at regular intervals during the next year is discussed, and the patient is informed about potential outcomes.

Empower the Patient

Nurses provide referrals to social workers, counselors, support groups, and law enforcement. If patients choose not to use these referrals, that is their decision, but nurses explain their options for seeking help, which will begin the process of empowerment. The nurse should educate the patient on the importance of and assist in developing a safety plan *prior* to discharge from the hospital (see Patient Teaching: Developing a Safety Plan in Exemplar 32.A on Abuse).

Evaluation

Patients are encouraged to ask any questions they may have, either about the examination process or about future testing and resources. Nurses explore all options with the patient as appropriate. Some potential outcomes are as follows:

- The patient expresses emotions regarding the rape.
- The patient is empowered to take control of the situation.
- The patient discusses any fears or questions about the examination.
- The patient employs healthy coping mechanisms.
- The patient asks for, and accepts, help when needed.
- The patient acknowledges that the rape was not his or her fault.

If outcomes are not met, the nurse should reassess the patient to determine if the patient needs additional time to meet the outcomes or if the outcomes were unrealistic. Working with survivors of rape requires compassion and understanding, because each person will cope differently. The patient is likely to be traumatized, which may interfere with their ability to understand or retain information. The nurse should demonstrate patience and review information as necessary.

Nursing Care Plan

A Patient Who Has Been Raped

Renee Meyers, age 23, comes into the emergency department after having been raped by her ex-boyfriend. She explains that the inci-

dent happened 4 hours ago, but she was hesitant to ask for help because she feels some responsibility for the attack.

ASSESSMENT	DIAGNOSES	PLANNING
<p>Camilla Wright, an RN in the ED, escorts Ms. Meyers to a private examination room. Ms. Meyers is resistant to talking about the events, repeating multiple times that she feels that the attack was her own fault and that she cannot believe this could have happened. Nurse Wright is patient and tells the patient to take her time in relaying the events as they occurred. The nurse also reassures the patient that she is perfectly safe in the hospital and that no action will be taken without her permission.</p> <p>After approximately 30 minutes, Ms. Meyers begins to discuss the details of the rape, reporting that her ex-boyfriend forced her to have sexual intercourse with him. When Ms. Meyers tried to resist, her attacker struck her repeatedly in the face with his fists. Nurse Wright notices slight discoloration near the patient's right eye, and the left side of her face is moderately swollen. The patient is visibly shaking, and she is fighting back tears. Ms. Meyers explains that the attacker did not use a condom and says she is very worried about becoming pregnant.</p> <p>Nurse Wright does not interrupt while Ms. Meyers is relaying the events; when she is finished, she asks if the patient has showered since the incident. Ms. Meyers reports that she has not showered. Nurse Wright then explains the process of collecting evidence and testing for sexually transmitted infections, and asks Ms. Meyers if she is willing to consent to the examination and completion of a rape kit. At first, Ms. Meyers is hesitant, but Nurse Wright does not try to pressure her into consent; instead, she asks the patient if she would like some time alone to think it over.</p> <p>Ms. Meyers takes some time alone and then informs Nurse Wright that she would like to have evidence collected. The patient also requests to be tested for sexually transmitted infections.</p>	<ul style="list-style-type: none"> ■ <i>Risk for Infection</i> related to STIs ■ <i>Rape-Trauma Syndrome</i> ■ <i>Fear</i> related to possible pregnancy ■ <i>Acute Pain</i> related to physical trauma ■ <i>Powerlessness</i> ■ <i>Ineffective Coping.</i> <p>(NANDA-I © 2014)</p>	<p>Goals for Ms. Meyers' care include:</p> <ul style="list-style-type: none"> ■ The patient will be tested and treated for any potential infections. ■ The patient will make an informed decision with regard to emergency contraceptive treatment. ■ The patient will report physical pain as absent or tolerable, as evidenced by patient rating of pain as 3 or less on a scale of 0–10. ■ The patient will make an informed decision with regard to reporting the sexual assault to law enforcement officials. ■ The patient will make an informed decision with regard to evidence collection for potential future prosecution of the perpetrator. ■ The patient will openly express emotions and concerns to trusted confidantes. ■ The patient will seek follow-up counseling and psychosocial care. ■ The patient will develop a safety plan prior to discharge.

IMPLEMENTATION

- | | |
|---|--|
| <ul style="list-style-type: none"> ■ Refer to rape advocacy program. ■ Administer prescribed analgesics as needed for pain control. ■ Administer medications as needed or desired to prevent sexually transmitted infections and pregnancy if patient agrees. ■ Support and educate about the physical examination and specimen collection process. | <ul style="list-style-type: none"> ■ Assist in collection of specimens following chain of custody using a rape evidence kit. ■ Inform of HIV testing. ■ Educate about legal procedures available to patient. ■ Educate on importance of and assist with completion of safety plan. |
|---|--|

EVALUATION

Ms. Meyers consented to collection of specimens and physical examination, which will aid in conviction of the rapist. She verbalizes pain as a 3 on a scale of 0–10 (with 0 being absence of pain and 10 being severe pain). Ms. Meyers agreed to speak with the rape victim advocate and was given community support phone numbers and

addresses. She has verbalized understanding of the need for future HIV and pregnancy testing and has completed a safety plan. She has called her best friend, Beth Adams, to drive her home when discharged.

CRITICAL THINKING

- | | |
|--|---|
| <ol style="list-style-type: none"> 1. How should the nurse respond to Ms. Meyers if she refused to have specimens collected or a physical examination at this time? 2. Explain how the nurse should describe emergency contraceptives and their actions. | <ol style="list-style-type: none"> 3. How might this patient's emotional state change over the next 24–48 hours? |
|--|---|

REVIEW Rape and Rape-Trauma Syndrome

RELATE Link the Concepts and Exemplars

Linking the exemplar of rape and rape-trauma syndrome with the concept of stress and coping:

1. What teaching would you provide a patient with rape-trauma syndrome about managing anxiety?
2. Describe the differences in communication strategy to assess for rape in a 12-year-old child versus a 30-year-old woman.

Linking the exemplar of rape and rape-trauma syndrome with the concept of self:

3. How will you plan to assist the victim of rape to regain her self-esteem?
4. When collecting specimens for use by law enforcement during the investigation of potential rape, what nursing interventions can be implemented to help the patient maintain a positive self-concept?

REFLECT Apply Your Knowledge

Damien Harris, a 31-year-old man, transports himself to the ED after having been raped near a local bar. Mr. Harris has numerous bruises to his back, face, and ribs; he also has a shallow cut along his neck. He tells the nurse that a man approached him while he was outside a local bar having a cigarette; the man claimed to be having car trouble. Mr. Harris offered to help the stranger with his car, but once they were away from the bar, the man began attacking him. The attacker put a knife to Mr. Harris's throat and threatened to kill him if he resisted. After the rape, the attacker struck Mr. Harris on the head and left him unconscious. Both his wallet and cell phone were taken by the attacker. Mr. Harris explains that his ribs hurt when he breathes and his head has begun throbbing since he regained consciousness. He has requested the use of a phone to call a friend.

1. What are the three primary nursing interventions for this patient?
2. What resources can be offered to Mr. Harris?
3. Would the nursing care plan be any different if the patient in this scenario were a woman? Explain your answer.

Part III

Reproduction Module

Part III consists of the module on reproduction, which falls within the individual domain. This module presents the concept of reproduction, with exemplars designed to take the nursing student through the

stages of pregnancy to caring for the newborn and the baby who is born prematurely. This module addresses care for newborn, mother, and family, including biophysical and psychosocial needs.

Module 33 Reproduction 2169

The Concept of Reproduction 2169

Exemplar 33.A Antepartum Care 2226

Exemplar 33.B Intrapartum Care 2269

Exemplar 33.C Postpartum Care 2329

Exemplar 33.D Newborn Care 2352

Exemplar 33.E Prematurity 2408

Module 33

Reproduction

Module Outline and Learning Outcomes

The Concept of Reproduction

Normal Presentation of the Female Reproductive System

33.1 Analyze the physiology of the reproductive system.

Conception and Embryonic Development

33.2 Explain the processes of conception and embryonic development.

Embryonic and Fetal Development

33.3 Explain the processes of embryonic and fetal development.

Physical and Psychologic Changes of Pregnancy

33.4 Analyze the physical and psychologic changes of pregnancy.

Concepts Related to Reproduction

33.5 Outline the relationship between reproduction and other concepts.

Health Promotion

33.6 Explain the promotion of healthy reproduction.

Nursing Assessment

33.7 Differentiate among common assessment procedures and tests used to examine reproduction.

Independent Interventions

33.8 Analyze independent interventions nurses can implement for patients with alterations in reproduction.

Collaborative Therapies

33.9 Summarize collaborative therapies used by inter-professional teams for patients with alterations in reproduction.

Lifespan Considerations

33.10 Differentiate considerations related to the care of patients with alterations in reproduction throughout the lifespan.

Reproduction Exemplars

Exemplar 33.A Antepartum Care

33.A Summarize antepartum care of the pregnant woman.

Exemplar 33.B Intrapartum Care

33.B Summarize intrapartum care of the pregnant woman.

Exemplar 33.C Postpartum Care

33.C Summarize postpartum care of the mother.

Exemplar 33.D Newborn Care

33.D Summarize care of newborns.

Exemplar 33.E Prematurity

33.E Summarize care of premature newborns.

Understanding reproduction requires more than understanding sexual intercourse or the process by which the female and male sex cells unite. The nurse also must be familiar with the structures and functions that make childbearing possible and the phenomena that initiate it. The primary functions of both female and male reproductive systems are to produce sex cells and transport them to locations where their union can occur. The sex cells, called **gametes**, are produced by specialized organs called *gonads*. A series of ducts and glands in both the male and female reproductive systems contribute to the production and transport of the gametes.

Normal Presentation of the Female Reproductive System

The female reproductive system is described in detail in the module on Sexuality. Two key components of the female reproductive system are discussed here in relation to their importance to conception and childbearing: the bony pelvis and the female reproductive cycle.

Bony Pelvis

The female bony pelvis has two unique functions:

- To support and protect the pelvic contents
- To form the relatively fixed axis of the birth passage.

The structure of the pelvis must be clearly understood because it is an essential component of the childbirth process.

Bony Structure

The pelvis is composed of four bones: two innominate bones, the sacrum, and the coccyx. The pelvis resembles a bowl or basin; its sides are the innominate bones, and its back is the sacrum and coccyx. Lined with fibrocartilage and held tightly together by ligaments, the four bones join at the symphysis pubis, the two sacroiliac joints, and the sacrococcygeal joints (**Figure 33–1** »).

The innominate bones, also known as the hip bones, are made up of three separate bones: the ilium, ischium, and pubis. These bones fuse to form a circular cavity, the acetabulum, which articulates with the femur.

The ilium is the broad, upper prominence of the hip. The iliac crest is the margin of the ilium. The ischial spines, the foremost projections nearest the groin, are the site of attachment for ligaments and muscles.

The ischium, the strongest bone, is under the ilium and below the acetabulum. The L-shaped ischium ends in a marked protuberance, the ischial tuberosity, on which the weight of a seated body rests. The ischial spines arise near the junction of the ilium and ischium and jut into the pelvic cavity. The shortest diameter of the pelvic cavity is between the ischial spines. The ischial spines serve as reference points

Figure 33–1 » Pelvic bones with supporting ligaments.

Figure 33-2 » Muscles of the pelvic floor. (The puborectalis, pubovaginalis, and coccygeal muscles cannot be seen from this view.)

during labor to evaluate the descent of the fetal head into the birth canal.

The pubis forms the slightly bowed front portion of the innominate bone. Extending medially from the acetabulum to the midpoint of the bony pelvis, each pubis meets the other to form a joint called the *symphysis pubis*. The triangular space below this junction is known as the *pubic arch*. The fetal head passes under this arch during birth. The symphysis pubis is formed by heavy fibrocartilage and the superior and inferior pubic ligaments. The mobility of the inferior ligament increases during a woman's first pregnancy and increases further in subsequent pregnancies.

The sacroiliac joints also have a degree of mobility that increases near the end of pregnancy as the result of an upward gliding movement. The pelvic outlet may be increased by 1.5–2 cm in the squatting and sitting positions. This relaxation of the joints is induced by *relaxin*, which is a pregnancy hormone.

The sacrum is a wedge-shaped bone formed by the fusion of five vertebrae. On the anterior upper portion of the sacrum is a projection into the pelvic cavity known as the *sacral promontory*. This projection is a guide in determining pelvic measurements.

The small triangular bone last on the vertebral column is the coccyx. It articulates with the sacrum at the sacrococcygeal joint. The coccyx usually moves backward during labor to provide more room for the fetus.

Pelvic Floor

The muscular pelvic floor of the bony pelvis is designed to overcome the force of gravity exerted on the pelvic organs. It acts as a supporting structure to the irregularly shaped

pelvic outlet, providing stability and support for surrounding structures.

Deep fascia, the levator ani, and coccygeal muscles form the part of the pelvic floor known as the pelvic diaphragm. The components of the pelvic diaphragm function as a whole, yet they are able to move over one another. This physiology provides an exceptional capacity for dilation during birth and return to prepregnancy condition following birth. Above the pelvic diaphragm is the pelvic cavity; below and behind it is the perineum. The sacrum is located posteriorly.

The levator ani muscle makes up the major portion of the pelvic diaphragm and consists of four muscles: the iliococcygeus, pubococcygeus, puborectalis, and pubovaginalis. The iliococcygeal muscle, a thin muscular sheet underlying the sacrospinous ligament, helps the levator ani support the pelvic organs. Muscles of the pelvic floor are shown in **Figure 33-2** ».

Pelvic Division

The pelvic cavity is divided into the false pelvis and the true pelvis. The **false pelvis** (**Figure 33-3A** »), the portion above the pelvic brim, or linea terminalis, supports the weight of the enlarged pregnant uterus and directs the presenting fetal part into the true pelvis below.

The **true pelvis** is the portion that lies below the linea terminalis (pelvic brim). The bony circumference of the true pelvis is made up of the sacrum, coccyx, and innominate bones and represents the bony limits of the birth canal. The relationship between the true pelvic cavity and the fetal head is of paramount importance: The size and shape of the true pelvis must be adequate for normal fetal passage during

Figure 33-3 >> Female pelvis. **A**, False pelvis is a shallow cavity above the inlet; true pelvis is the deeper portion of the cavity below the inlet. **B**, True pelvis consists of inlet, cavity (midpelvis), and outlet.

labor and at birth. The true pelvis consists of three parts: the inlet, the pelvic cavity, and the outlet (Figure 33-3B). Each part has distinct measurements that aid in evaluating the adequacy of the pelvis for childbirth.

The **pelvic inlet** is the upper border of the true pelvis and is typically rounded. Its size and shape are determined by assessing three anteroposterior diameters. The **diagonal conjugate** extends from the subpubic angle to the middle of the sacral promontory and is typically 12.5 to 13 cm in

diameter. The diagonal conjugate can be measured manually during a pelvic examination. The **obstetric conjugate** extends from the middle of the sacral promontory to an area approximately 1 cm below the pubic crest. Its length is estimated by subtracting 1.5 to 2 cm from the diagonal conjugate (Figure 33-4 >>). The fetus passes through the obstetric conjugate, whose diameter determines whether the fetus can move down into the birth canal for engagement to occur. The true (anatomic) conjugate, or **conjugate vera**, extends from the middle of the sacral promontory to the middle of the pubic crest (superior surface of the symphysis). One additional measurement, the transverse diameter, helps determine the shape of the inlet. The **transverse diameter** is the largest diameter of the inlet and is measured by using the linea terminalis as the point of reference.

The midpelvis or pelvic cavity (canal) is a curved canal with a longer posterior than anterior wall. A change in the lumbar curve can increase or decrease the tilt of the pelvis and influence the progress of labor because the fetus has to adjust itself to this curved path as well as to the different diameters of the true pelvis (see Figure 33-3B).

The **pelvic outlet** is at the lower border of the true pelvis. The size of the pelvic outlet can be determined by assessing the transverse diameter. The anteroposterior diameter of the pelvic outlet increases during birth as the presenting part of the fetus pushes the coccyx posteriorly at the mobile sacrococcygeal joint. Decreased mobility, a large fetal head, and/or a forceful birth can cause the coccyx to break. As the fetus' head emerges, the long diameter of the head (occipital frontal) parallels the long diameter of the outlet (anteroposterior).

The transverse diameter (bi-ischial or intertuberous) extends from the inner surface of one ischial tuberosity to the other. It is the shortest diameter of the pelvic outlet and is even shorter in a woman who has a narrowed pubic arch. The pubic arch is of great importance because the fetus must pass under it during birth. If it is narrow, the baby's head may be pushed backward toward the coccyx, making extension of the head difficult. This situation, known as outlet dystocia, may require the use of forceps or a cesarean birth. The shoulders of a large baby also may become wedged under the pubic arch, making birth more difficult.

Pelvic Types

The Caldwell–Moloy classification of pelves is still sometimes used to differentiate bony pelvic types (Caldwell & Moloy, 1933). The four basic types are gynecoid, android, anthropoid, and platypelloid (Figure 33-5 >>). However, variations in the female pelvis are so great that classic types are not usual. Each type has a characteristic shape, and each shape has implications for labor and birth. The types are described here, along with their implications for labor and birth.

Gynecoid Pelvis

The most common female pelvis is the gynecoid type. All of the inlet diameters are at least adequate for a vaginal birth. The gynecoid pelvic outlet has a wide and round pubic arch; the inferior pubic rami are short and concave. The anteroposterior diameter is long; the transverse diameter, adequate. The overall capacity of the outlet is adequate

Figure 33-4 » Pelvic planes: coronal section and diameters of the bony pelvis.

for a vaginal birth. Approximately 50% of female pelvises are classified as gynecoid (Caldwell & Moloy, 1933).

Android Pelvis

The normal male pelvis is the android type; this type is occasionally seen in females. The inlet is heart shaped. The anteroposterior and transverse diameters are adequate for a vaginal birth, but the posterior sagittal diameter is too short, and the anterior sagittal diameter is long. The android outlet has a narrow, sharp, and deep pubic arch; the inferior pubic rami are straight and long. The anteroposterior diameter is short, and the transverse diameter is narrow. The capacity of the outlet is reduced. Approximately 20% of female pelvises are classified as android (Caldwell & Moloy, 1933). The structure of an android pelvis is not favorable for a vaginal birth. Cesarean birth may be required.

Anthropoid Pelvis

The inlet of an anthropoid pelvis is oval, with a long anteroposterior diameter and an adequate but rather short transverse diameter. The midpelvic diameters are at least adequate, making its capacity adequate for a vaginal birth. The anthropoid outlet has a normal or moderately narrow pubic arch; the interior pubic rami are long and narrow. The outlet capacity is adequate. Approximately 25% of female pelvises are classified as anthropoid (Caldwell & Moloy, 1933).

Platypelloid Pelvis

The platypelloid type refers to the flat female pelvis. The inlet is a distinctly transverse oval with a short anteroposterior and extremely short transverse diameter. The transverse diameter is wide, but the anteroposterior diameter is short. The outlet capacity may be inadequate for a vaginal birth. The platypelloid bones are similar to those of a gynecoid pelvis. Only 5% of female pelvises are classified as platypelloid (Caldwell & Moloy, 1933).

Female Reproductive Cycle

The **female reproductive cycle** is composed of the ovarian cycle, during which **ovulation**, the release of a mature egg from an ovary, occurs, and the uterine cycle, during which menstruation occurs. These two cycles take place simultaneously (**Figure 33-6** »).

Effects of Female Hormones

After menarche, a female undergoes a cyclic pattern of ovulation and menstruation, which is disrupted only by pregnancy, for a period of 30–40 years. This cycle is an orderly process under neurohormonal control. Each month multiple oocytes mature, with typically one, and sometimes more than one, rupturing from the ovary and entering the fallopian tube. The ovary, vagina, uterus, and fallopian tubes are major target organs for female hormones.

Estrogen

The ovaries produce mature gametes and secrete hormones (estrogens, progesterone, and testosterone). Estrogens cause the uterus to increase in size and weight because of increased glycogen, amino acids, electrolytes, and water. Blood supply is expanded as well. Under the influence of estrogens, myometrial contractility increases in both the uterus and fallopian tubes. Uterine sensitivity to oxytocin also increases. Estrogens inhibit follicle-stimulating hormone (FSH) production and stimulate luteinizing hormone (LH) production.

Estrogens have effects on many hormones and other carrier proteins. For example, they contribute to the increased amount of protein-bound iodine in pregnant women and in women who use oral contraceptives containing estrogen. Estrogens decrease the excitability of the hypothalamus, which may cause an increase in sexual desire.

Figure 33-5 >> Comparison of Caldwell-Moloy pelvic types.

Progesterone

Progesterone is secreted by the corpus luteum and is found in greatest amounts during the secretory (luteal or progestational) phase of the menstrual cycle. Progesterone is often called the *hormone of pregnancy* because its effects on the uterus allow pregnancy to be maintained. Under the influence of progesterone, the vaginal epithelium proliferates, the cervix secretes thick, viscous mucus, and contractility of the uterus is suppressed. Breast glandular tissue increases in size and complexity. Progesterone also prepares the breasts for lactation and may contribute to constipation in pregnancy due to relaxation of smooth muscle, which results in decreased peristalsis.

Prostaglandins

Prostaglandins (PGs), which are oxygenated fatty acids, are produced by the cells of the endometrium. They are classified as hormones. Prostaglandins have varied action in the body. The two primary types of PGs are groups E and F. Generally, PGE relaxes smooth muscles and is a potent vasodilator; PGF is a potent vasoconstrictor and increases the contractility of muscles and arteries. Although the primary actions of PGE and PGF seem antagonistic, their basic regulatory functions in cells are achieved through an intricate pattern of reciprocal events.

Prostaglandin production increases during follicular maturation, is dependent on gonadotropins, and seems to be

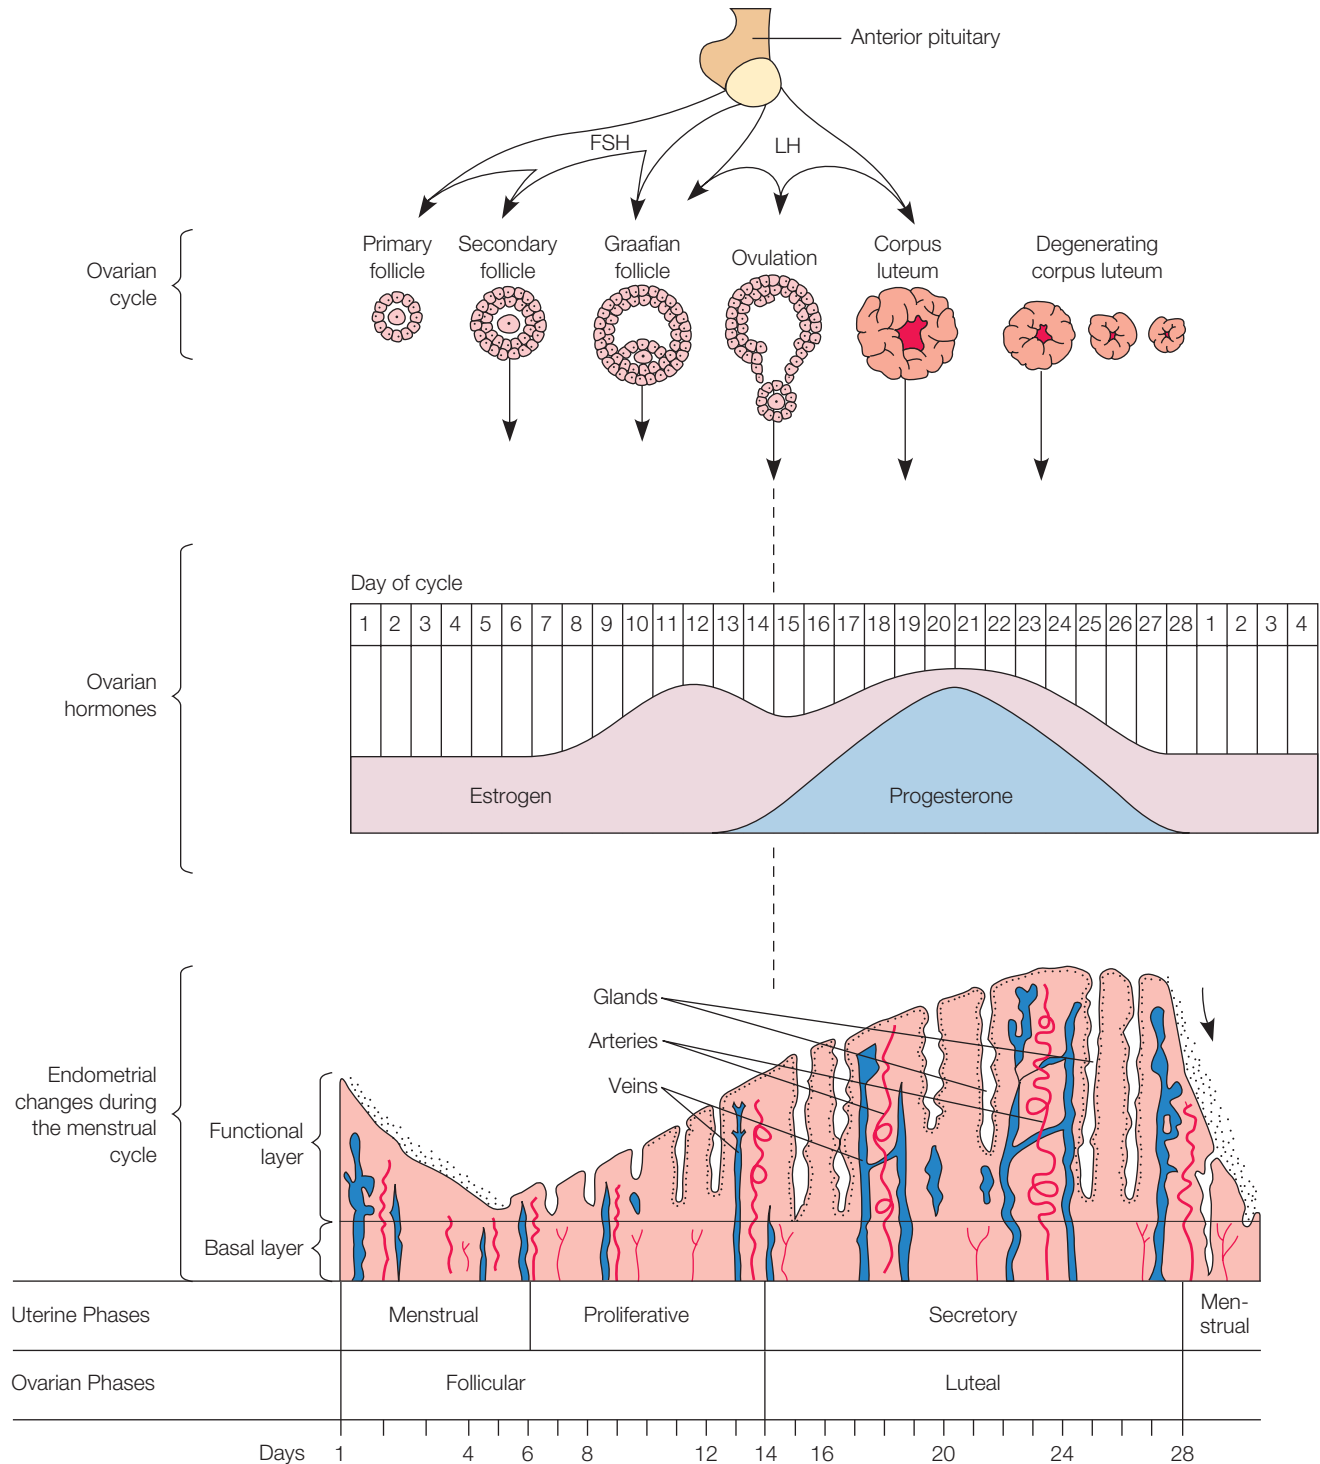

Figure 33-6 » Female reproductive cycle: interrelationships of hormones with the three phases of the uterine cycle and the two phases of the ovarian cycle in an ideal 28-day cycle.

critical to follicular rupture (Cunningham et al., 2014). Extrusion of the ovum, resulting from follicular swelling and increased contractility of the smooth muscle in the theca externa layer of the mature follicle, is thought to be caused in part by $\text{PGF}_{2\alpha}$. Significant amounts of PGs are found in and around the follicle at the time of ovulation.

Neurohumoral Basis of the Female Reproductive Cycle

The female reproductive cycle is controlled by complex interactions between the nervous and endocrine systems and their target tissues. These interactions involve the hypothalamus, anterior pituitary, and ovaries.

The hypothalamus secretes *gonadotropin-releasing hormone (GnRH)* to the pituitary gland in response to signals received from the central nervous system (CNS). This releasing hormone also is called *luteinizing hormone-releasing hormone (LHRH)* and *follicle-stimulating hormone-releasing hormone (FSHRH)* (Blackburn, 2013).

In response to GnRH, the anterior pituitary secretes the gonadotropic hormones FSH and LH. FSH is primarily responsible for the maturation of the ovarian follicle. As the follicle matures, it secretes increasing amounts of estrogen, which enhances the development of the follicle (Cunningham et al., 2014). This estrogen is also responsible for the rebuilding or proliferation phase of the endometrium after it is shed during menstruation.

Final maturation of the follicle cannot occur without the action of LH. The anterior pituitary's production of LH increases 6- to 10-fold as the follicle matures. The peak production of LH can precede ovulation by as much as 12 to 24 hours (Cunningham et al., 2014). The LH is also responsible for the increase in production of progesterone by the granulosa cells of the follicle, thereby stimulating ovulation. As a result, estrogen production is reduced and progesterone secretion continues. Although estrogen levels fall a day before ovulation, small amounts of progesterone continue to be present. Ovulation takes place following the very rapid growth of the follicle, as the sustained high level of estrogen diminishes and progesterone secretion begins.

The ruptured follicle undergoes rapid change, complete luteinization occurs, and the mass of cells becomes the **corpus luteum**. The lutein cells secrete large amounts of progesterone with smaller amounts of estrogen. Concurrently, the excessive amounts of progesterone are responsible for the secretory phase of the uterine cycle. On day 7 or 8 following ovulation, if pregnancy does not occur, the corpus luteum begins to involute, or decrease in size and functional activity. It loses its secretory function, severely diminishing the production of progesterone and estrogen. The anterior pituitary responds with increasingly large amounts of FSH, and LH production begins a few days later. As a result, new follicles become responsive to subsequent ovarian cycles and begin maturing.

Ovarian Cycle

The ovarian cycle has two phases. During a 28-day cycle, the *follicular phase* occurs during days 1–14 and the *luteal phase* occurs during days 15–28. **Figure 33–7** depicts the changes the follicle undergoes during the ovarian cycle. In women whose menstrual cycles vary, usually only the length of the follicular phase varies because the luteal phase is of fixed length. During the follicular phase, the immature follicle matures as a result of FSH. Within the follicle, the oocyte grows.

A mature **graafian follicle** appears about the 14th day under dual control of FSH and LH. It is a large structure, measuring about 5 to 10 mm, which produces increasing amounts of estrogen. In the mature graafian follicle, the cells surrounding the fluid-filled antral cavity are called granulosa cells. The mass of granulosa cells surrounding the oocyte and follicular fluid is called the cumulus oophorus. In the fully mature graafian follicle, the zona pellucida, a thick elastic capsule, develops around the oocyte. Just before

Figure 33–7 » Various stages of development of the ovarian follicles.

ovulation, the mature oocyte completes its first meiotic division. As a result of this division, two cells are formed: a small cell, called a *polar body*, and a larger cell, called a secondary oocyte. The secondary oocyte matures into the ovum.

As the graafian follicle matures and enlarges, it comes close to the surface of the ovary. The ovary surface forms a blister-like protrusion 10–15 mm in diameter, and the follicle walls become thin. The secondary oocyte, polar body, and follicular fluid are pushed out. The ovum is discharged near the fimbria of the fallopian tube and pulled into the tube to begin its journey toward the uterus.

In some women, ovulation is accompanied by midcycle pain known as *mittelschmerz*. This pain may be caused by a local peritoneal reaction to the expulsion of the ovum. Vaginal discharge may increase during ovulation, and a small amount of blood (midcycle spotting) may be discharged as well.

The body temperature increases about 0.3°–0.6°C (0.5°–1.0°F) 24–48 hours after ovulation. It remains elevated until the day before menstruation begins. There may be an accompanying sharp drop in basal body temperature before the increase. These temperature changes are useful clinically to determine the approximate time ovulation occurs (Blackburn, 2013).

Generally, the ovum takes several minutes to travel through the ruptured follicle to the fallopian tube opening. The contractions of the tube's smooth muscle and its ciliary action propel the ovum through the tube. The ovum remains in the ampulla, where, if it is fertilized, cleavage can begin. The ovum is thought to be fertile for only 6–24 hours. It reaches the uterus 72–96 hours after its release from the ovary.

The luteal phase begins when the ovum leaves its follicle. Under the influence of LH, the corpus luteum develops from the ruptured follicle. Within 2 or 3 days, the corpus luteum becomes yellowish and spherical and increases in vascularity.

If the ovum is fertilized and implants in the endometrium, the fertilized egg begins to secrete *human chorionic gonadotropin (hCG)*, which is needed to maintain the corpus luteum. If fertilization does not occur, within about a week after ovulation, the corpus luteum begins to degenerate, eventually becoming a connective tissue scar called the corpus albicans. With degeneration comes a decrease in estrogen and progesterone. This triggers the hypothalamus to release *gonadotropin-releasing hormone (GnRH)*, which stimulates the synthesis and secretion of LH and FSH. This process initiates a new ovulatory cycle.

Menstrual Cycle

Menstruation is cyclic uterine bleeding in response to cyclic hormonal changes. Menstruation occurs when the ovum is not fertilized and begins about 14 days after ovulation in an ideal 28-day cycle. The menstrual discharge, also referred to as the menses or menstrual flow, is composed of blood mixed with fluid, cervical and vaginal secretions, bacteria, mucus, leukocytes, and other cellular debris. The menstrual discharge is dark red and has a distinctive odor.

Menstrual parameters vary greatly among individuals. Generally, menstruation occurs every 29 days, but the cycle varies from 21 to 35 days. Some women have longer cycles, which can skew standard calculations of the estimated date of birth (EDB). Emotional and physical factors such as illness, excessive fatigue, stress or anxiety, and vigorous exercise programs can alter the cycle interval. Certain environmental factors such as temperature and altitude also may affect the cycle. The duration of menses is from 2 to 8 days, with the blood loss averaging 25–60 mL and the loss of iron averaging 0.5–1 mg daily.

The uterine (menstrual) cycle has three phases: menstrual, proliferative, and secretory. Menstruation occurs during the *menstrual phase*. Some endometrial areas are shed, although others remain. Some of the remaining tips of the endometrial glands begin to regenerate. The endometrium is in a resting state following menstruation. Estrogen levels are low, and the endometrium is 1–2 mm deep. During this part of the cycle, the cervical mucus is scanty, viscous, and opaque.

The *proliferative phase* begins when the endometrial glands enlarge, becoming twisted and longer in response to increasing amounts of estrogen. The blood vessels become prominent and dilated, and the endometrium increases in thickness six- to eightfold. This gradual process reaches its peak just before ovulation. The cervical mucus becomes thin, clear, watery, and more alkaline, making the mucosa more favorable to spermatozoa. As ovulation nears, the cervical mucus shows increased elasticity, called *spinnbarkeit*. At ovulation, the mucus will stretch more than 5 cm. The pH of the cervical mucus increases from below 7.0 to 7.5 at the time of ovulation. On microscopic examination, the mucus shows a characteristic ferning pattern (**Figure 33–8** »). This fern pattern is useful in assessing ovulation time.

The *secretory phase* follows ovulation. The endometrium, under estrogenic influence, undergoes slight cellular growth. Progesterone, however, causes such marked swelling and growth that the epithelium is warped into folds. The amount of tissue glycogen increases. The glandular epithelial cells begin to fill with cellular debris, become twisted, and dilate. The glands secrete small quantities of endometrial fluid in preparation for

Figure 33–8 » Ferning pattern.

a fertilized ovum. The vascularity of the entire uterus increases greatly, providing a nourishing bed for implantation. If implantation occurs, the endometrium, under the influence of progesterone, continues to develop and becomes even.

If fertilization does not occur, the *menstrual phase* begins. The corpus luteum begins to degenerate, and as a result, both estrogen and progesterone levels fall. Areas of necrosis appear under the epithelial lining. Extensive vascular changes also occur. Small blood vessels rupture, and the spiral arteries constrict and retract, causing a deficiency of blood in the endometrium, which becomes pale. This phase is characterized by the escape of blood into the stromal cells of the uterus. The menstrual flow begins, thus beginning the menstrual cycle again. After menstruation, the basal layer remains so that the tips of the glands can regenerate the new functional endometrial layer. (For more about the female reproductive cycle, see the module on Sexuality.)

Conception and Embryonic Development

Each human begins life as a single cell called a fertilized ovum, or zygote. This single cell reproduces itself and, in turn, each resulting cell reproduces itself in a continuing process. The new cells are similar to the cells from which they came. Cells are reproduced by mitosis or meiosis, two different but related processes.

Mitosis results in the production of diploid body (somatic) cells, which are exact copies of the original cell. Mitosis makes growth and development possible, and in mature individuals, it is the process by which the body's cells continue to divide and replace themselves. **Meiosis** is a process of cell division leading to the development of the eggs and sperm needed to produce a new organism. Unlike cells produced during mitosis, the cells produced during meiosis contain only half the genetic material or number of chromosomes (the haploid number).

Mitosis

During mitosis, the cell undergoes several changes, ending in cell division. As the last phase of cell division nears completion, a furrow develops in the cell cytoplasm, which divides it into two daughter cells, each with its own nucleus. Daughter cells have the same diploid number of chromosomes

(46) and same genetic makeup as the cell from which they came. After a cell with 46 chromosomes goes through mitosis, the result is two identical cells, each with 46 chromosomes.

Meiosis

Meiosis is a special type of cell division by which diploid cells in the testes and ovaries give rise to gametes (sperm and ova) with the haploid number of chromosomes, which is 23.

Meiosis consists of two successive cell divisions. In the first division, the chromosomes replicate. Next, a pairing takes place between homologous chromosomes (Sadler, 2015). Instead of separating immediately, as in mitosis, the chromosomes become closely intertwined. At each point of contact, a physical exchange of genetic material takes place between the chromatids (the arms of the chromosomes). New combinations are provided by the newly formed chromosomes; these combinations account for the wide variation of traits in people (e.g., hair and eye color). The chromosome pairs then separate, and the members of the pair move to opposite sides of the cell. In contrast, during mitosis, the chromatids of each chromosome separate and move to opposite poles. The cell divides, forming two daughter cells, each with 23 double-structured chromosomes; thus each contains the same amount of deoxyribonucleic acid (DNA) as a normal somatic cell. In the second division, the chromatids of each chromosome separate and move to opposite poles of each of the daughter cells. Cell division occurs, resulting in the formation of four cells, each containing 23 single chromosomes, identified as the haploid number of chromosomes. These daughter cells contain only half the DNA of a normal somatic cell (Sadler, 2015).

Mutations may occur during the second meiotic division if two of the chromatids do not move apart rapidly enough when the cell divides. The still-paired chromatids are carried into one of the daughter cells and eventually form an extra chromosome. This condition, autosomal nondisjunction (chromosomal mutation), is harmful to the offspring that may result should fertilization occur. Another type of chromosomal mutation can occur if chromosomes break during meiosis. If the broken segment is lost, the result is a shorter chromosome—a situation known as deletion. If the broken segment becomes attached to another chromosome, a harmful mutation called a translocation results.

Gametogenesis

Meiosis occurs during **gametogenesis**, the process by which germ cells, or gametes (*ovum* and *sperm*), are produced. These cells contain only half the genetic material of a typical body cell. The gametes must have a haploid number (23) of chromosomes so that when the female gamete (egg or ovum) and the male gamete (sperm or spermatozoon) unite to form the **zygote** (fertilized ovum), the normal human diploid number of chromosomes (46) is reestablished.

Oogenesis

Oogenesis is the process that produces the female gamete, called an ovum (egg). The ovaries begin to develop early in the fetal life of the female. All of the ova that the female will produce in her lifetime are present at birth. The ovary gives

rise to oogonial cells, which develop into oocytes. Meiosis begins in all oocytes before the female fetus is born, but stops before the first division is complete and remains in this arrested phase until puberty. During puberty, the mature primary oocyte proceeds (by oogenesis) through the first meiotic division in the graafian follicle of the ovary.

The first meiotic division produces two cells of unequal size with different amounts of cytoplasm but with the same number of chromosomes. These two cells are the secondary oocyte and the first polar body. Both the secondary oocyte and the first polar body contain 22 double-structured autosomal chromosomes and one double-structured sex chromosome (X).

At ovulation, a second meiotic division begins immediately and proceeds as the oocyte moves down the fallopian tube. Division is again not equal, and the secondary oocyte moves into the metaphase stage of cell division, where its meiotic division is arrested until and unless the oocyte is fertilized.

When the secondary oocyte completes the second meiotic division after fertilization, the result is a mature ovum with the haploid number of chromosomes and virtually all of the cytoplasm. In addition, the second polar body (also haploid) forms at this time. The first polar body now has also divided, producing two additional polar bodies. Thus, at the completion of meiosis, four haploid cells have been produced: the three polar bodies, which eventually disintegrate, and one ovum (Sadler, 2015).

Spermatogenesis

During puberty, the germinal epithelium in the seminiferous tubules of the testes begins the process of **spermatogenesis**, which produces the male gamete (sperm). The diploid spermatogonium replicates before it enters the first meiotic division, during which it is called the primary spermatocyte. During this first meiotic division, the spermatogonium replicates and forms two haploid cells called secondary spermatocytes, each of which contains 22 double-structured autosomal chromosomes and either a double-structured X sex chromosome or a double-structured Y sex chromosome. During the second meiotic division, they divide to form four spermatids, each with the haploid number of chromosomes. The spermatids undergo a series of changes during which they lose most of their cytoplasm and become sperm (spermatozoa). The nucleus becomes compacted into the head of the sperm, which is covered by a cap called an acrosome that is, in turn, covered by a plasma membrane. A long tail is produced from one of the centrioles.

Fertilization

Fertilization is the process by which a sperm fuses with an ovum to form a new diploid cell, or zygote. The zygote begins life as a single cell with a complete set of genetic material, 23 chromosomes from the mother's ovum and 23 chromosomes from the father's sperm for a total of 46 chromosomes. The following events lead to fertilization.

Preparation for Fertilization

The mature ovum and spermatozoon have only a brief time to unite. Ova are considered fertile for about 12–24 hours after ovulation. Sperm can survive in the female reproductive

tract for 48–72 hours, but they are believed to be healthy and highly fertile for only the first 24 hours.

The ovum's cell membrane is surrounded by two layers of tissue. The layer closest to the cell membrane is called the *zona pellucida*. It is a clear, noncellular layer whose thickness influences the fertilization rate. Surrounding the *zona pellucida* is a ring of elongated cells, called the *corona radiata* because they radiate from the ovum like the gaseous corona around the sun. These cells are held together by hyaluronic acid. The ovum has no inherent power of movement. During ovulation, high estrogen levels increase peristalsis in the fallopian tubes, which helps move the ovum through the tube toward the uterus. The high estrogen levels also cause a thinning of the cervical mucus, facilitating movement of the sperm through the cervix, into the uterus, and up the fallopian tube.

The process of fertilization takes place in the ampulla (outer third) of the fallopian tube. In a single ejaculation, the male deposits approximately 200–500 million spermatozoa into the vagina, of which only approximately one thousand sperm actually reach the ampulla (Sadler, 2015). Fructose in the semen, secreted by the seminal vesicles, is the energy source for the sperm. The spermatozoa propel themselves up the female tract by the flagellar movement of their tails. Transit time from the cervix into the fallopian tube can be as short as 5 minutes but usually takes an average of 2–7 hours after ejaculation (Sadler, 2015). Prostaglandins in the semen may increase uterine smooth muscle contractions, which help transport the sperm. The fallopian tubes have a dual ciliary action that facilitates movement of the ovum toward the uterus and movement of the sperm from the uterus toward the ovary.

The sperm must undergo two processes before fertilization can occur: capacitation and the acrosomal reaction. **Capacitation** is the removal of the plasma membrane overlying the spermatozoa's acrosomal area and the loss of seminal plasma proteins. If the glycoprotein coat is not removed, the sperm will not be able to fertilize the ovum (Sadler, 2015). Capacitation occurs in the female reproductive tract (aided by uterine enzymes) and is thought to take about 7 hours. Sperm that undergo capacitation take on three characteristics: (1) the ability to undergo the acrosomal reaction, (2) the ability to bind to the *zona pellucida*, and (3) the acquisition of hypermotility.

The **acrosomal reaction** follows capacitation, whereby the acrosomes of the sperm surrounding the ovum release their enzymes (hyaluronidase, a protease called acrosin, and trypsinlike substances) and thus break down the hyaluronic acid in the ovum's *corona radiata* (Sadler, 2015). Approximately a thousand acrosomes must rupture before enough hyaluronic acid is cleared for a single sperm to penetrate the ovum's *zona pellucida* successfully.

At the moment of penetration by a fertilizing sperm, the *zona pellucida* undergoes a reaction that prevents additional sperm from entering a single ovum. This is known as the block to polyspermy. This cellular change is mediated by release of materials from the cortical granules, organelles found just below the ovum's surface, and is called the *cortical reaction*.

The Moment of Fertilization

After the sperm enters the ovum, a chemical signal prompts the secondary oocyte to complete the second meiotic division,

forming the nucleus of the ovum and ejecting the second polar body. Then the nuclei of the ovum and sperm swell and approach each other. The true moment of fertilization occurs as the nuclei unite. Their individual nuclear membranes disappear, and their chromosomes pair up to produce the diploid zygote. Because each nucleus contains a haploid number of chromosomes (23), this union restores the diploid number (46). The zygote contains a new combination of genetic material that results in an individual different from either parent and from anyone else.

The sex of the zygote is determined at the moment of fertilization. The two chromosomes (the sex chromosomes) of the 23rd pair—either XX or XY—determine the sex of an individual. The X chromosome is larger and bears more genes than the Y chromosome. Females have two X chromosomes, and males have an X and a Y chromosome. Whereas the mature ovum produced by oogenesis can have only one type of sex chromosome—an X—spermatogenesis produces two sperm with an X chromosome and two sperm with a Y chromosome. When each gamete contributes an X chromosome, the resulting zygote is female. When the ovum contributes an X and the sperm contributes a Y chromosome, the resulting zygote is male. Certain traits are termed *sex-linked* because they are controlled by the genes on the X sex chromosome. Two examples of sex-linked traits are color blindness and hemophilia.

Preembryonic Development

The first 14 days of development, starting the day the ovum is fertilized (conception), make up the preembryonic stage, or the stage of the ovum. Development after fertilization can be divided into two phases: cellular multiplication and cellular differentiation. These phases are characterized by rapid cellular multiplication and differentiation and establishment of the primary germ layers and embryonic membranes. Synchronized development of the endometrium and the embryo is a prerequisite for implantation to succeed (Moore, Persaud, & Torchia, 2016). These phases and the process of implantation (nidation), which occurs between them, are discussed next.

Cellular Multiplication

Cellular multiplication begins as the zygote moves through the fallopian tube toward the cavity of the uterus. This transport takes 3 days or more and is accomplished mainly by a weak fluid current in the fallopian tube resulting from the beating action of the ciliated epithelia that line the tube.

The zygote now enters a period of rapid mitotic divisions called cleavage, during which it divides into 2 cells, 4 cells, 8 cells, and so on. These cells, called blastomeres, are so small that the developing cell mass is only slightly larger than the original zygote. The blastomeres are held together by the *zona pellucida*, which is under the *corona radiata*. The blastomeres eventually form a solid ball of 12–32 cells called the **morula**.

As the morula enters the uterus, two things happen: The intracellular fluid in the morula increases, and a central cavity forms within the cell mass. Inside this cavity is an inner solid mass of cells called the **blastocyst**. The outer layer of cells that surrounds the cavity and replaces the *zona pellucida* is the **trophoblast**. Eventually, the trophoblast develops

Figure 33-9 >> During ovulation, the ovum leaves the ovary and enters the fallopian tube. Fertilization generally occurs in the outer third of the fallopian tube. The figure depicts subsequent changes in the fertilized ovum from conception to implantation.

into one of the two embryonic membranes, the *chorion*. The blastocyst develops into a double layer of cells called the embryonic disc, from which the *embryo* and the *amnion* (embryonic membrane) develop. The journey of the fertilized ovum to its destination in the uterus is illustrated in **Figure 33-9**.

Early pregnancy factor (EPF), an immunosuppressant protein, is secreted by the trophoblastic cells. This factor appears in the maternal serum within 24–48 hours after fertilization and forms the basis of a pregnancy test during the first 10 days of development (Caudle, 2014; Moore et al., 2016).

Implantation (Nidation)

While floating in the uterine cavity, the blastocyst is nourished by the uterine glands, which secrete a mixture of lipids, mucopolysaccharides, and glycogen. The trophoblast attaches to the surface of the endometrium for further nourishment. The most frequent site of attachment is the upper part of the posterior uterine wall. Between 7 and 10 days after fertilization, the zona pellucida disappears and the blastocyst implants itself by burrowing into the uterine lining and penetrating down toward the maternal capillaries until it is completely covered (Moore et al., 2016). The lining of the uterus thickens below the implanted blastocyst, and the cells of the trophoblast grow down into the thickened lining, forming processes that are called *chorionic villi*.

Under the influence of progesterone, the endometrium increases in thickness and vascularity in preparation for implantation and nutrition of the ovum. After implantation,

the endometrium is called the decidua. The portion of the decidua that covers the blastocyst is called the decidua capsularis, the portion directly under the implanted blastocyst is the decidua basalis, and the portion that lines the rest of the uterine cavity is the decidua vera (parietalis). The maternal part of the placenta develops from the decidua basalis, which contains large numbers of blood vessels (magnified inset in Figure 33-9) (London et al., 2017). The chorionic villi (discussed shortly) in contact with the decidua basalis will form the fetal portion of the placenta.

Cellular Differentiation

Primary Germ Layers

About the 10th to 14th day after conception, the homogeneous mass of blastocyst cells differentiates into the primary germ layers. These three layers—the ectoderm, mesoderm, and endoderm—are formed at the same time as the embryonic membranes. All tissues, organs, and organ systems will develop from these primary germ cell layers.

Embryonic Membranes

The **embryonic membranes** begin to form at the time of implantation (**Figure 33-10**). These membranes protect and support the embryo as it grows and develops inside the uterus. The first and outermost membrane to form is the **chorion**. This thick membrane develops from the trophoblast and has many fingerlike projections called chorionic villi on its surface. These chorionic villi can be used for early genetic testing of the embryo at 10–11 weeks' gestation by

Figure 33-10 » Early development of primary embryonic membranes. At 4½ weeks, the decidua capsularis (placental portion enclosing the embryo on the uterine surface) and decidua basalis (placental portion encompassing the elaborate chorionic villi and maternal endometrium) are well formed. The chorionic villi lie in blood-filled intervillous spaces within the endometrium. The amnion and yolk sac are well developed.

chorionic villus sampling (CVS). As the pregnancy progresses, the chorionic villi begin to degenerate, except for those just under the embryo, which grow and branch into depressions in the uterine wall, forming the fetal portion of the placenta. By the fourth month of pregnancy, the surface of the chorion is smooth except at the place of attachment to the uterine wall.

The second membrane to form, the amnion, originates from the ectoderm, a primary germ layer, during the early stages of embryonic development. The **amnion** is a thin protective membrane that contains amniotic fluid. The space between the membrane and the embryo is the amniotic cavity. This cavity surrounds the embryo and yolk sac, except where the developing embryo (germ-layer disc) attaches to the trophoblast via the umbilical cord. As the embryo grows, the amnion expands until it comes in contact with the chorion. These two slightly adherent membranes form the fluid-filled amniotic sac, which protects the floating embryo.

Amniotic Fluid

The primary functions of **amniotic fluid** are to:

- Act as a cushion to protect the fetus against mechanical injury during pregnancy and labor.
- Help control the embryo's temperature (the embryo relies on the mother to release heat).
- Permit symmetrical external growth and development of the embryo.
- Prevent adherence of the embryo–fetus to the amnion (decreases chance of amniotic band syndrome) to allow freedom of movement so that the embryo–fetus can change position (flexion and extension), thus aiding in musculoskeletal development.

- Allow the umbilical cord to be relatively free of compression.
- Act as an extension of fetal extracellular space (hydropic fetuses have increased amniotic fluid).
- Permit fetal swallowing and excretion, thus serving as a waste repository.

Amniotic fluid is slightly alkaline and contains albumin, urea, uric acid, creatinine, lecithin, sphingomyelin, bilirubin, fat, fructose, leukocytes, proteins, epithelial cells, enzymes, and fine hair called lanugo. The amount of amniotic fluid at 10 weeks is about 30 mL, and it increases to 210 mL at 16 weeks (Cunningham et al., 2014). After 28 weeks, the volume ranges from 700 to 1000 mL. As the pregnancy continues, the fetus influences the volume of amniotic fluid by swallowing the fluid and excreting lung fluid and urine into the amniotic fluid (London et al., 2017). The fetus swallows up to 262 mL/kg/day. Between 29 and 30 weeks, the amniotic fluid volume changes very little. After 39 weeks the amniotic fluid begins to dramatically decrease. Abnormal variations are *oligohydramnios* (too little amniotic fluid) and *polyhydramnios* (too much amniotic fluid or an amniotic fluid index greater than the 97.5 percentile for the corresponding gestational age). Polyhydramnios is also called *hydramnios*.

Yolk Sac

In humans, the yolk sac is small, and it functions only in early embryonic life. It develops as a second cavity in the blastocyst on about day 8 or 9 after conception. It forms primitive red blood cells (RBCs) during the first 6 weeks of development, until the embryo's liver takes over the process. As the embryo develops, the yolk sac is incorporated into the umbilical cord, where it can be seen as a degenerated structure after birth.

Umbilical Cord

As the placenta develops, the **umbilical cord** is being formed from the mesoderm and is covered by the amnion. The body stalk, which attaches the embryo to the yolk sac, contains blood vessels that extend into the chorionic villi. The body stalk fuses with the embryonic portion of the placenta to provide a circulatory pathway from the chorionic villi to the embryo. As the body stalk elongates to become the umbilical cord, the vessels in the cord decrease to one large vein and two smaller arteries. About 1% of umbilical cords have only two vessels: an artery and a vein. This condition may be associated with congenital malformations primarily of the renal, gastrointestinal, and cardiovascular systems. A specialized connective tissue known as **Wharton jelly** surrounds the blood vessels in the umbilical cord. This tissue, in addition to the high blood volume pulsating through the vessels, prevents compression of the umbilical cord in utero. The umbilical cord has no sensory or motor innervation, so cutting the cord after birth is not painful. At term (37–42 weeks' gestation), the average cord is 2 cm (0.8 in.) across and about 55 cm (22 in.) long. The cord can attach itself to the placenta at various sites. Central insertion into the placenta is considered normal.

Figure 33-11 >> **A**, Dizygotic (fraternal) twins. (Note separate placentas.) **B**, Monozygotic (identical) twins.

Umbilical cords appear twisted or spiraled, which is most likely caused by fetal movement. A true knot in the umbilical cord rarely occurs; if it does, the cord is longer than usual. More common are so-called false knots, caused by the folding of cord vessels. A *nuchal cord* is said to exist when the umbilical cord encircles the fetal neck.

Twins

Twins normally occur in approximately 1 in 80 pregnancies, and triplets occur in 1 in 8000 pregnancies. The current rate of twinning is attributed to delayed childbearing and the use of artificial reproductive treatments (London et al., 2017). Twins may be fraternal or identical (**Figure 33-11** >>).

>> Go to **Pearson MyLab Nursing and eText** for a MiniModule on twins.

Development and Functions of the Placenta

The **placenta** is the means of metabolic and nutrient exchange between the embryonic and maternal circulations. Placental development and circulation do not begin until the third week of embryonic development. The placenta develops at the site where the embryo attaches to the uterine wall. Expansion of the placenta continues until about 20 weeks, when it covers approximately one half of the internal

surface of the uterus. After 20 weeks' gestation, the placenta becomes thicker but not wider. At 40 weeks' gestation, the placenta is about 15–20 cm (5.9–7.9 in.) in diameter and 2.5–3 cm (1–1.2 in.) in thickness. At that time, it weighs about 400–600 g (14–21 oz).

The placenta has two parts: the maternal and fetal portions. The maternal portion consists of the decidua basalis and its circulation. Its surface is red and fleshlike. The fetal portion consists of the chorionic villi and their circulation. The fetal surface of the placenta is covered by the amnion, which gives it a shiny gray appearance (**Figures 33-12** >> and **33-13** >>).

Development of the placenta begins with the chorionic villi. The trophoblastic cells of the chorionic villi form spaces in the tissue of the decidua basalis. These spaces fill with maternal blood, and the chorionic villi grow into them. As the chorionic villi differentiate, two trophoblastic layers appear: an outer layer, called the syncytium (consisting of syncytiotrophoblasts), and an inner layer, known as the cytotrophoblast. The cytotrophoblast thins out and disappears around the fifth month, leaving only a single layer of syncytium covering the chorionic villi. The syncytium is in direct contact with the maternal blood in the intervillous spaces. It is the functional layer of the placenta, and it secretes the placental hormones of pregnancy.

A third inner layer of connective mesoderm develops in the chorionic villi, forming anchoring villi. These anchoring

Figure 33-12 » Maternal side of placenta.

villi eventually form the septa (partitions) of the placenta. The septa divide the mature placenta into 15–20 segments called **cotyledons** (subdivisions of the placenta made up of anchoring villi and decidual tissue). In each cotyledon, the branching villi form a highly complex vascular system that allows compartmentalization of the uteroplacental circulation. The exchange of gases and nutrients takes place across these vascular systems.

Placental Circulation

After implantation of the blastocyst, the cells distinguish themselves into fetal cells and trophoblastic cells. The proliferating trophoblast successfully invades the decidua basalis of the endometrium, first opening the uterine capillaries and later opening the larger uterine vessels. The chorionic villi are an outgrowth of the blastocystic tissue. As these villi continue to grow and divide, the fetal vessels begin to form. The intervillous spaces in the decidua basalis develop as the endometrial spiral arteries are opened.

By the end of the fourth week, the placenta has begun to function as a means of metabolic exchange between embryo and mother. The completion of the maternal–placental–fetal circulation occurs about 17 days after conception, when the embryonic heart begins functioning (Moore et al., 2016). By 14 weeks, the placenta is a discrete organ. It has grown in thickness as a result of growth in the length and size of the chorionic villi and accompanying expansion of the intervillous space.

In the fully developed placenta's umbilical cord, fetal blood flows through the two umbilical arteries to the capillaries of the villi, becomes oxygen enriched, and then flows back through the umbilical vein into the fetus (**Figure 33-14** »). Late in pregnancy a soft blowing sound (funic souffle) can be heard over the area of the umbilical cord. The sound is synchronous with the fetal heartbeat and fetal blood flow through the umbilical arteries.

Source: Courtesy of Marcia London.

Figure 33-13 » Fetal side of placenta.

Maternal blood, rich in oxygen and nutrients, moves from the arcuate artery to the radial artery to the uterine spiral arteries and then spurts into the intervillous spaces. These spurts are produced by the maternal blood pressure. The spurt of blood is directed toward the chorionic plate, and as the blood loses pressure, it becomes lateral (spreads out). Fresh blood enters continuously and exerts pressure on the contents of the intervillous spaces, pushing blood toward the exits in the basal plate. The blood then drains through the uterine and other pelvic veins. A uterine souffle, timed precisely with the mother's pulse, also is heard just above the mother's symphysis pubis during the last months of pregnancy. This souffle is caused by the augmented blood flow entering the dilated uterine arteries.

Braxton Hicks contractions are intermittent painless uterine contractions that may occur every 10–20 minutes; they occur more frequently near the end of pregnancy. These contractions are believed to facilitate placental circulation by enhancing the movement of blood from the center of the cotyledon through the intervillous space. Placental blood flow is enhanced when the woman is lying on her left side because venous return from the lower extremities is not compromised (Blackburn, 2013).

Placental Functions

Placental exchange functions occur only in those fetal vessels that are in intimate contact with the covering syncytial membrane. The syncytium villi have brush borders containing many microvilli, which greatly increase the exchange rate between maternal and fetal circulation (Blackburn, 2013; Sadler, 2015).

The placental functions, many of which begin soon after implantation, include fetal respiration, nutrition, and excretion. To carry out these functions, the placenta is involved in metabolic and transfer activities. In addition, it has

Figure 33-14 >> Vascular arrangement of the placenta. Arrows indicate the direction of blood flow. Maternal blood flows through the uterine arteries to the intervillous spaces of the placenta and returns through the uterine veins to maternal circulation. Fetal blood flows through the umbilical arteries into the villous capillaries of the placenta and returns through the umbilical vein to the fetal circulation.

endocrine functions and special immunologic properties. (See the discussion later in this section.)

Metabolic Activities

The placenta continuously produces glycogen, cholesterol, and fatty acids for fetal use and hormone production. The placenta also produces numerous enzymes, such as sulfatase, which enhances excretion of fetal estrogen precursors, and insulinase, which increases the barrier to insulin. These enzymes are required for fetoplacental transfer. The placenta breaks down certain substances such as epinephrine and histamine (Blackburn, 2013). In addition, it stores glycogen and iron.

Transport Function

The placental membranes actively control the transfer of a wide range of substances by a variety of transport mechanisms.

- **Simple diffusion** moves substances from an area of higher concentration to an area of lower concentration. Substances that move across the placenta by simple diffusion include water, oxygen, carbon dioxide, electrolytes (sodium and chloride), anesthetic gases, and drugs. Insulin and steroid hormones originating from the adrenals, as well as thyroid hormones, also cross the placenta. However, this happens at a very slow rate. The rate of oxygen transfer across the placental membrane is greater than that allowed by simple diffusion, indicating that oxygen also is transferred by some type of facilitated diffusion transport. Unfortunately, many substances of

abuse, such as cocaine and heroin, cross the placenta via simple diffusion.

- **Facilitated transport** involves a carrier system to move molecules from an area of greater concentration to an area of lower concentration. Molecules such as glucose, galactose, and some oxygen are transported by this method. Ordinarily, the glucose level in the fetal blood is approximately 20–30% lower than the glucose level in the maternal blood because the fetus is metabolizing glucose rapidly. This, in turn, causes rapid transport of additional glucose from the maternal blood to the fetal blood.
- **Active transport** can work against a concentration gradient and allows molecules to move from areas of lower concentration to areas of higher concentration. Amino acids, calcium, iron, iodine, water-soluble vitamins, and glucose are transferred across the placenta this way. The measured amino acid content of fetal blood is greater than that of maternal blood, and calcium and inorganic phosphate occur in greater concentration in fetal blood than in maternal blood (Blackburn, 2013).

In addition, fetal RBCs can pass into the maternal circulation through breaks in the capillaries and placental membrane, particularly during labor and birth. Certain cells (e.g., maternal leukocytes) and microorganisms such as viruses (e.g., HIV, which causes AIDS), and the bacterium *Treponema pallidum* (which causes syphilis), can cross the placental membrane under their own power (Moore et al., 2016). Some bacteria and protozoa infect the placenta by causing lesions and then entering the fetal blood system.

Reduction of the placental surface area, as with abruptio placentae (partial or complete premature separation of the placenta), lessens the area that is functional for exchange. Placental diffusion distance also affects exchange. In conditions such as diabetes and placental infection, edema of the villi increases the diffusion distance, thus increasing the distance the substance must be transferred.

Blood flow alteration changes the transfer rate of substances. Decreased blood flow in the intervillous space is seen in labor and with certain maternal diseases such as hypertension. Mild fetal hypoxia increases the umbilical blood flow, but severe hypoxia results in decreased blood flow.

As the maternal blood picks up fetal waste products and carbon dioxide, it drains back into the maternal circulation through the veins in the basal plate. Fetal blood is hypoxic in comparison to maternal blood; therefore, it attracts oxygen from the mother's blood. Affinity for oxygen increases as the fetal blood gives up its carbon dioxide, which also decreases its acidity.

Endocrine Functions

The placenta produces hormones that are vital to the survival of the fetus. These include hCG; human placental lactogen (hPL); and two steroid hormones, estrogen and progesterone.

The hormone hCG is similar to LH and prevents the normal involution of the corpus luteum at the end of the menstrual cycle. If the corpus luteum stops functioning before the 11th week of pregnancy, spontaneous abortion occurs. The hCG also causes the corpus luteum to secrete increased amounts of estrogen and progesterone.

After the 11th week, the placenta produces enough progesterone and estrogen to maintain pregnancy. In the male fetus, hCG also exerts an interstitial cell-stimulating effect on the testes, resulting in the production of testosterone. This small secretion of testosterone during embryonic development is the factor that causes male sex organs to grow. The hormone hCG may play a role in the trophoblast's immunologic capabilities (ability to exempt the placenta and embryo from rejection by the mother's system). This hormone is used as a basis for pregnancy tests. (Placental hormones are discussed further in the Endocrine System section.)

Development of the Fetal Circulatory System

The circulatory system of the fetus has several unique features that, by maintaining the blood flow to the placenta, provide the fetus with oxygen and nutrients while removing carbon dioxide and other waste products.

Most of the blood supply bypasses the fetal lungs because they do not carry out respiratory gas exchange. The placenta assumes the function of the fetal lungs by supplying oxygen and allowing the fetus to excrete carbon dioxide into the maternal bloodstream. **Figure 33-15 »** shows the fetal circulatory system. The blood from the placenta flows through the umbilical vein, which enters the abdominal wall of the fetus at the site that, after birth, is the umbilicus (belly button). As umbilical venous blood approaches the liver, a small portion of the blood enters the liver sinusoids, mixes with blood from the portal circulation, and then enters the inferior

vena cava via hepatic veins. Most of the umbilical vein's blood flows through the **ductus venosus** directly into the inferior vena cava, bypassing the liver. This blood then enters the right atrium, passes through the **foramen ovale** into the left atrium, and pours into the left ventricle, which pumps blood into the aorta. Some blood returning from the head and upper extremities by way of the superior vena cava is emptied into the right atrium and passes through the tricuspid valve into the right ventricle. This blood is pumped into the pulmonary artery, and a small amount passes to the lungs for nourishment only. The larger portion of blood passes from the pulmonary artery through the **ductus arteriosus** into the descending aorta, bypassing the lungs. Finally, blood returns to the placenta through the two umbilical arteries, and the process is repeated.

The fetus obtains oxygen via diffusion from the maternal circulation because of the gradient difference of 50 mmHg PO₂ in maternal blood in the placenta to 30 mmHg PO₂ in the fetus. At term, the fetus receives oxygen from the mother's circulation at a rate of 20–30 mL/min (Sadler, 2015). Fetal hemoglobin facilitates obtaining oxygen from the maternal circulation because it carries as much as 20–30% more oxygen than adult hemoglobin.

Fetal circulation delivers the highest available oxygen concentration to the head, neck, brain, and heart (coronary circulation) and a lesser amount of oxygenated blood to the abdominal organs and the lower body. This circulatory pattern leads to cephalocaudal (head-to-tail) development in the fetus.

Fetal Heart

The heart of the fetus, like that of the adult, is controlled by its own pacemaker. The sinoatrial (SA) node sets the rate and is supplied by the vagus nerve. Bridging the atrium and the ventricle is the atrioventricular (AV) node, also supplied by the vagus nerve. Baseline changes in the fetal heartbeat have been shown to be under the influence of this nerve. When the fetus is stressed, the sympathetic nervous system causes the release of norepinephrine, which increases the fetal heart rate. To counteract the increase in blood pressure, baroreceptors, which respond to the increase in pressure, are present in the vessel walls at the junction of the internal and external carotid arteries. When stimulated, these receptors, under the influence of the vagus and glossopharyngeal nerves, cause the heart rate to slow. Chemoreceptors in the fetal peripheral and central nervous systems respond to decreased oxygen tensions and to increased carbon dioxide tensions, leading to fetal tachycardia and an increase in blood pressure. The CNS also has control over heart rate. Increased activity of the fetus in a wakeful period is exhibited in an *increase* in the variability of the fetal heart baseline. Sleep patterns involve a *decrease* in the baseline variability. In cases of severe hypoxia, the release of epinephrine and norepinephrine will cause an increase in the fetal heart rate.

Embryonic and Fetal Development

Pregnancy is calculated to last an average of 10 lunar months: 40 weeks, or 280 days. This period of 280 days is calculated from the onset of the last normal menstrual period to the time of birth. **Estimated date of birth (EDB)**, the date

Figure 33-15 » Fetal circulation. Blood leaves the placenta and enters the fetus through the umbilical vein. After circulating through the fetus, the blood returns to the placenta through the umbilical arteries. The ductus venosus, the foramen ovale, and the ductus arteriosus allow the blood to bypass the fetal liver and lungs.

around which childbirth will occur, and sometimes referred to as the estimated date of delivery (EDD), usually is calculated by this method. Most fetuses are born within 10–14 days of the calculated date of birth. The fertilization age (or **postconception age**) of the fetus is calculated to be about 2 weeks less, or 266 days (38 weeks), or 9.5 calendar months. The latter measurement is more accurate because it measures time from the fertilization of the ovum, or conception.

» Go to **Pearson MyLab Nursing and eText** for Chart 1: Organ Development in the Embryo and Fetus.

In review, human development follows three stages. The preembryonic stage, as discussed earlier in this module,

consists of the first 14 days of development after the ovum is fertilized. The embryonic stage covers the period from day 15 until approximately the end of the eighth week, and the fetal stage extends from the end of the eighth week until birth (**Figure 33-16** »).

Embryonic Stage

The stage of the **embryo** starts on day 15 (the beginning of the third week after conception) and continues until approximately the eighth week, or until the embryo reaches a crown–rump length (CRL) of 3 cm (1.2 in.). This length is usually reached about 56 days after fertilization (the end of the eighth gestational week). During the embryonic stage,

Figure 33-16 » The actual size of a human conceptus from fertilization to the early fetal stage. The embryonic stage begins in the third week after fertilization; the fetal stage begins in the ninth week.

tissues differentiate into essential organs and the main external features develop. The embryo is most vulnerable to *teratogens* during this period (**Figure 33-17** »).

Fetal Stage

By the end of the eighth week, the embryo is sufficiently developed to be called a **fetus**. Every organ system and external structure that will be found in the full-term newborn is present. The remainder of gestation is devoted to refining structures and perfecting function. **Figure 33-18** » shows the fetus at 20 weeks' gestation.

Full Term

The fetus is considered full term at 37 completed weeks and up to 40 weeks. The crown–heel length (CHL) varies from 48 to 52 cm (19 to 21 in.), with males usually longer than females. Males also usually weigh more than females. The weight at term is about 3000–3600 g (6 lb 10 oz–7 lb 15 oz) and varies in different ethnic groups. Skin color also varies and has a smooth, polished look. The only lanugo left is on the upper arms and shoulders. The hair on the head is no longer woolly, but is coarse and about 2.5 cm (1 in.) long. Vernix caseosa is present, with heavier deposits remaining in the creases and folds of the skin. The body and extremities are plump, with good skin turgor, and the fingernails extend beyond the fingertips. The chest is prominent but still a little smaller than the head, and mammary glands protrude in

both sexes. In males, the testes are in the scrotum or are palpable in the inguinal canals.

As the fetus enlarges, amniotic fluid diminishes to about 500 mL or less and the fetal body mass fills the uterine cavity.

Source: Petit Format/Science Source.

Figure 33-17 » The embryo at 7 weeks. The head is rounded and nearly erect. The eyes have shifted forward and closer together, and the eyelids begin to form.

Source: James Stevenson/Science Source.

Figure 33-18 » The fetus at 20 weeks. The fetus now weighs 435–465 g (15.2–16.3 oz) and measures about 19 cm (7.5 in.). Subcutaneous deposits of brown fat make the skin a little less transparent. “Woolly” hair covers the head, and nails have developed on the fingers and toes.

The fetus assumes what is called its *position of comfort*, or *lie*. The head is generally pointed downward, following the shape of the uterus (and possibly because the head is heavier than the feet). The extremities, and often the head, are well flexed. After 5 months, patterns in feeding, sleeping, and activity become established; so at term, the fetus has its own body rhythms and individual style of response.

Physical and Psychologic Changes of Pregnancy

The growth of the developing fetus and the physical and psychologic changes that occur in the pregnant mother continue to inspire feelings of awe and amazement, not to mention curiosity. First, it is nothing short of a miracle that the union of two microscopic entities—an ovum and a sperm—can produce a living being. Second, the woman’s body must undergo extraordinary physical changes to maintain a pregnancy.

Pregnancy is divided into three trimesters, each approximately a 3-month period. Each trimester brings predictable changes for both mother and fetus. This section describes these physical and psychologic changes. It also presents the various cultural factors that can affect a pregnant woman’s well-being.

Anatomy and Physiology of Pregnancy

The changes that occur in the pregnant woman’s body may result from hormonal influences, the growth of the fetus, and the mother’s physiologic adaptation to the pregnancy.

Virtually every system must adapt to support the growing fetus and maintain the pregnant woman’s body functions.

Reproductive System

Some of the most dramatic changes of pregnancy occur in the reproductive organs.

Uterus

The changes in the uterus during pregnancy are significant. Before pregnancy, the uterus is a small, semisolid, pear-shaped organ measuring approximately $7.5 \times 5 \times 2.5$ cm and weighing about 60 g (2 oz). At the end of pregnancy, it measures about $28 \times 24 \times 21$ cm and weighs approximately 1100 g (2.5 lb); its capacity also has increased from about 10 mL to 5000 mL (5 L) or more (Cunningham et al., 2014).

The enlargement of the uterus is primarily caused by the enlargement (hypertrophy) of the preexisting myometrial cells as a result of the stimulating influence of estrogen and the distention caused by the growing fetus. Only a limited increase in cell number (hyperplasia) occurs. The fibrous tissue between the muscle bands increases markedly, which adds to the strength and elasticity of the muscle wall. The enlarging uterus, developing placenta, and growing fetus require additional blood flow to the uterus. By the end of pregnancy, one sixth of the total maternal blood volume is contained in the vascular system of the uterus.

Cervix

Estrogen stimulates the glandular tissue of the cervix, which increases in cell number and becomes hyperactive. The endocervical glands secrete a thick, sticky mucus that accumulates and forms a mucous plug, which seals the endocervical canal and prevents the ascent of microorganisms into the uterus. This plug is expelled when cervical dilation begins. The hyperactivity of the glandular tissue also increases the normal physiologic mucorrhea, at times resulting in profuse discharge. Increased cervical vascularity also causes both the softening of the cervix (**Goodell sign**) and its blue-purple discoloration (**Chadwick sign**).

Ovaries

The ovaries stop producing ova during pregnancy. During early pregnancy, hCG maintains the corpus luteum, which persists and produces hormones until weeks 6–8 of pregnancy. The corpus luteum secretes progesterone to maintain the endometrium until the placenta produces enough progesterone to maintain the pregnancy. The corpus luteum then begins to disintegrate slowly.

Vagina

Estrogen causes a thickening of the vaginal mucosa, a loosening of the connective tissue, and an increase in vaginal secretions. These secretions are thick, white, and acidic (pH 3.5–6.0). The acid pH helps prevent bacterial infection but favors the growth of yeast organisms. Thus, the pregnant woman is more susceptible to *Candida* infection than usual.

The supportive connective tissue of the vagina loosens throughout pregnancy. By the end of pregnancy, the vagina and perineal body are sufficiently relaxed to permit passage of the baby. Because blood flow to the vagina is increased, the vagina may show the same blue-purple color (Chadwick sign) as the cervix.

Breasts

Estrogen and progesterone cause many changes in the breasts. They enlarge and become more nodular as the milk producing glands increase in size and number in preparation for lactation. Superficial veins become more prominent, the nipples become more erectile, and the areolas darken. Montgomery's follicles (sebaceous glands) enlarge, and **striae** (reddish stretch marks that slowly turn silver after childbirth) may develop.

Colostrum, an antibody-rich yellow secretion, may leak or be expressed from the breasts during the last trimester. Colostrum gradually converts to mature milk during the first few days after childbirth.

Respiratory System

Many respiratory changes occur to meet the increased oxygen requirements of a pregnant woman. The volume of air breathed each minute increases 30–40%. In addition, progesterone decreases airway resistance, permitting a 15–20% increase in oxygen consumption as well as increases in carbon dioxide production and in the respiratory functional reserve.

As the uterus enlarges, it presses upward and elevates the diaphragm. The subcostal angle increases, so that the rib cage flares. The anteroposterior diameter increases, and the chest circumference expands by as much as 6 cm; as a result, there is no significant loss of intrathoracic volume. Breathing changes from abdominal to thoracic as pregnancy progresses, and descent of the diaphragm on inspiration becomes less possible. Some hyperventilation and difficulty in breathing may occur.

Nasal stuffiness and epistaxis (nosebleeds) also may occur because of estrogen-induced edema and vascular congestion of the nasal mucosa.

Cardiovascular System

During pregnancy, blood flow increases to organ systems with an increased workload. Thus, blood flow increases to the uterus, placenta, and breasts, whereas hepatic and cerebral flow remains unchanged. Cardiac output begins to increase early in pregnancy and peaks at 25–30 weeks' gestation at 30–50% above prepregnancy levels. It generally remains elevated in the third trimester.

The pulse may increase by as many as 10–15 beats/min at term. The blood pressure decreases slightly, reaching its lowest point during the second trimester. It gradually increases to near prepregnancy levels by the end of the third trimester.

The enlarging uterus puts pressure on pelvic and femoral vessels, interfering with returning blood flow and causing stasis of blood in the lower extremities. This condition may lead to dependent edema and varicosity of the veins in the legs, vulva, and rectum (hemorrhoids) in late pregnancy. This increased blood volume in the lower legs also may make the pregnant woman prone to postural hypotension.

When the pregnant woman lies supine, the enlarging uterus may press on the vena cava. This reduces blood flow to the right atrium; lowers blood pressure; and causes dizziness, pallor, and clamminess. Research indicates that the enlarging uterus also may press on the aorta and its collateral

Figure 33–19 » Vena caval syndrome. The gravid uterus compresses the vena cava when the woman is supine. This reduces the blood flow returning to the heart and may cause maternal hypotension.

circulation (Cunningham et al., 2014). This condition is called **supine hypotensive syndrome**. It also may be referred to as **vena caval syndrome** or **aortocaval compression** (**Figure 33–19** »). It can be corrected by having the woman lie on her side, preferably on her left. Blood volume progressively increases beginning in the first trimester, increases rapidly until about 30–34 weeks' gestation, and then plateaus until birth at about 40–50% above nonpregnancy levels. This increase occurs because of increases in both erythrocytes and plasma (Cao & O'Brien, 2013).

The total erythrocyte (RBC) volume increases by about 25%. This increase in erythrocytes is necessary to transport the additional oxygen required during pregnancy. However, the increase in plasma volume during pregnancy averages about 50%. Because the plasma volume increase (50%) is greater than the erythrocyte increase (25%), the hematocrit, which measures the concentration of RBCs in the plasma, decreases slightly (Cao & O'Brien, 2013). This decrease is referred to as the **physiologic anemia of pregnancy** (pseudanemia).

Iron is necessary for hemoglobin formation, and hemoglobin is the oxygen-carrying component of erythrocytes. Thus, the increase in erythrocyte levels results in the pregnant woman's increased need for iron. Even though the gastrointestinal absorption of iron is moderately increased during pregnancy, it is usually necessary to add supplemental iron to the diet to meet the expanded RBC and fetal needs. Women who are diagnosed with anemia prior to pregnancy may require more iron supplementation.

Leukocyte production increases slightly to an average of 8500 mm³, with a range of 5600–12,200 mm³. During labor and the early postpartum period, these levels may reach 25,000/mm³ or higher (Gordon, 2012). Although the cause of leukocytosis is not known, this increase is a normal finding (Cunningham et al., 2014).

Both the fibrin and plasma fibrinogen levels increase during pregnancy. Although the blood-clotting time of a pregnant woman does not differ significantly from that of a nonpregnant woman, clotting factors VII, VIII, IX, and X

increase; thus, pregnancy is a somewhat hypercoagulable state. These changes, coupled with venous stasis in late pregnancy, increase the pregnant woman's risk of developing venous thrombosis.

Gastrointestinal System

Nausea and vomiting are common during the first trimester because of elevated hCG levels and changed carbohydrate metabolism. Gum tissue may soften and bleed easily. The secretion of saliva may increase and even become excessive (ptyalism).

Elevated progesterone levels cause smooth muscle relaxation, resulting in delayed gastric emptying and decreased peristalsis. As a result, the pregnant woman may complain of bloating and constipation. These symptoms are aggravated as the enlarging uterus displaces the stomach upward and the intestines are moved laterally and posteriorly. The cardiac sphincter also relaxes, and heartburn (pyrosis) may occur because of reflux of acidic secretions into the lower esophagus. Hemorrhoids frequently develop in late pregnancy from constipation and from pressure on vessels below the level of the uterus.

Only minor liver changes occur with pregnancy. Plasma albumin concentrations and serum cholinesterase activity decrease with normal pregnancy, as with certain liver diseases.

The emptying time of the gallbladder is prolonged during pregnancy as a result of smooth muscle relaxation from progesterone. This, coupled with the elevated levels of cholesterol in the bile, can predispose the woman to gallstone formation.

Urinary Tract

During the first trimester, the enlarging uterus is still a pelvic organ and presses against the bladder, producing urinary frequency. This symptom decreases during the second trimester, when the uterus becomes an abdominal organ and pressure against the bladder lessens. Frequency reappears during the third trimester, when the presenting part descends into the pelvis and again presses on the bladder, reducing bladder capacity, contributing to hyperemia, and irritating the bladder.

The ureters (especially the right ureter) elongate and dilate above the pelvic brim. The glomerular filtration rate (GFR) rises by as much as 50% beginning in the second trimester and remains elevated until birth. To compensate for this increase, renal tubular reabsorption also increases. However, glycosuria sometimes is seen during pregnancy because of the kidneys' inability to reabsorb all of the glucose filtered by the glomeruli. Glycosuria may be normal or may indicate *gestational diabetes mellitus* (GDM) (diabetes mellitus with onset or first recognition during pregnancy), so it always warrants further testing.

Skin and Hair

Changes in skin pigmentation commonly occur during pregnancy. Increased estrogen, progesterone, and α -melanocyte-stimulating hormone levels are thought to stimulate these changes. Pigmentation of the skin increases primarily in areas that are already hyperpigmented: the areola, the nipples, the vulva, the perianal area, and the linea alba. The linea alba refers to the midline of the abdomen from the pubic area to the umbilicus and above. During

Figure 33-20 » Linea nigra.

pregnancy, this area darkens and is referred to as the *linea nigra* (Figure 33-20 »). Facial **chloasma**, or **melasma gravidarum** (also known as the “mask of pregnancy”), a darkening of the skin over the cheeks, nose, and forehead, may develop. Chloasma or melasma is more prominent in dark-haired women and is aggravated by exposure to the sun. The condition fades or becomes less prominent soon after childbirth, when the hormonal influence of pregnancy subsides.

The sweat and sebaceous glands are often hyperactive during pregnancy. Some women may notice heavy perspiration, night sweats, and the development of acne even if they have never experienced these symptoms before.

Striae may appear on the abdomen, thighs, buttocks, and breasts. They result from reduced connective tissue strength because of elevated adrenal steroid levels.

Vascular spider nevi—small, bright red elevations of the skin radiating from a central body—may develop on the chest, neck, face, arms, and legs. They may be caused by increased subcutaneous blood flow in response to elevated estrogen levels.

The rate of hair growth may decrease during pregnancy; the number of hair follicles in the resting or dormant phase also decreases. After birth, the number of hair follicles in the resting phase increases sharply and the woman may notice increased hair shedding for 1–4 months. However, practically all hair is replaced within 6–12 months (Cunningham et al., 2014).

Musculoskeletal System

No demonstrable changes occur in the teeth of pregnant women. The dental caries that sometimes accompany pregnancy are probably caused by inadequate oral hygiene and dental care, especially if the woman has problems with bleeding gums or nausea and vomiting.

Figure 33-21 » Postural changes during pregnancy. Note the increasing lordosis of the lumbosacral spine and the increasing curvature of the thoracic area.

The joints of the pelvis relax somewhat because of hormonal influences. The result is often a waddling gait. As the pregnant woman's center of gravity gradually changes, the lumbodorsal spinal curve becomes accentuated and her posture changes (**Figure 33-21** »). This posture change compensates for the increased weight of the uterus anteriorly and frequently results in low backache.

Pressure of the enlarging uterus on the abdominal muscles may cause the rectus abdominis muscle to separate, producing **diastasis recti**. If the separation is severe and muscle tone is not regained postpartum, subsequent pregnancies will not have adequate support and the woman's abdomen may appear pendulous.

Eyes

Two changes generally occur in the eyes during pregnancy. First, intraocular pressure decreases, probably as a result of increased vitreous outflow. Second, a slight thickening of the cornea occurs, which is generally attributed to fluid retention (Gordon, 2012). Although these changes are not readily perceived, some pregnant women experience difficulty wearing previously comfortable contact lenses. The change in the corneas generally disappears by 6 weeks postpartum (Davidson, London, & Ladewig, 2017).

Central Nervous System

Pregnant women frequently describe decreased attention, concentration, and memory during and shortly after pregnancy, but few studies have explored this phenomenon. One study did compare a group of pregnant women and a control group, finding a decline in memory among the pregnant women that could not be attributed to depression, anxiety, sleep deprivation, or other physical changes of pregnancy. This memory loss disappeared soon after childbirth. Another study found that sleep problems are common in pregnancy. These include difficulty going to sleep, frequent awakenings, fewer hours of night sleep, and reduced sleep efficiency (Cunningham et al., 2014).

Metabolism

Most metabolic functions accelerate during pregnancy to support the additional demands of the growing fetus and its support system. The expectant mother must meet her own tissue replacement needs, those of the fetus, and tissue changes preparatory for labor and lactation. No other event in life induces such profound metabolic changes.

Weight Gain

Growth of the uterus and its contents, growth of the breasts, and increases in intravascular fluids account for most of the weight gain in pregnancy. In addition, extra water, fat, and protein are stored; these are called *maternal reserves*.

Adequate nutrition and weight gain are important during pregnancy. The recommended total weight gain during pregnancy for a woman of normal weight before pregnancy is 11.5–16 kg (25–35 lb); for women who were overweight before becoming pregnant, the recommended gain is 6.8–11.5 kg (15–25 lb). Obese women are advised to limit weight gain to 5–9 kg (11–20 lb). Underweight women are advised to gain 12.7–18.1 kg (28–40 lb) (American College of Obstetricians and Gynecologists [ACOG], 2013a). Weight may decrease slightly during the first trimester because of nausea, vomiting, and food intolerances of early pregnancy. The lost weight is soon regained, and for normal women, the ACOG (2013a) recommends a gain of 0.5–2 kg (1.1–4.4 lb) during the first trimester, followed by an average gain of about 0.45 kg (1 lb) per week during the last two trimesters.

Water Metabolism

Increased water retention is a basic chemical alteration of pregnancy. Several interrelated factors cause this phenomenon. The increased level of steroid sex hormones affects sodium and fluid retention. The lowered serum protein also influences the fluid balance, as do the increased intracapillary pressure and permeability. The extra water is needed for the products of conception—the fetus, placenta, and

amniotic fluid—and the mother's increased blood volume, interstitial fluids, and enlarged organs.

Nutrient Metabolism

The fetus makes its greatest protein and fat demands during the second half of gestation, doubling in weight in the last 6–8 weeks. The increased protein retention that begins in early pregnancy is initially used for hyperplasia and hypertrophy of maternal tissues, such as the uterus and breasts. Protein must also be stored during pregnancy to maintain a constant level within the breast milk and to avoid depletion of maternal tissues.

Fats are more completely absorbed during pregnancy, resulting in a marked increase in the serum lipids, lipoproteins, and cholesterol and decreased elimination through the bowel. Fat deposits in the fetus increase from about 2% at midpregnancy to almost 12% at term. The excess nitrogen and lipidemia are considered to be a preparation for lactation. In addition, the woman's body switches from glucose metabolism to lipid metabolism once glucose from food intake has been used up. This leads to an increased tendency to develop ketosis between meals and overnight. The demand for carbohydrate increases, especially during the last two trimesters. Intermittent glycosuria is not uncommon during pregnancy. When it is not accompanied by a rise in blood sugar levels, glycosuria is secondary to the increased glomerular filtration rate. Fasting blood sugar levels tend to fall slightly, returning to more normal levels by the sixth postpartum month. The oral glucose tolerance test shows no change with pregnancy.

The possibility of diabetes during pregnancy must not be overlooked. Plasma levels of insulin increase during pregnancy (probably because of hormonal changes that cause increased tissue resistance) and rapid destruction of insulin takes place within the placenta. The woman's insulin production must increase during the second trimester, and any marginal pancreatic function quickly becomes apparent. The woman with diabetes often experiences increased exogenous insulin demands during pregnancy.

The demand for iron during pregnancy is accelerated, and the pregnant woman needs to guard against anemia. Iron is necessary for the increase in erythrocytes, hemoglobin, and blood volume, as well as for the increased tissue demands of both woman and fetus. Iron transfer takes place at the placenta in only one direction: toward the fetus. It has been demonstrated that approximately five sixths of the iron stored in the fetal liver is assimilated during the last trimester of pregnancy. This stored iron in the fetal liver compensates in the first 4 months of neonatal life for the normal inadequate amounts of iron available in breast milk and non-iron-fortified formulas.

The progressive absorption and retention of calcium during pregnancy have been noted. The maternal plasma concentration of bound calcium decreases as the levels of bindable plasma proteins fall. Approximately 30 g of calcium is retained in maternal bone for fetal deposition late in pregnancy.

Endocrine System

Hormonal changes of pregnancy affect endocrine function in various ways. Alterations are typically temporary and

resolve within 6 weeks of delivery. Common changes in glandular function during pregnancy involve the thyroid, parathyroid, pituitary, and adrenal glands.

Thyroid

Pregnancy influences the thyroid gland's size and activity. Often a palpable change is noted, which represents an increase in vascularity and hyperplasia of glandular tissue. Total serum thyroxine (T_4) increases in early pregnancy, and thyroid-stimulating hormone (TSH) decreases. The elevated levels of total T_4 continue until several weeks postpartum, although the level of free serum T_4 returns to normal after the first trimester (Cunningham et al., 2014).

Increased thyroxine-binding capacity is evidenced by an increase in serum protein-bound iodine, probably due to the increased levels of circulating estrogens. The basal metabolic rate increases by as much as 20–25% during pregnancy. The increased oxygen consumption is due primarily to fetal metabolic activity.

Parathyroid

The concentration of the parathyroid hormone and the size of the parathyroid glands increase, paralleling the fetal calcium requirements. Parathyroid hormone concentration reaches its highest level of approximately twofold between 15 and 35 weeks of gestation, returning to a normal or even subnormal level before childbirth.

Pituitary

Pregnancy is made possible by the hypothalamic stimulation of the anterior pituitary gland. The anterior pituitary produces *FSH*, which stimulates follicle growth in the ovary, and *LH*, which affects ovulation. Stimulation of the pituitary also prolongs the ovary's corpus luteal phase, which maintains the secretory endometrium in preparation for pregnancy. *Prolactin*, another anterior pituitary hormone, is responsible for initial lactation.

The posterior pituitary secretes *vasopressin* (antidiuretic hormone) and *oxytocin*. Vasopressin causes vasoconstriction, which results in increased blood pressure; it also helps regulate water balance. Oxytocin promotes uterine contractility and stimulates ejection of milk from the breasts (the let-down reflex) in the postpartum period.

Adrenals

Little structural change occurs in the adrenal glands during a normal pregnancy. Estrogen-induced increases in the levels of circulating cortisol result primarily from lowered renal excretion. The circulating cortisol levels regulate carbohydrate and protein metabolism. A normal level resumes 1–6 weeks postpartum.

The adrenals secrete increased levels of aldosterone by the early part of the second trimester. The levels of secretion are even more elevated in the woman on a sodium-restricted diet. This increase in aldosterone in a normal pregnancy may be the body's protective response to the increased sodium excretion associated with progesterone (Cunningham et al., 2014).

Pancreas

The islets of Langerhans are stressed to meet the increased demand for insulin during pregnancy, and a latent deficiency

may become apparent during pregnancy, producing symptoms of gestational diabetes.

Hormones in Pregnancy

Several hormones are required to maintain pregnancy. Most of these are produced initially by the corpus luteum; the placenta then assumes production.

- **Human chorionic gonadotropin:** The trophoblast secretes hCG in early pregnancy. This hormone stimulates progesterone and estrogen production by the corpus luteum to maintain the pregnancy until the placenta is developed sufficiently to assume that function.
- **Human placental lactogen:** Also called human chorionic somatomammotropin (hCS), hPL is produced by the syncytiotrophoblast. This hormone is an antagonist of insulin; it increases the amount of circulating free fatty acids for maternal metabolic needs and decreases maternal metabolism of glucose to favor fetal growth.
- **Estrogen:** Secreted originally by the corpus luteum, estrogen is produced primarily by the placenta as early as the seventh week of pregnancy. Estrogen stimulates uterine development to provide a suitable environment for the fetus. It also helps to develop the ductal system of the breasts in preparation for lactation.
- **Progesterone:** Progesterone, also produced initially by the corpus luteum and then by the placenta, plays the greatest role in maintaining pregnancy. It maintains the endometrium and also inhibits spontaneous uterine contractility, thus preventing early spontaneous abortion due to uterine activity. In addition, progesterone helps develop the ductal system of the breasts in preparation for lactation.
- **Relaxin:** Relaxin is detectable in the serum of a pregnant woman by the time of the first missed menstrual period. Relaxin inhibits uterine activity, diminishes the strength of uterine contractions, aids in the softening of the cervix, and has the long-term effect of remodeling collagen. Its primary source is the corpus luteum, but small amounts are believed to be produced by the placenta and uterine decidua throughout pregnancy.

Prostaglandins in Pregnancy

Prostaglandins (PGs) are lipid substances that can arise from most body tissues but occur in high concentrations in the female reproductive tract and are present in the decidua during pregnancy. Although their exact functions during pregnancy are still unknown, it has been proposed that PGs are responsible for maintaining reduced placental vascular resistance. Decreased PG levels may contribute to hypertension and preeclampsia. Prostaglandins are also believed to play a role in the complex biochemistry that initiates labor, although their specific functions are still being defined.

Signs of Pregnancy

Many of the changes women experience during pregnancy are used to diagnose the pregnancy itself. They are called the subjective, or presumptive, changes; the objective, or probable, changes; and the diagnostic, or positive, changes of pregnancy.

Subjective (Presumptive) Changes

The subjective changes of pregnancy are the symptoms the woman experiences and reports. Because they can be caused by other conditions, they cannot be considered proof of pregnancy.

» Go to **Pearson MyLab Nursing and eText** for Chart 2: *Differential Diagnosis of Pregnancy—Subjective Changes*.

Amenorrhea, or the absence of menses, is the earliest symptom of pregnancy. The missing of more than one menstrual period, especially in a woman whose cycle is ordinarily regular, is an especially useful diagnostic clue. Excessive fatigue may be noted within a few weeks after the first missed menstrual period and may persist throughout the first trimester. Urinary frequency is experienced during the first trimester as the enlarging uterus presses on the bladder. This improves during the second trimester when the enlarging uterus escapes the pelvis, and then recurs in the third trimester when the growing fetus presses on the bladder.

Nausea and vomiting in pregnancy (NVP) occur frequently during the first trimester and may be the result of elevated hCG levels and changed carbohydrate metabolism. Because these symptoms often occur in the early part of the day, they are commonly referred to as **morning sickness**. In reality, the symptoms may occur at any time and can range from a mere distaste for food to severe vomiting.

Changes in the breasts are frequently noted in early pregnancy. These changes include tenderness and tingling sensations, increased pigmentation of the areola and nipple, and changes in the Montgomery glands. The veins in the breasts also become more visible and form a bluish pattern beneath the skin.

Quickening, or the mother's perception of fetal movement, occurs about 18–20 weeks after the last menstrual period (LMP) in a woman pregnant for the first time, but may occur as early as 16 weeks in a woman who has been pregnant before. Quickening is a fluttering sensation in the abdomen that gradually increases in intensity and frequency.

Objective (Probable) Changes

An examiner can perceive the objective changes that occur in pregnancy. Because these changes also have other causes, they do not confirm pregnancy.

» Go to **Pearson MyLab Nursing and eText** for Chart 3: *Differential Diagnosis of Pregnancy—Objective Changes*.

The only physical changes detectable during the first 3 months of pregnancy are caused by increased vascular congestion. These changes are noted on pelvic examination. As noted earlier, there is a softening of the cervix called the Goodell sign. The Chadwick sign is a bluish, purple, or deep red discoloration of the mucous membranes of the cervix, vagina, and vulva. (Some sources consider this a presumptive sign.) The **Hegar sign** is a softening of the isthmus of the uterus, the area between the cervix and the body of the uterus. The **McDonald sign** is an ease in flexing the body of the uterus against the cervix.

General enlargement and softening of the body of the uterus can be noted after the eighth week of pregnancy. The fundus of the uterus is palpable just above the symphysis

Figure 33-22 » Approximate height of the fundus at various weeks of pregnancy.

pubis at about 10–12 weeks' gestation and at the level of the umbilicus at 20–22 weeks' gestation (**Figure 33-22** »).

Enlargement of the abdomen during the childbearing years is usually regarded as evidence of pregnancy, especially if it is continuous and accompanied by amenorrhea. Braxton Hicks contractions are palpable with abdominal palpation after week 28. As the woman approaches the end of pregnancy, these contractions may become uncomfortable.

Uterine souffle may be heard when the examiner auscultates the abdomen over the uterus. It is a soft blowing sound that occurs at the same rate as the maternal pulse. The funic souffle occurs at the same rate as the fetal heart rate (FHR).

The fetal outline may be identified by palpation in many pregnant women after 24 weeks' gestation. **Ballottement** is the passive fetal movement elicited when the examiner inserts two gloved fingers into the vagina and pushes against the cervix. This action pushes the fetal body up, and as it falls back, the examiner feels a rebound.

Pregnancy tests are based on analysis of maternal blood or urine for the detection of hCG, the hormone secreted by the trophoblast. These tests are not considered positive signs of pregnancy because the similarity of hCG and the pituitary-secreted LH occasionally results in cross-reactions. In addition, certain conditions other than pregnancy can cause elevated levels of hCG.

Clinical Pregnancy Tests

The most commonly used assay for pregnancy diagnosis is measuring the beta subunit of hCG in either urine or serum. Currently four main hCG tests are used: (1) *radioimmunoassay*, (2) *immunoradiometric assay*, (3) *enzyme-linked immunosorbent assay (ELISA)*, and (4) *fluoroimmunoassay*. hCG is detectable in more than 97% of patients (Greene et al.,

2013). False-negative or false-positive results can also occur. In pregnancy, levels normally peak at 10–12 weeks' gestation, and this initial rise is important in monitoring high-risk pregnancies where viability has not been documented. Failure to observe the expected rise may suggest an ectopic pregnancy or spontaneous abortion. An abnormally high level or accelerated rise can also prompt investigation into possible disorders such as molar pregnancy, multiple gestations, or chromosomal abnormalities. There is a rapid decline in the hCG levels until 22 weeks' gestation when another gradual rise occurs (Cunningham et al., 2014).

Diagnostic (Positive) Changes

The positive signs of pregnancy are completely objective, cannot be confused with a pathologic state, and offer conclusive proof of pregnancy.

The fetal heartbeat can be detected with a fetoscope by approximately weeks 17–20 of pregnancy. With an electronic Doppler device, the fetal heartbeat can be detected as early as weeks 10–12. The fetal heart rate is between 110 and 160 beats/min and must be counted and compared with the maternal pulse for differentiation. Auscultation of the abdomen may reveal sounds other than that of the fetal heart. The maternal pulse, emanating from the abdominal aorta, may be unusually loud, or a uterine souffle may be heard.

Fetal movement is actively palpable by a trained examiner after about 20 weeks' gestation. The movements vary from a faint flutter in the early months to more vigorous movements late in pregnancy.

Visualization of the fetus by ultrasound confirms a pregnancy. The gestational sac can be observed by 4–5 weeks' gestation (2–3 weeks after conception). Fetal parts and fetal heart movement can be seen as early as 8 weeks. A transvaginal ultrasound has been used to detect a gestational sac as early as 10 days after implantation (Cunningham et al., 2014).

Psychologic Response of the Expectant Family to Pregnancy

Pregnancy is a turning point in a family's life, accompanied by stress and anxiety, whether the pregnancy is desired or not. Especially when this is their first child, the expectant parents may be unaware of the physical, emotional, and cognitive changes of pregnancy and may anticipate no problems from such a normal event. Thus, they may be confused and distressed by new feelings and behaviors that are essentially normal.

For beginning families, pregnancy is the transition period from childlessness to parenthood. If the expectant woman is married or has a stable partner, she is no longer only a mate, but also must assume the role of mother. Her partner, whether male or female, will become a parent, too. The anticipation of parenthood brings significant role changes for them. Career goals and mobility may be affected, and the couple's relationship takes on a different meaning to them and within the larger family and community. If the pregnancy results in the birth of a child, the couple enters a new, irreversible stage of their life together. With each subsequent pregnancy, routines and family dynamics are again altered, requiring readjustment and realignment.

In most pregnancies, finances are an important consideration. Pregnant women with or without stable partners recognize the financial impact of a child and may be concerned about financial issues. Decisions about financial matters need to be made at this time. Will both parents work outside the home during the pregnancy or after the child is born? If so, who will provide child care? Couples also may need to decide about the division of domestic tasks. Any differences of opinion must be discussed openly and resolved so that the family can meet the needs of its members.

If the pregnant woman has no stable partner, she must deal with the role changes, fears, and adjustments of pregnancy, as well as financial uncertainty, alone or seek support from family or friends. She also faces the reality of planning for the future as a single parent. Even if the pregnant woman plans to relinquish her baby, she still must deal with the adjustments of pregnancy. This can be especially difficult without a good support system.

Developmental Tasks of the Expectant Couple

Pregnancy can be viewed as a developmental stage with its own distinct developmental tasks. For a couple, it can be a time of support or conflict depending on the amount of adjustment each is willing to make to maintain the family's equilibrium.

During a first pregnancy, the couple plans together for the child's arrival, collecting information on how to be parents. At the same time, each member of the couple continues to participate in some separate activities with friends or family members. The availability of social support is an important factor in psychosocial well-being during pregnancy. The social network is often a major source of advice for the pregnant woman; however, both sound and unsound information may be conveyed.

During pregnancy, the expectant parents face significant changes and must deal with major psychosocial adjustments. Other family members, especially other children of the woman or couple and the grandparents-to-be, also must adjust to the pregnancy.

» Go to **Pearson MyLab Nursing and eText** to see Chart 4: Parental Reactions to Pregnancy.

For some individuals or couples, pregnancy is more than a developmental stage; it is a crisis. *Crisis* can be defined as "a disturbance or conflict in which the individual cannot maintain a state of equilibrium." Pregnancy can be considered a *maturational crisis*, because it is a common event in the normal growth and development of the family. During such a crisis, the individual or family is in disequilibrium. Egos weaken, usual defense mechanisms are not effective, unresolved issues from the past reappear, and relationships shift. This period of disequilibrium and disorganization is marked by unsuccessful attempts to solve the perceived problems. If the crisis is not resolved, it will result in maladaptive behaviors in one or more family members and possible disintegration of the family. Families that are able to resolve a maturational crisis will return successfully to normal functioning and can even strengthen the bonds in the family relationship.

The Mother

Pregnancy is a condition that alters body image and necessitates a reordering of social relationships and changes in the

roles of family members. The way each woman meets the stresses of pregnancy is influenced by her emotional makeup, her sociologic and cultural background, and her acceptance or rejection of the pregnancy. However, many women manifest similar psychologic and emotional responses during pregnancy, including ambivalence, acceptance, introversion, mood swings, and changes in body image.

A woman's attitude toward her pregnancy can be a significant factor in its outcome. Even if the pregnancy is planned, there is an element of surprise at first. Many women commonly experience feelings of ambivalence during early pregnancy. This ambivalence may be related to feelings that the timing is somehow wrong; worries about the need to modify existing relationships or career plans; fears about assuming a new role; unresolved emotional conflicts with the woman's own mother; and fears about pregnancy, labor, and birth. These feelings may be more pronounced if the pregnancy is unplanned or unwanted. Indirect expressions of ambivalence include complaints about considerable physical discomfort, prolonged or frequent depression, significant dissatisfaction with changing body shape, excessive mood swings, and difficulty in accepting the life changes resulting from the pregnancy.

Many pregnancies are unintended, but not all unintended pregnancies are unwanted. A pregnancy can be unintended and wanted at the same time. However, an unintended pregnancy can be a risk factor for depression. Higher levels of depression are also found in women who report more negative responses to pregnancy, who believe the pregnancy has greater consequences, and who experience more symptoms, especially in the third trimester (Jessop, Craig, & Ayers, 2014).

Conflicts about adapting to pregnancy are no more pronounced for older pregnant women (age 35 and over) than for younger ones. Moreover, older pregnant women tend to be less concerned about the normal physical changes of pregnancy and are confident about handling issues that arise during pregnancy and parenting. This difference may result because older pregnant women have more experience with problem solving. However, older pregnant women may have fewer pregnant peers and thus may have fewer people with whom to share concerns and expectations.

Pregnancy produces marked changes in a woman's body within a relatively short period of time. Pregnant women experience changes in body image because of physical alterations and may feel a loss of control over their bodies during pregnancy and later during childbirth. These perceptions are related to a certain extent to personality factors, social network responses, and attitudes toward pregnancy. Although changes in body image are normal, they can be very stressful for the woman. Explanation and discussion of the changes may help both the woman and her partner deal with the stress associated with this aspect of pregnancy.

Fantasies about the unborn child are common among pregnant women. The themes of the fantasies (baby's appearance, gender, traits, impact on parents, and so on) vary by trimester and differ among women who are pregnant for the first time and women who already have children.

First Trimester

During the first trimester, feelings of disbelief and ambivalence are common. The woman's baby does not seem real,

and she focuses on herself and her pregnancy. She may experience one or more of the early symptoms of pregnancy, such as breast tenderness or morning sickness, which are unsettling and at times unpleasant.

At this time, the expectant mother also begins to exhibit some characteristic behavioral changes. She may become increasingly introspective and passive. She may be emotionally labile, with characteristic mood swings from joy to despair. She may fantasize about a miscarriage and feel guilty because of these fantasies. She may worry that these thoughts will harm the baby in some way. Nursing responsibilities at this time include helping the mother to identify coping strategies and providing options and counseling for women experiencing a pregnancy that is both unintended and unwanted.

Second Trimester

During the second trimester, quickening occurs around 20 weeks. This perception of fetal movement helps the woman think of her baby as a separate individual, and she generally becomes excited about the pregnancy even if she had not been looking forward to the pregnancy earlier. The woman becomes increasingly introspective as she evaluates her life, her plans, and her child's future. This introspection helps the woman prepare for her new mothering role. Emotional lability, which may be unsettling to her partner, persists. In some instances, the partner may react by withdrawing. This withdrawal is especially distressing to the woman because she needs increased love and affection. Once the couple understands that these behaviors are characteristic of pregnancy, it is easier for the couple to deal with them effectively, although to some extent they may be sources of stress throughout pregnancy. As pregnancy becomes more noticeable, the woman's body image changes. She may feel great pride, embarrassment, or concern. Generally, women feel best during the second trimester, which is a relatively tranquil time.

Third Trimester

In the third trimester, the woman feels both pride about her pregnancy and anxiety about labor and birth. Physical discomforts increase, and the woman is eager for the pregnancy to end. She experiences increased fatigue, her body movements are more awkward, and her interest in sexual activity may decrease. During this time, the woman tends to be concerned about the health and safety of her unborn child and may worry that she will not cope well during childbirth. Toward the end of this period, the woman often experiences a surge of energy as she prepares for childbirth. Many women report bursts of energy, during which they vigorously clean and organize the home ("nesting").

Psychologic Tasks of the Mother

Rubin (1984) identified four major tasks that the pregnant woman undertakes to maintain her intactness and that of her family and at the same time to incorporate her new child into the family system. These tasks form the foundation for a mutually gratifying relationship with her baby:

1. **Ensuring safe passage through pregnancy, labor, and birth.** The pregnant woman feels concern for her

unborn child and for herself. She looks for competent prenatal care to provide a sense of control. She may seek information from literature, observe other pregnant women and new mothers, and discuss with others. She also attempts to ensure safe passage by engaging in self-care activities related to diet, exercise, alcohol consumption, and the like. In the third trimester, she becomes more aware of external threats in the environment—a toy on the stairs, the awkwardness of an escalator—that pose a threat to her well-being. She may worry if her partner is late or if she is home alone. Sleep becomes more difficult, and she longs for birth even though it, too, is frightening.

2. **Seeking acceptance of this child by others.** The birth of a child alters a woman's primary support group (her family) and her secondary affiliate groups. The woman slowly and subtly alters her network to meet the needs of her pregnancy. In this adjustment, the woman's partner is the most important figure. The partner's support and acceptance help form a maternal identity. If there are other children in the home, the mother also works to ensure their acceptance of the coming child. Acceptance of the anticipated change is sometimes stressful, and the woman may work to maintain special time with her partner or older children. The woman without a partner looks to others, such as a family member or friend, for this support.
3. **Seeking commitment and acceptance of herself as mother to the newborn (binding in).** During the first trimester, the child remains a rather abstract concept. With quickening, however, the child begins to become a real individual, and the mother begins to develop bonds of attachment. The mother experiences the movement of the child within her in an intimate, exclusive way, and out of this experience, bonds of love form. This binding-in process, characterized by its strong emotional component, motivates the pregnant woman to become competent in her role and provides satisfaction for her in the role of mother. This possessive love increases her maternal commitment to protect her fetus now and her child after he or she is born.
4. **Learning to give of oneself on behalf of one's child.** Childbirth involves many acts of giving. A man "gives" a child to a woman; she in turn "gives" a child to her partner. Life is given to a baby; a sibling is given to older children of the family. The woman begins to develop a capacity for self-denial and learns to delay immediate personal gratification to meet the needs of another. Baby showers and gifts are acts of giving that increase the mother's self-esteem and help her recognize the separateness and needs of the coming baby.

Accomplishment of these tasks helps the expectant woman develop her self-concept as a mother. The expectant woman who was well nurtured by her own mother may view her mother as a role model and emulate her; the woman who views her mother as a poor mother may worry that she will make similar mistakes. A woman's self-concept

as a mother expands with experience and continues to grow through subsequent childbearing and childrearing.

The Father

Until fairly recently, the expectant father or partner was often viewed as a “bystander” or observer of the pregnancy. He was necessary for conception, for bill paying, and for providing male guidance as his child matured. This view has changed, and the father is now expected to be a nurturing, caring, involved parent as well as a provider. In response to societal pressures, the influence of the feminist movement, and the economic pressures that have resulted in more women being employed outside the home, shared parenting and shared breadwinning have become more common. Many men have actively sought to be more involved in the experience of childbirth and parenting.

Expectant fathers experience many of the same feelings and conflicts experienced by expectant mothers when the pregnancy has been confirmed. Initially, expectant fathers may feel pride in their virility, which pregnancy confirms, but also have ambivalent feelings. The extent of ambivalence depends on many factors, including the father’s relationship with his partner, his previous experience with pregnancy, his age, his economic stability, and whether the pregnancy was planned. The expectant father must first deal with the reality of the pregnancy and then struggle to gain recognition as a parent from his partner, family, friends, coworkers, society—and from his baby as well. The expectant mother can help her partner be a participant and not merely a helpmate to her if she has a definite sense of the experience as *their* pregnancy and *their* baby and not *her* pregnancy and *her* baby.

Men whose partners are pregnant following a previous pregnancy loss may experience a variety of emotions attributable to the loss. These emotions might include an increased sense of risk, feelings of increased concern about the outcome of the current pregnancy, the recognition that something could go wrong again, and the sense that increased vigilance is essential. These fathers may call home more often to check on the mother’s condition and the baby and may also feel an increased need to be involved more actively in the current pregnancy.

In general, the expectant father faces psychologic stress as he makes the transition from nonparent to parent or from parent of one to parent of two or more. Sources of stress include financial issues, unexpected events during pregnancy, concern that the baby will not be healthy and normal, worry about the pain the partner will experience in childbirth, and his role during labor and birth. Other sources of stress for expectant fathers include concern over the changing relationship with their partners, diminished sexual responsiveness in their partners or in themselves, changes in relationships with their families or male friends, and their ability to parent.

The role of the father is crucial both prenatally and postnatally. Healthcare providers need to encourage and welcome the father’s involvement during the pregnancy. It is important to educate fathers about the role they can play in promoting healthy child development and how they can best support the mother during pregnancy to enhance healthy outcomes (Alio et al., 2013).

The expectant father must establish a fatherhood role just as the expectant mother develops a motherhood role. The mother experiences biologic changes of pregnancy that aid in the transition to motherhood. Fathers may feel left out because they are unable to experience what their partner is experiencing. The fathers who are most successful at developing a fatherhood role generally like children, are excited about the prospect of fatherhood, are eager to nurture a child, have confidence in their ability to be a parent, and share the experiences of pregnancy and childbirth with their partners. Fathers may have a lack of understanding of their role if they came from dysfunctional families, if they lacked positive role models, or if there was a general lack of education available to them (Alio et al., 2013).

First Trimester

After the initial excitement of announcing the pregnancy to friends and relatives and receiving their congratulations, an expectant father may begin to feel left out of the pregnancy. He is also often confused by his partner’s mood changes and perhaps bewildered by his responses to her changing body. He may resent the attention given to the woman and the changes in their relationship as she experiences fatigue and a decreased interest in sex.

During this time, his child is a “potential baby.” Fathers often picture interacting with a child of age 5 or 6 rather than a newborn. Even the pregnancy itself may seem unreal until the woman shows more physical signs.

Second Trimester

The father’s role in the pregnancy is still vague in the second trimester, but his involvement can be increased by his watching and feeling fetal movement. It is helpful if the father, as well as the mother, has the opportunity to hear the fetal heartbeat. That requires a visit to the healthcare provider’s office. Involvement of fathers in antepartum care is increasing and may even be an expectation of their partner. For many men, seeing the fetus on ultrasound is an important experience in accepting the reality of the pregnancy.

Like expectant mothers, expectant fathers need to confront and resolve some of their own conflicts about the fathering they received. A father needs to sort out those behaviors in his own fathering that he wants to imitate and those he wishes to avoid.

The anxiety experienced by the father-to-be is lessened if both parents agree on the support role the man is to assume during pregnancy and on his projected paternal role. For example, if both see his role as that of breadwinner, the man’s stress is low. However, if the man views his role as that of breadwinner and the woman expects him to be actively involved in preparations and child care, his stress increases. An open and honest discussion about the expectations each parent has about their roles will help the father-to-be in his transition to fatherhood (London et al., 2017).

The woman’s appearance begins to alter at this time, and men react differently to the physical change. For some it decreases sexual interest; for others it may have the opposite effect. Both partners experience a multitude of emotions, and it continues to be important for them to

communicate and accept each other's feelings and concerns. In situations in which the expectant mother's demands dominate the relationship, the expectant father's resentment may increase to the point that he is spending more time at work, involved in a hobby, or with his friends. The behavior is even more likely if the expectant father did not want the pregnancy or if the relationship was not a good one before the pregnancy.

Third Trimester

If the couple have communicated their concerns and feelings to one another and grown in their relationship, the third trimester is a special and rewarding time. A more clearly defined role evolves at this time for the expectant father, and it becomes more obvious how the couple can prepare together for the coming event. They may become involved in childbirth education classes and make concrete preparations for the arrival of the baby, such as shopping for a crib, car seat, and other equipment. If the expectant father has developed a detached attitude about the pregnancy before this time, however, it is unlikely that he will become a willing participant even though his role becomes more obvious.

Concerns and fears may recur. Many men are afraid of hurting the unborn baby during intercourse. The father may also begin to have anxiety and fantasies about what could happen to his partner and the unborn baby during labor and birth and feels a great sense of responsibility. The questions asked earlier in pregnancy emerge again. What kind of parents will he and his partner be? Will he really be able to help his partner in labor? Can they afford to have a baby?

The nurse needs to be prepared to meet the needs of lesbian or gay families as well. While all 50 states in the United States now recognize same-sex marriage, these couples may still face unique challenges in completing their developmental tasks.

Siblings

The introduction of a new baby into the family often leads to sibling rivalry, which results from children's fear of change in the security of their relationships with their parents. Some of the behaviors demonstrating feelings of sibling rivalry may even be directed toward the mother during the pregnancy as she experiences more fatigue and less patience with her toddler, for example. Parents who recognize the situation early in pregnancy and make constructive responses can help minimize the problems of sibling rivalry.

Preparation of the young child for a new sibling should begin several weeks before the anticipated birth and is best designed according to the age and experience of the child. The mother may let the child feel the fetus moving in her uterus, explaining that this is "a special place where babies grow." The child can help the parents put the baby clothes in drawers or prepare the baby's room. Because they do not have a clear concept of time, young children should not be told too early about the pregnancy.

Consistency is important in dealing with young children. They need reassurance that certain people, special things, and familiar places will continue to exist after the new baby

arrives. The crib is an important though transient object in a child's life. If it is to be given to the new baby, the parents should thoughtfully help the child adjust to this change. Any move from crib to bed or from one room to another should precede the baby's birth by several weeks or more. If the new baby is to share a room with one or more siblings, the parents must discuss this with them.

Some parents advocate cosleeping or bed sharing (one or both parents sleeping with their baby or young child), and so the crib is less of an issue. Cosleeping (newborn/infant sleeping in the same bed with the mother), which is common in many non-Western cultures, is on the increase in the United States. Opinion varies sharply about the advantages and risks of the practice. In 2005 the American Academy of Pediatrics (AAP) issued a policy statement recommending against cosleeping because of the increased risk of sudden infant death syndrome (SIDS) (Blair, 2015). The AAP and forensic researchers recommend that the safest place for the baby to sleep is in the parents' room with the baby in a crib in proximity to the parents for the first 6 months of life (Blair, 2015).

If the sibling is ready for toilet training, it is most effectively done several months before or after the baby's arrival. Parents should know that the older, toilet-trained child may regress to wetting or soiling because he or she sees the new baby getting attention for such behavior. The older, weaned child may want to drink from the breast or bottle again after the new baby comes. If the new mother anticipates these behaviors, they will be less frustrating during her early postpartum days.

During the pregnancy, older children should be introduced to a new baby for short periods to get an idea of what a new baby is like. This introduction dispels fantasies that the new arrival will be big enough to be a playmate. Pregnant women may also find it helpful to bring their children to a prenatal visit after they have been told about the expected baby. The children are encouraged to become involved in prenatal care and to ask any questions they may have. They are also given the opportunity to hear the fetal heartbeat, either with a stethoscope or with the Doppler device. This helps make the baby more real to them.

If siblings are school-age children, the pregnancy should be viewed as a family affair. Teaching about the pregnancy should be based on the child's level of understanding and interest. Overeager parents may go into longer and more in-depth responses than the child is able to understand. Some children are more curious than others. Books at their level of understanding can be made available in the home. Involvement in family discussions, attendance at sibling preparation classes, encouragement to feel fetal movement, and an opportunity to listen to the fetal heart supplement the learning process and help make the school-age child feel part of the pregnancy. Sibling preparation classes assist in the transition process for both parents and children. After attending the classes, children often exhibit an increased ability to express their feelings and less anxiety.

Older children or adolescents may appear to have a sophisticated knowledge base, but it may be intermingled with many misconceptions. Thus, parents should make

opportunities to discuss their concerns and should involve the children in preparation for the new baby.

Even after the birth, siblings need to feel that they are part of a family event. Changes in hospital regulations allowing siblings to be present at the birth or to visit their mother and the new baby facilitate this process. Participation in special programs for siblings may help in this process. On arrival at home, siblings can share in “showing off” the new baby.

Sibling preparation for the arrival of a new baby is essential, but other factors are equally important. These include the amount of parental attention focused on the new arrival, the amount of parental attention given the older child after the birth of the new arrival, and parental skill in dealing effectively with regressive or aggressive behavior.

Grandparents

The first relatives told about a pregnancy are usually the grandparents. Often the expectant grandparents become increasingly supportive of the couple even if conflicts existed previously. But even sensitive grandparents may have difficulty knowing how deeply to become involved in the childrearing process.

Because grandparenting can occur over a wide expanse of years, people’s response to this role varies considerably. Younger grandparents leading active lives may not demonstrate as much interest as the young couple would like. In other cases, expectant grandparents may freely give advice and gifts, sometimes to excess. For grandparents, conflict may be related to the expectant couple’s need to feel in control of their lives, or it may stem from events signaling changing roles in the grandparents’ lives (e.g., retirement, financial concerns, menopause, or death of a friend). Some parents of expectant couples may already be grandparents with a developed style of grandparenting. This influences their response to the pregnancy.

Because childbearing and childrearing practices have changed, family cohesiveness is promoted by effective communication and frank discussion between young couples and interested grandparents about the changes and the reasons for those changes. Clarifying the role of the grandparents ensures a comfortable situation for all.

Classes for grandparents may provide information about changes in birth and parenting practices. These classes help familiarize grandparents with new parents’ needs and may offer suggestions for ways in which the grandparents can support the childbearing couple.

Cultural Values and Pregnancy

A universal tendency exists to create ceremonial rituals or rites around important life events. Thus, rituals are often tied to pregnancy, childbirth, marriage, and death. The rituals and customs of a group are a reflection of the group’s values. Therefore, the identification of cultural values is useful in predicting reactions to pregnancy. An understanding of male and female roles, family lifestyles, religious values, or the meaning of children in a culture may explain reactions of joy or shame.

Generalization about cultural characteristics or values is difficult because not every individual in a culture may display these characteristics. Just as variations are seen

Focus on Diversity and Culture

Providing Culturally Competent Care

Nurses who are interacting with expectant families from a different culture or ethnic group can provide more effective, culturally competent nursing care by

- Critically examining their own cultural beliefs
- Identifying personal biases, attitudes, stereotypes, and prejudices
- Making a conscious commitment to respect and study the values and beliefs of others
- Using sensitive, current language when describing others’ cultures
- Learning the rituals, customs, and practices of the major cultural and ethnic groups with whom they have contact
- Including cultural assessment and assessment of the family’s expectations of the healthcare system as a routine part of prenatal nursing care
- Incorporating the family’s cultural and spiritual practices into prenatal care as much as possible
- Fostering an attitude of respect for and cooperation with alternative healers and caregivers when possible
- Providing for the services of an interpreter when language barriers exist
- Learning the language (or at least several key phrases) of at least one of the cultural groups with whom they interact
- Recognizing that ultimately it is the woman’s right to make her own healthcare choices
- Evaluating whether the woman’s healthcare beliefs have any potential negative consequences for her health.

between cultures, they are also seen within cultures. For example, because of their exposure to the American culture, a third-generation Chinese American family might have different values and beliefs from those of a Chinese family that has recently immigrated to America. For this reason, the nurse needs to supplement a general knowledge of cultural values and practices with a complete assessment of the individual’s values and practices. Focus on Diversity and Culture: Providing Culturally Competent Care summarizes the key actions a nurse can take to become more culturally aware.

Cultural assessment is an important aspect of prenatal care. Increasingly, healthcare professionals know that they must address cultural needs during a prenatal assessment to provide culturally competent healthcare during pregnancy. The nurse needs to identify the prospective parents’ main beliefs, values, and behaviors related to pregnancy and childbearing. This includes information about ethnic background, degree of affiliation with the ethnic group, patterns of decision making, religious preference, language, communication style, and common etiquette practices. The nurse also can explore the woman’s (or family’s) expectations of the healthcare system. Once this information has been gathered, the nurse can plan and provide care that is appropriate and responsive to a family’s needs.

Case Study » Part 1

Emma Halleck is a 22-year-old woman who presented at the antepartum clinic on June 15. She suspects that she is pregnant: A home pregnancy test was positive. Her last menstrual period began on April 10. She reports having urinary frequency, breast tenderness, fatigue, and occasional nausea and vomiting. She has begun to have some light-headedness and dizziness when she first gets up after sitting or sleeping.

Mrs. Halleck tells you she is married and states that this is her second pregnancy. She miscarried at 10 weeks approximately 6 months ago. She denies any history of drug or alcohol use, sexually transmitted infections (STIs), multiple partners, family violence, medical-surgical disorders, or mental illness. Mrs. Halleck is excited about the pregnancy, and she reports that her husband is, too. She does express concern over her ability to carry the pregnancy to term, although she feels relieved that she is beyond the time of her first pregnancy loss. This pregnancy was a planned pregnancy. Mrs. Halleck is a college graduate, employed as a teacher, and has group health insurance through the local public school system.

Exam

Weight 122 lb (prepregnant weight usually between 115 and 120 lb)

Height 5'4"

BP 110/60 mmHg, P 82 beats/min, R 16/min

Hgb 12, Hct 33%, WBC 5000

UA, blood glucose, and protein all negative

Rubella titer—immune

HIV, STIs—negative

Hepatitis antibody—negative

Immunoassay pregnancy test—positive

Mother: O Rh negative; father: O Rh positive.

On pelvic exam, the physician determines that Mrs. Halleck's uterus is enlarged and at the top of the symphysis pubis. The lower uterine segment is soft; the cervix is soft and bluish in color. There is an increase in vaginal and cervical secretions. The physician determines that Mrs. Halleck's pelvis is adequate for a normal vaginal birth. Vaginal ultrasound confirms pregnancy with fetal heart tones at 120 beats per minute.

Clinical Reasoning Questions Level I

1. Why is Mrs. Halleck experiencing urinary frequency?
2. Why is Mrs. Halleck having breast tenderness at this time?
3. Are light-headedness and dizziness normal? Why or why not? What nursing intervention should be taught to all pregnant women to avoid these symptoms?

Clinical Reasoning Questions Level II

4. Are the uterine changes assessed on examination considered normal? Why or why not?
5. How does the body maintain pregnancy during the first 12 weeks?
6. Which developmental stage of pregnancy is Mrs. Halleck in? How did you determine this?
7. How would you assess whether fetal attachment is occurring?

feature outlines some, but not all, of the concepts that are integral to pregnancy. They are presented in alphabetical order.

Sexuality is a key concept in reproductive health, as intercourse is the means by which conception occurs. Anatomic and hormonal changes of pregnancy may alter sexual activity between partners, affecting intimacy and relationships. An additional concern is the potential for unprotected sex before or during pregnancy. Unprotected sex may lead to STIs, which could result in infertility, fetal loss, or complications for mother and fetus. Sexuality is considered as families plan the timing of pregnancies and consider future pregnancies.

Expected physiologic changes in pregnancy often result in discomfort. Anatomic adjustments occur over time as the fetus grows and maternal tissues and structures adapt to physical and hormonal changes. Chronic pain caused by existing diagnoses may increase as pregnancy progresses. During labor, contractions, cervical dilation, and vaginal distention cause pain that may be managed using nonpharmacologic and pharmacologic interventions. The source of postpartum pain varies depending on the length of labor and pushing, types of delivery, and potential perineal trauma. Cramping and discomfort that may accompany breastfeeding are also possible.

Antepartum monitoring includes methods to assess perfusion of mother and fetus. Because poor tissue perfusion decreases the amount of oxygen that reaches the tissues, it is important to maintain normal hemoglobin and hematocrit levels to promote the production and function of red blood cells. In addition, screening allows for early identification of conditions that may impair perfusion, including congenital anomalies, abnormalities of the placenta, and nutritional deficits. Hypertensive disorders of pregnancy may decrease perfusion, resulting in poor fetal growth or neurologic risks for the mother. Conditions that threaten the viability of mother or fetus may require preterm delivery.

Prenatal nutrition is crucial for adequate growth and development of fetal tissues. Nutritional assessment occurs throughout pregnancy via laboratory values and monitoring of weight gain. Nutritional deficits may occur in vulnerable populations or for those diagnosed with hyperemesis or other gastrointestinal disorders. Adequate nutrition is also required for the production of nutrient-dense breast milk and continues to be a critical component of continued growth and development of the newborn.

Hormonal influences may alter carbohydrate metabolism during pregnancy, leading to the development of gestational diabetes mellitus (GDM). Increased maternal glucose levels may cause the fetus to become large for gestational age (LGA), leading to potential complications for mother and fetus during and after delivery. Patients with an existing diagnosis of diabetes mellitus (DM) may develop vascular changes that impair fetal perfusion, resulting in a newborn that is small for gestational age (SGA). Glucose tolerance tests occur during pregnancy to screen for and diagnose GDM. (GDM is discussed in detail in Exemplar 33.A.)

Oxygenation is essential for normal tissue growth and function. Alterations in oxygenation may cause fetal acidosis, which could result in impaired function of the newborn or fetal loss (see the module on Acid-Base Balance). Existing

Concepts Related to Reproduction

Pregnancy is directly related to reproduction, but affects all body systems and many concepts. Changes and alterations may involve multiple aspects of health. A holistic model of nursing care assists the nurse to engage in patient-centered care focusing on the physical, psychosocial, and spiritual needs of the patient. The Concepts Related to Reproduction

Concepts Related to Reproduction

CONCEPT	RELATIONSHIP TO REPRODUCTION	NURSING IMPLICATIONS
Comfort	Pregnancy discomforts Labor pain Postpartum pain.	<ul style="list-style-type: none"> Pregnancy: provide comfort measures for common discomforts. Labor: provide comfort measures for labor (relaxation, hot/cold, positioning, ambulating, birthing balls, hydrotherapy), medications for pain relief, including IVP and epidurals. Postpartum: Provide instruction on Kegel exercises, sitz baths.
Metabolism	Diabetes, gestational diabetes ↑ risks to both mother and baby.	<ul style="list-style-type: none"> Assess for signs/symptoms of hypoglycemia and hyperglycemia. Encourage 30 minutes of exercise after each meal. Conduct fetal kick counts twice daily beginning at 28 weeks. Teach blood glucose monitoring. Refer to dietitian. Encourage frequent prenatal visits. Encourage verbalization of feelings related to diabetes diagnosis.
Nutrition	Prenatal nutrition is critical for a healthy fetus. Breastfeeding.	<ul style="list-style-type: none"> Educate patient on need to increase calories and fluid intake and on safe food consumption during pregnancy. Provide health promotion strategies to enhance fetal/neonatal health: <ul style="list-style-type: none"> Easily digested foods Decreased allergies, risk for illness Promotion of self-regulation of feedings.
Oxygenation	Untreated or undertreated respiratory disease ↑ risk of inadequate oxygenation to fetus.	<ul style="list-style-type: none"> Educate patient regarding need to adhere to therapeutic regimen for respiratory conditions such as asthma. Refer patients who need specialized care who do not already have a provider (e.g., pulmonologist). Assess respiratory status, patient signs/symptoms at each healthcare interaction.
Perfusion	↓ tissue perfusion creates oxygen deficit to organs.	<ul style="list-style-type: none"> Assess perfusion, including pulses, nail beds, color, body position for comfort, orientation. Be alert for tachycardia, then hypotension, cool clammy skin, altered level of consciousness (LOC). Administer oxygen. Replace IV fluids. Weigh pads. Administer pharmacotherapy to contract uterus.
Sexuality	Unprotected intercourse ↑ likelihood of pregnancy, ↑ risk for sexually transmitted infections. Anatomic and hormonal changes.	<ul style="list-style-type: none"> Educate patient regarding safe sex practices. Assess risk factors. Provide additional education related to risk factors. Educate couple about normal alterations affecting intimacy.
Stress and Coping	Emotional and relational changes occur with growth of the family. Responsibilities expand with incorporation of a new child. Expected physical changes may impact self-esteem. Pregnancy, delivery, and recovery may not meet expectations. (i.e., birth experience and idealized child).	<ul style="list-style-type: none"> Encourage expression of concerns. Assess patient's and family's past coping strategies. Reinforce adaptive coping. Reinforce realistic expectations.
Teaching and Learning	Patient/couples education enhances pregnancy outcomes.	<ul style="list-style-type: none"> Educate patient/couple about labor and comfort measures. Inform patient about expected physiologic and psychologic changes associated with pregnancy. Provide information about purpose and significance of findings.

maternal diagnoses such as asthma may cause poor maternal oxygenation, which, in turn, disrupts placental gas exchange for the fetus. Assessment of fetal oxygenation occurs via monitoring of the fetal heart rate, and takes place in the clinic, antepartum testing unit, or the labor and delivery unit. Adequate maternal nutrition, avoidance of the supine position, and treatment of respiratory conditions help to maintain oxygenation of the mother and fetus.

The addition of a child to the family unit requires role transitions for each family member. Impaired coping may disrupt normal family processes and relationships as members adjust to pregnancy, prepare for delivery, and incorporate the new child into the family. Ineffective coping skills may result in alterations in family dynamics and relationships as members compare the reality of the birth experience with expectations. Negative responses to expected physical changes of pregnancy may also have an impact on body image, which could result in unhealthy behaviors involving nutrition and physical activity.

Effective teaching and learning are key factors that may improve patient outcomes. Pregnant women, especially those who are pregnant for the first time, require a great deal of education and support from healthcare providers. Patient understanding of the need for antepartal testing and regular clinic visits improves compliance and leads to better patient outcomes. Anticipation of expected changes of pregnancy may enhance the pregnancy experience, especially if both the mother and father understand the physiology of pregnancy and normal changes that may occur. The labor process may be enriched if couples attend childbirth classes in preparation for the delivery.

Health Promotion

The nurse can help promote maternal and fetal well-being by providing expectant couples with accurate, complete information about health behaviors and issues that can affect pregnancy and childbirth. Health behaviors, such as breast care, rest, sexual activity, and exercise, help protect both the fetus and the mother and decrease the discomfort of the mother during both pregnancy and labor. Issues that can affect pregnancy range from clothing to employment to travel. The nurse working with pregnant women needs to be able to provide patient teaching in all of these areas.

Breast Care

Whether the pregnant woman plans to formula-feed or breastfeed her baby, support of the breasts is important to promote comfort and prevent back strain, particularly if the breasts become large and pendulous. The sensitivity of the breasts in pregnancy is frequently relieved by good support.

Wearing a well-fitting, supportive brassiere that has the following qualities is essential:

- The straps are wide and do not stretch (elastic straps soon lose their tautness with the weight of the breasts and frequent washing).
- The cup holds all breast tissue comfortably.
- Tucks or other devices allow the brassiere to expand, thus accommodating the enlarging chest circumference.

Figure 33-23 » This breast shell is designed to increase the protractility of inverted nipples. Worn the last 3–4 weeks of pregnancy, it exerts gentle pulling pressure at the edge of the areola, gradually forcing the nipple through the center of the shield. It may be used after birth if necessary.

- The brassiere supports the nipple line approximately midway between the elbow and shoulder but is not pulled up in the back by the weight of the breasts.

Cleanliness of the breasts also is important, especially if they begin leaking colostrum, which may occur during the last trimester (or earlier in women pregnant with multiples). If colostrum crusts on the nipples, it can be removed with warm water. The woman planning to breastfeed is advised not to use soap on her nipples because of its drying effect.

Some women have flat or inverted nipples. True nipple inversion, which is rare, is usually diagnosed during the initial prenatal assessment. Breast shells designed to correct inverted nipples are effective for some women, but others gain no benefit from them (**Figure 33-23 »**).

Activity and Rest

Exercise during pregnancy helps maintain maternal fitness and muscle tone, leads to improved self-image, promotes regular bowel function, increases energy, improves sleep, relieves tension, helps control weight gain, and is associated with improved postpartum recovery. Normal participation in exercise can continue throughout an uncomplicated pregnancy and, in fact, is encouraged.

The woman can check with her certified nurse-midwife (CNM) or obstetrician about taking part in strenuous sports, such as skiing and horseback riding. In general, the skilled sportswoman is not discouraged from participating in these activities if her pregnancy is uncomplicated. However, pregnancy is not the appropriate time to learn a new sport.

Certain conditions contraindicate exercise. These conditions include rupture of the membranes, preeclampsia–eclampsia,

Patient Teaching

Pregnant Women and Exercise

The following guidelines are helpful in counseling pregnant women about exercise:

- Even mild to moderate exercise is beneficial during pregnancy. Regular exercise—at least 30 minutes of moderate exercise daily or most days—is preferred (Kimberly, Neibyl, & Johnson, 2012).
- After the first trimester, women should avoid exercising in the supine position. In most pregnant women, the supine position is associated with decreased cardiac output. Because uterine blood flow is reduced during exercise as blood is shunted from the visceral organs to the muscles, the remaining cardiac output is further decreased. Similarly, women should avoid standing motionless for prolonged periods (Katz, 2012).
- Because decreased oxygen is available for aerobic exercise during pregnancy, women should modify the intensity of their exercise based on their symptoms, should stop when they become fatigued, and should avoid exercising to the point of exhaustion. Non-weight-bearing exercises, such as swimming and cycling, are recommended because they decrease the risk of injury and provide fitness with comfort.
- As pregnancy progresses and the center of gravity changes, especially in the third trimester, women should avoid exercises in which the loss of balance could pose a risk to mother or fetus. Similarly, women should avoid any type of exercise that might result in even mild abdominal trauma.
- A normal pregnancy requires an additional 300 kcal/day of nutritional intake. Women who exercise regularly during pregnancy should be careful to ensure that they consume an adequate diet.
- To augment heat dissipation, especially during the first trimester, pregnant women should wear clothing that is comfortable and loose while exercising, ensure adequate hydration, and avoid prolonged overheating. For the same reason, pregnant women are advised to avoid hot tubs and saunas. If a pregnant woman is unable to talk or feels unable to breathe, the exercise effort is too high.
- As a result of the cardiovascular changes of pregnancy, heart rate is not an accurate indicator in pregnant women for the intensity of exercise. If a pregnant woman is unable to maintain a conversation while exercising, then her exercise effort is too high (Field, 2012).

shortened cervix on transvaginal ultrasound or cerclage placement, persistent vaginal bleeding in the second and third trimesters, risk factors for preterm labor or a history of preterm labor in a prior or current pregnancy, placenta previa after 23 weeks of gestation, and chronic medical conditions that might be negatively impacted by vigorous exercise, such as significant heart disease (American Academy of Pediatrics & American College of Obstetricians and Gynecologists [AAP & ACOG], 2012). See Patient Teaching: Pregnant Women and Exercise.

The nurse may suggest that the woman wear a supportive bra and appropriate shoes when exercising. The nurse should advise the woman to warm up and stretch to help prepare the joints for activity and, after exercising, to cool

Focus on Integrative Health

Yoga During Pregnancy

Yoga may build strength and alleviate stress and physiologic discomforts in pregnancy. Pregnant women should attend only yoga classes designed for pregnancy unless they are familiar with potentially harmful yoga positions and can avoid them when attending regular yoga classes. The following advice is important for women who practice yoga during pregnancy (Field, 2012):

- During pregnancy, some yoga poses or positions are contraindicated. Pregnant women should avoid poses that put pressure on the uterus as well as any extreme stretching positions.
- Because of the changed center of gravity that occurs as pregnancy progresses, pregnant women need to be especially careful to maintain balance when stretching.
- Pregnant women should avoid stomach-lying for any poses. After 20 weeks of gestation, they should lie on their side rather than on their back for floor positions.
- In the last trimester, pregnant women may experience vena caval syndrome resulting in reduced blood flow back to the heart as the growing fetus puts pressure on the major vessels when lying flat on their backs.
- Pregnant women should immediately stop any pose that is uncomfortable.
- Warning signs that indicate the need to contact the health-care provider immediately include dizziness, extreme shortness of breath, sudden swelling, contractions, leaking of fluid, and vaginal bleeding.

down with a period of mild activity to help restore circulation and avoid pooling of blood. A moderate, rhythmic exercise routine involving large muscle groups, such as swimming, cycling, or brisk walking, is best. Jogging or running is acceptable for women already conditioned to these activities as long as they avoid exercising at maximum effort and overheating. See Focus on Integrative Health: Yoga During Pregnancy.

During exercise, warning signs include pain of any kind, difficulty walking, dizziness, headache, muscle weakness, dyspnea before exertion, uterine contractions, vaginal bleeding, or fluid loss from the vagina (AAP & ACOG, 2012). The woman should stop exercising if these symptoms occur and modify her exercise program. If the symptoms persist, the woman should contact her healthcare provider.

Adequate rest in pregnancy is important for both physical and emotional health. Women need more sleep throughout pregnancy, particularly in the first and last trimesters when they tire easily. Without adequate rest, pregnant women have less resilience. Finding time to rest during the day may be difficult for women who work outside the home or have small children. The nurse can help the expectant mother examine her daily schedule to develop a realistic plan for short periods of rest and relaxation.

Sleeping becomes more difficult during the last trimester because of the enlarged abdomen, increased frequency of urination, and greater activity of the fetus. Finding a comfortable position becomes difficult for the pregnant woman.

Progressive relaxation techniques similar to those taught in childbirth classes can help prepare the woman for sleep.

Sexual Activity

As a result of the physiologic, anatomic, and emotional changes of pregnancy, couples usually have many questions and concerns about sexual activity during pregnancy. Often, these questions are about possible injury to the baby or the woman during intercourse and about changes in the desire each partner feels.

In the past, couples often were warned to avoid sexual intercourse during the last 6–8 weeks of pregnancy in order to prevent complications, such as infection or premature rupture of the membranes. However, these fears seem to be unfounded. In a healthy pregnancy, there is no medical reason to limit sexual activity. Intercourse is contraindicated for medical reasons, such as rupture of membranes, placenta previa, threatened spontaneous abortion, or the risk of preterm labor (Cunningham et al., 2014).

The expectant mother may experience changes in sexual desire and response. Often, these changes are related to the various discomforts that occur throughout pregnancy. For instance, during the first trimester, fatigue or nausea and vomiting may decrease desire, and breast tenderness may make the woman less responsive to fondling of her breasts. During the second trimester, many of the discomforts have lessened, and with the vascular congestion of the pelvis, the woman may experience greater sexual satisfaction than she experienced before pregnancy.

During the third trimester, interest in coitus may again decrease as the woman becomes more uncomfortable and fatigued. In addition, shortness of breath, painful pelvic ligaments, urinary frequency, leg cramps, and decreased mobility may lessen sexual desire and activity. If they are not already doing so, the heterosexual couple should consider coital positions other than male superior, such as side by side, female superior, and vaginal rear entry.

Sexual activity does not have to include intercourse. Many of the nurturing and sexual needs of the pregnant woman can be satisfied by cuddling, kissing, and being held. The warm, sensual feelings that accompany these activities can be an end in themselves. Her partner, however, may choose to masturbate.

The sexual desires of partners of pregnant women are also affected by many factors in pregnancy. These factors include the previous relationship with the partner, acceptance of the pregnancy, attitudes toward the partner's change of appearance, and concern about hurting the expectant mother or baby. Some find it difficult to view their partners as sexually appealing while they are adjusting to the concept of their partners as mothers. Others find their partners' pregnancies arousing and experience feelings of increased happiness, intimacy, and closeness.

The expectant couple should be aware of their changing sexual desires, the normality of these changes, and the importance of communicating these changes to each other so that they can make nurturing adaptations. The nurse has an important role in helping the expectant couple adapt. The couple should feel free to express concerns about sexual activity, and the nurse should be able to respond and give anticipatory guidance in a comfortable

manner. See Patient Teaching: Sexual Activity During Pregnancy.

Dental Care

Proper dental hygiene is important in pregnancy because ensuring a healthy oral environment is essential to overall health. Periodontal disease is a contributing factor to preterm labor (ACOG, 2013b). In spite of such discomforts as nausea and vomiting, gum hypertrophy and tenderness, possible ptyalism (excessive, often bitter salivation), and heartburn, pregnant women need to maintain regular oral hygiene by brushing at least twice a day and flossing daily.

The nurse should encourage the pregnant woman to have a dental checkup early in her pregnancy. Dentistry should proceed as needed in pregnancy. Local anesthesia is fine, but epinephrine should not be used. The woman should inform her dentist of her pregnancy so that she is not exposed to teratogenic substances. See the exemplar on Oral Health in the module on Health, Wellness, Illness, and Injury.

Other Health Promotion Measures

A number of health promotion measures not directly related to pregnancy are necessary to ensure the health of the mother and fetus. Some of these measures relate to immunizations, clothing, bathing, maternal employment, and travel.

Immunizations

All women of childbearing age need to be aware of the risks of receiving certain immunizations if pregnancy is possible. The influenza and Tdap vaccines are recommended for pregnant women (Centers for Disease Control and Prevention [CDC], 2014a). Immunizations with attenuated live viruses, such as rubella vaccine, should not be given in pregnancy because of the teratogenic effect of the live viruses on the developing embryo. The most current recommendations on vaccines related to pregnancy should be obtained from the CDC website (www.cdc.gov).

Clothing

Traditionally, maternity clothes have been constructed with fuller lines to allow for the increase in abdominal size during pregnancy. However, maternity wear has changed in recent years and now also includes clothes that are more fitted, with little attempt to hide the pregnant abdomen. Maternity clothing can be expensive, and it is worn for a relatively short time. Women can economize by sharing clothes with friends, sewing their own garments, or buying used maternity clothes.

High-heeled shoes tend to aggravate back discomfort by increasing the curvature of the lower back. They are best avoided if the woman experiences backache or has problems with balance. Shoes should fit properly and feel comfortable.

Bathing

Because perspiration and mucoid vaginal discharge increase during pregnancy, hygiene is important. Practices related to cleansing the body are often influenced by cultural norms; thus, a pregnant woman may choose to cleanse only some portions of her body daily or may elect to take daily showers or tub baths. Caution is needed during tub baths because balance becomes a problem in late pregnancy. Rubber mats

Patient Teaching

Sexual Activity During Pregnancy

Discussion about various sexual activities requires that the nurse be comfortable with his or her sexuality and also be tactful. A discussion of sexuality and sexual activity should stress the importance of open communication so that the couple feels comfortable expressing feelings, preferences, and concerns. The nurse can assist the couple regarding sexual activity during pregnancy with the following patient teaching:

- Begin by explaining that the pregnant woman may experience changes in desire during the course of pregnancy. During the first trimester, discomforts such as nausea, fatigue, and breast tenderness may make intercourse less desirable for many pregnant women. Universal statements that give permission, such as “Many couples experience changes in sexual desire during pregnancy. What kind of changes have you experienced?” are often effective in starting discussion. Depending on the woman’s (or couple’s) level of knowledge and sophistication, part or all of this discussion may be necessary.
- In the second trimester, as symptoms decrease, desire may increase. In the third trimester, discomfort and fatigue may lead to decreased desire in the pregnant woman. If the partner is present, approach the partner in the same nonjudgmental way discussed previously. If not, ask the pregnant woman if she has noticed any changes in her partner or if her partner has expressed any concerns.
- Explain that partners of pregnant women may notice changes in their level of desire, too. Among other things, this change may be related to feelings about their partner’s changing appearance, their belief about the acceptability of sexual activity with a pregnant woman, or concern about hurting the woman or fetus. Some partners find the changes of pregnancy erotic; others must adjust to the notion of their partners as mothers. Deal with any specific questions about the physical and psychologic changes that the couple may have.
- Explain that the woman may notice that orgasms are much more intense during the last weeks of pregnancy and may be followed by cramping. Because of the pressure of the enlarging uterus on the vena cava, the pregnant woman should not lie flat on her back for intercourse after about the fourth month. If the couple prefers that position, a pillow should be placed under the pregnant woman’s right hip to displace the uterus. Alternative positions such as side by side, female superior, or vaginal rear entry may become necessary as her uterus enlarges.
- Stress that sexual activities both partners enjoy are generally acceptable. It is not advisable, however, for couples who favor anal sex to go from anal penetration to vaginal penetration because of the risk of introducing *Escherichia coli* into the vagina. The couple may be content with these approaches to meeting their sexual needs, or they may require assurance that such approaches are indeed “normal.”
- Suggest that alternative methods of expressing intimacy and affection, such as cuddling, holding and stroking each other, and kissing, may help maintain the couple’s feelings of warmth and closeness. If the partner feels desire for further sexual release, the pregnant woman may help her partner masturbate to climax, or the partner may prefer to masturbate in private.
- Advise the pregnant woman who is interested in masturbation as a form of gratification that the orgasmic contractions may be especially intense during later pregnancy.
- Stress that sexual intercourse is contraindicated once the membranes have ruptured or if bleeding is present. Pregnant women with a history of preterm labor may be advised to avoid intercourse, because the oxytocin that is released with orgasm stimulates uterine contractions and may trigger preterm labor. Because oxytocin is also released with nipple stimulation, fondling the breasts may be contraindicated in those cases as well.
- Some couples are skilled at expressing their feelings about sexual activity. Others find it difficult and can benefit from specific suggestions. The nurse should provide opportunities for discussion throughout the talk. An explanation of the contraindications accompanied by their rationale provides specific guidelines that most couples find helpful. Specific handouts on sexual activity are helpful for couples and may address topics that were not discussed.

and hand grips are important safety devices. Vasodilation caused by warm water may make the woman feel faint when she attempts to get out of the tub, so she may require assistance, especially during the last trimester. During the first trimester, pregnant women should avoid hyperthermia associated with the use of a hot tub or Jacuzzi, because it may increase the risk for miscarriage or neural tube defects (Snijder et al., 2012).

Employment

Pregnant women who have no complications can usually continue to work until they go into labor (AAP & ACOG, 2012). Although pregnant women who are employed in jobs that require prolonged standing (>5 hours) do have a higher incidence of preterm birth, prolonged standing has no effect on fetal growth (Snijder et al., 2012).

Fetotoxic hazards are always a concern to the expectant couple. The pregnant woman (or the woman contemplating pregnancy) who works in industry should contact her

company physician or nurse about possible hazards in her work environment and do her own reading and research on environmental hazards as well. Similarly, a male partner can seek information about hazards in his workplace that might affect his sperm.

Travel

If medical or pregnancy complications are not present, there are no restrictions on travel. Pregnant women are advised to avoid travel if they have a history of bleeding or preeclampsia or if multiple births are anticipated. Availability of medical care at the destination is an important factor for the near-term woman who travels. It may be helpful to travel with a copy of the woman’s medical record.

Travel by automobile can be especially fatiguing, aggravating many of the discomforts of pregnancy. The pregnant woman needs frequent opportunities to get out of the car and walk. (A good pattern is to stop every 2 hours and walk around for approximately 10 minutes.) She should wear

both lap and shoulder belts; the lap belt should fit snugly and be positioned under the abdomen and across the upper thighs. The shoulder strap should rest comfortably between the woman's breasts. Seat belts play an important role in preventing fetal and maternal morbidity and mortality with subsequent fetal death (Cunningham et al., 2014). Fetal death in car crashes is related to placental separation (abruptio placentae) as a result of uterine trauma. Use of the shoulder belt decreases the risk of traumatic flexion of the woman's body, thereby decreasing the risk of placental separation.

As pregnancy progresses, long-distance trips are best taken by plane or train. Currently, flying is considered to be safe up to 36 weeks of gestation in the absence of any complications (AAP & ACOG, 2012). Before flying, the woman should check with her airline to see if they have any travel restrictions. Prolonged air travel may lead to edema in the lower extremities and the development of venous thrombotic events. To minimize complications, the traveler should consider wearing support stockings, maintain oral hydration, periodically move the lower extremities, change positions frequently, and move about the cabin at least every 2 hours when conditions are favorable (AAP & ACOG, 2012).

SAFETY ALERT Although the Zika virus was discovered in the 1940s, the recently identified adverse effects on fetal development resulted in research involving transmission and pregnancy risks. Researchers determined that the virus is transmitted directly from mother to fetus through the placenta, resulting in neural damage.

Transmission of the Zika virus occurs via mosquito bites and through sexual contact. Only one in five people with Zika infection will exhibit symptoms. Once infected, individuals are protected from future infection.

Symptoms of Zika infection include mild fever, maculopapular rash, headache, arthralgia (joint pain), and myalgia (muscle pain).

Prevention of infection includes:

- Wearing long-sleeved shirts and pants
- Using mosquito bed nets or window screens
- Applying topical products containing DEET
- Eliminating standing water, which is where mosquitoes breed
- Avoiding traveling to areas where the virus is actively circulating.

Source: Hamel, M. S., & Hughes, B. L. (2016). Zika infection in pregnancy. *Contemporary OB/GYN*, 61(8), 16–42.

Complementary Health Approaches

Many pregnant women elect to use complementary health approaches, such as homeopathy, herbal medicine, acupuncture and acupuncture, biofeedback, therapeutic touch, massage, and chiropractic, as part of a holistic approach to their healthcare regimens. The nurse should inquire about the use of complementary health approaches as part of a routine nursing assessment. The nurse working with pregnant women and childbearing families should develop a general understanding of the more commonly used therapies in order to be able to answer basic questions and provide resources as needed.

Pregnant women should understand that herbs are considered to be dietary supplements and are not regulated through the U.S. Food and Drug Administration (FDA), as prescription or over-the-counter (OTC) drugs are. Because of limited scientific evaluation of potential harmful effects

on the fetus, herbal supplements should be avoided, particularly in the first trimester (Romm, 2011).

» **Stay Current:** Additional information about herbs, homeopathic remedies, and other alternative options may be accessed at the website of the National Center for Complementary and Integrative Health, <http://nccam.nih.gov>.

Teratogenic Substances

Substances that adversely affect the normal growth and development of the fetus are called **teratogens**. The nurse who is caring for the pregnant woman, or for the woman who is trying to become pregnant, should teach her about teratogenic substances, including alcohol, and emphasize the need for the woman to discuss the use of any and all medications, including psychotropic drugs, with her obstetrician. Obstetricians and nurse-midwives are the most informed about the potential effects of medications on the fetus. The nurse should also instruct the patient with a chronic condition, such as asthma or diabetes, to inform her treating physician if she is (or is trying to become) pregnant. The pregnant woman with a chronic condition should be encouraged to use a single pharmacy and to inform the pharmacy staff that she is pregnant. Discussing potential hazards in the work and home environments, such as pesticides and exposure to x-rays in the first trimester, is important for preventing teratogenic effects on the fetus.

For a more thorough discussion of the risks of substance abuse during pregnancy, see the exemplar on Substance Abuse in the module on Addiction. An overview of the risks associated with tobacco use is provided here.

Tobacco

In the United States, smoking tobacco during pregnancy is one of the most significant, modifiable causes of poor pregnancy outcomes. Smoking during pregnancy has a strong association with low-birth-weight neonates. In addition, mothers who smoke have an increased risk of preterm birth, premature rupture of the membranes, fetal demise, placental previa, abruptio placentae, premature rupture of membranes, and preterm birth (Cunningham et al., 2014). Pregnant women who smoke tobacco and participate in other unhealthy behaviors, such as alcohol use, further increase their risk for low-birth-weight newborns (Barron, 2014). Research also links maternal tobacco smoking, both during and after pregnancy, with an increased risk of SIDS. Maternal smoking exposes young children to other risks of secondhand smoke, including middle ear infections, acute and chronic respiratory tract illnesses, and behavioral and learning disabilities (Al-Sayed & Ibrahim, 2014).

Nursing Assessment

The nurse caring for a woman who is pregnant establishes an environment of comfort and open communication with each antepartum visit. The nurse conveys interest in the woman as an individual and discusses the woman's concerns and desires. Typically, the registered nurse may complete many areas of prenatal assessment. Advanced practice nurses such as CNMs and certified women's health nurse practitioners have the education and skill to perform full and complete antepartum assessments. This section focuses on the initial prenatal assessment.

Box 33–1

Definition of Terms

The following terms are used in recording the history of prenatal patients:

Abortion: Spontaneous loss or termination of pregnancy that occurs before the end of 20 weeks' gestation or the birth of a fetus–newborn who weighs less than 500 g (Cunningham et al., 2014)

Antepartum: Time between conception and the onset of labor; often used to describe the period during which a woman is pregnant; used interchangeably with **prenatal**

Gestation: The number of weeks since the first day of the last menstrual period

Gravida*: The number of pregnancies in the woman's lifetime, regardless of duration, including current pregnancy

Intrapartum: Time from the onset of true labor until the birth of the baby and placenta

Multigravida: A woman who is in her second or any subsequent pregnancy

Multipara: A woman who has had two or more births at more than 20 weeks' gestation

Nulligravida: A woman who has never been pregnant

Nullipara: A woman who has had no births at more than 20 weeks' gestation

Para*: Birth after 20 weeks' gestation regardless of whether the baby is born alive or dead

Postpartum: Time from birth until the woman's body returns to an essentially prepregnant condition

Postterm labor: Labor that occurs after 42 weeks' gestation

Prenatal: Time between conception and the onset of labor; antepartum

Preterm or premature labor: Labor that occurs after 20 weeks' gestation but before completion of 37 weeks' gestation

Primigravida: A woman who is pregnant for the first time

Primipara: A woman who has had one birth at more than 20 weeks' gestation, regardless of whether the baby was born alive or dead

Stillbirth: A baby born dead after at least 20 weeks' gestation

Term: A word that was formerly used to identify the normal duration of pregnancy. The stand-alone use of this word is now discouraged because it represents such a wide range of time and related risks (Spong, 2013). ACOG (2013c) recommends that the following definitions be used:

- Late preterm: births that occur before 34 0/7 through 36 6/7 weeks' gestation
- Early term: births that occur between 37 weeks 0 days and 38 weeks 6 days
- Full term: births that occur between 39 weeks 0 days and 40 weeks 6 days

*The terms *gravida* and *para* are used in relation to pregnancies, not the number of fetuses. Thus, twins, triplets, and so on, count as one pregnancy and one birth.

Patient Interview

The course of a pregnancy depends on a number of factors, including the woman's prepregnancy health, the presence of disease states, the woman's emotional status, and her past healthcare. A thorough history is useful in determining the status of a woman's prepregnancy health. Terms useful for recording the history of prenatal patients are listed in **Box 33–1** ».

Patient Profile

The history is essentially a screening tool that identifies factors that may place the mother or fetus at risk during the pregnancy. The following information is obtained for each pregnant woman at the first prenatal assessment:

1. Current Pregnancy

- First day of last normal menstrual period (Is she sure or unsure of the date? Do her cycles normally occur every 28 days, or do her cycles tend to be longer?)
- Presence of cramping, bleeding, or spotting since LMP
- Woman's opinion about the time when conception occurred and when baby is due
- Woman's attitude toward pregnancy (Is this pregnancy planned? Wanted?)
- Results of pregnancy tests, if completed
- Any discomforts since LMP (e.g., nausea, vomiting, urinary frequency, fatigue, or breast tenderness)

2. Past Pregnancies

- Number of pregnancies
- Number of abortions, spontaneous or therapeutic
- Number of living children
- History of previous pregnancies, length of pregnancy, length of labor and birth, type of birth (vaginal, forceps- or vacuum-assisted, or cesarean), type of anesthesia used (if any), woman's perception of the experience, and complications (antepartum, intrapartum, and postpartum)
- Neonatal status of previous children: Apgar scores (see Exemplar 33.D, Newborn Care, for a discussion of Apgar scoring), birth weights, general development, complications, and feeding patterns (breast milk or formula)
- Loss of a child (miscarriage, elective or medically indicated abortion, stillbirth, neonatal death, relinquishment, or death after the neonatal period) (What was the experience like for her? What coping skills helped? How did her partner, if involved, respond?)
- If Rh negative, was Rh immune globulin received during pregnancy and/or after birth/miscarriage/abortion to prevent sensitization?
- Prenatal education classes and resources (books)

3. Gynecologic History

- Date of last Pap smear; any history of abnormal Pap smear; any follow-up therapy completed

- Previous infections: vaginal, cervical, tubal, sexually transmitted (see the exemplar on Sexually Transmitted Infections in the module on Sexuality)
- Previous surgery (uterine/ovarian)
- Age at menarche
- Regularity, frequency, and duration of menstrual flow
- History of dysmenorrhea
- Sexual history
- Contraceptive history (If birth control pills were used, did pregnancy occur immediately following cessation of pills? If not, how long after?)
- Any issues related to infertility or fertility treatments

4. **Current Medical History**

- Weight
- Blood type and Rh factor if known
- General health, including nutrition (dietary practices such as vegetarianism) and regular exercise program (type, frequency, and duration)
- Any medications currently being taken (including nonprescription, homeopathic, or herbal medications) or taken since the onset of pregnancy
- Previous or present use of alcohol, tobacco, or caffeine (Ask specifically about the amount of alcohol, cigarettes, and caffeine [specify coffee, tea, cola, and chocolate] consumed each day)
- Illicit drug use or abuse (Ask about specific drugs such as cocaine, crack, methamphetamines, and marijuana)
- Drug allergies and other allergies (Ask about latex allergies or sensitivities)
- Potential teratogenic insults to this pregnancy, such as viral infections, medications, x-ray examinations, surgery, or cats in the home (possible source of toxoplasmosis)
- Presence of disease conditions such as diabetes, hypertension, cardiovascular disease, renal problems, or thyroid disorder
- Record of immunizations
- Presence of any abnormal symptoms

5. **Past Medical History**

- Childhood diseases
- Past treatment for any disease condition
- Surgical procedures
- Presence of bleeding disorders or tendencies
- Accidents requiring hospitalizations
- Blood transfusions

6. **Family Medical History**

- Presence of diabetes, cardiovascular disease, cancer, hypertension, hematologic disorders, tuberculosis, or preeclampsia-eclampsia
- Occurrence of multiple births
- History of congenital diseases or deformities
- History of mental illness
- Causes of death of deceased parents or siblings
- Occurrence of cesarean births and cause if known

7. **Religious, Spiritual, and Cultural History**

- Does the woman want to specify a religious preference on her chart? Does she have any spiritual

beliefs or practices that might influence her health-care or that of her child, such as prohibition against receiving blood products, dietary considerations, or circumcision rites?

- What practices are important to maintaining her spiritual well-being?
- Might practices in her culture or that of her partner influence her care or that of her child?

8. **Occupational History**

- Occupation
- Physical demands (Does she stand all day, or are there opportunities to sit and elevate her legs? Any heavy lifting?)
- Exposure to chemicals or other harmful substances
- Opportunity for regular meals and breaks for nutritious snacks
- Provision for maternity or family leave

9. **Partner's History**

- Presence of genetic conditions or diseases in him or in his family history, if partner is the father
- Age
- Significant health problems
- Previous or current alcohol intake, drug use, or tobacco use
- Blood type and Rh factor, if partner is the father
- Occupation
- Educational level; methods by which the partner learns best
- Attitude toward the pregnancy

10. **Personal information about the mother (social history)**

- Age
- Educational level; methods by which she learns best
- Race or ethnic group (to identify need for prenatal genetic screening and racially or ethnically related risk factors)
- Housing; stability of living conditions
- Economic level
- Acceptance of pregnancy, whether intended or unintended
- Any history of emotional or physical deprivation or abuse of herself or children or any abuse in her current relationship (Ask specifically whether she has been hit, slapped, kicked, or hurt within the past year or since she has become pregnant. Ask whether she is afraid of her partner or anyone else. If yes, of whom is she afraid? *Note:* Ask these questions when the woman is alone)
- History of emotional problems
- Support systems
- Personal preferences about the birth (expectations of both the woman and her partner, presence of others, and so on)
- Plans for care of child following birth
- Feeding preference for the baby (breast milk or formula?)

Obtaining Data

In many instances, a questionnaire is used to obtain information. The woman should complete the questionnaire in a

quiet place with a minimum of distractions. The nurse can obtain further information in an interview, which allows the pregnant woman to clarify her responses to questions and gives the nurse and the woman the opportunity to develop rapport.

The expectant father or partner can be encouraged to attend the prenatal examinations; the individual is often able to contribute to the history. The nurse should encourage partners to use the opportunity to ask questions or express concerns that are important to them.

Prenatal High-Risk Screening

Risk factors are any findings that suggest that the pregnancy may have a negative outcome, for either the woman or her unborn child. Screening for risk factors is an important part of the prenatal assessment. Many risk factors can be identified during the initial assessment; others may be detected during subsequent prenatal visits. It is important to identify high-risk pregnancies early so that appropriate interventions can be started promptly. Not all risk factors threaten a pregnancy equally; thus, many agencies use a scoring sheet to determine the degree of risk. Information must be updated throughout the pregnancy as necessary. A pregnancy may begin as low risk and change to high risk because of complications.

Obstetric History

The nurse interviews the patient regarding previous pregnancies, which affect the woman's plan of care. A woman who has experienced previous miscarriages or complications of pregnancy may require increased monitoring and a greater level of support than a woman who has already had one or more successful pregnancies without complication.

The terms *gravida* and *para* are used in relation to pregnancies, not to the number of fetuses. Thus, twins, triplets, and other multiples count as one pregnancy and one birth. Miscarriages and fetal losses before viability at 24 weeks of gestation are called fetal demise. Those before 20 weeks are called abortions.

The following examples illustrate how these terms are applied in clinical situations:

1. Jean Sanchez has one child born at 38 weeks of gestation and is pregnant for the second time. At her initial prenatal visit, the nurse indicates her obstetric history as "gravida 2 para 1 ab 0." Jean Sanchez's present pregnancy terminates at 16 weeks of gestation. She is now "gravida 2 para 1 ab 1."
2. Tracy Hopkins is pregnant for the fourth time. At home, she has a child who was born at term. Her second pregnancy ended at 10 weeks of gestation. She then gave birth to twins at 35 weeks of gestation. One of the twins died soon after birth. At her antepartum assessment, the nurse records her obstetric history as "gravida 4 para 2 ab 1."

To avoid confusion, it is best for practicing nurses to clarify the recording system used at their facilities.

A useful acronym for remembering the detailed system is **G TPAL**:

G: number of pregnancies (**G**ravida)

T: number of **T**erm babies born—that is, the number of babies born after 37 weeks of gestation

P: number of **P**reterm babies born—that is, the number of babies born after 20 weeks but before the completion of 37 weeks of gestation

A: number of pregnancies ending in either spontaneous or therapeutic **A**bstortion

L: number of currently **L**iving children

Using this approach, the nurse would have initially described Jean Sanchez (see the first example) as "gravida 2 para 1001." Following Jean's spontaneous abortion, she would be "gravida 2 para 1011." Tracy Hopkins would be described as "gravida 4 para 1212." **Figure 33-24** » illustrates this method.

SAFETY ALERT In general, it is best to avoid an initial discussion of a woman's obstetric history in front of her partner. It is possible that the woman had a previous pregnancy she has not mentioned to her partner, and revealing this information could violate her right to privacy.

Determining Due Date

Families generally want to know the "due date," or the date around which childbirth will occur. Historically, the due date has been called the estimated date of confinement (EDC). However, the concept of *confinement* is rather negative, and many caregivers avoid it by referring to the due date as the estimated date of delivery. Even then, childbirth educators often stress that babies are not "delivered" like a package; they are born. In keeping with a view that emphasizes the normalcy of the process, this text refers to the due date as the estimated date of birth (EDB).

To calculate the EDB, it is helpful to know the date of the woman's last menstrual period. However, some women have episodes of irregular bleeding or fail to keep track of menstrual cycles. Thus, other techniques also help determine how far along a woman is in her pregnancy—that is, at how many weeks of gestation she is. These techniques include evaluating uterine size, determining when quickening occurs, and auscultating FHR with a Doppler device or ultrasound and, later, with a fetoscope.

The most common method of determining the EDB is to use the **Nägele rule**. To use this method, one begins with the

Name	Gravida	Term	Preterm	Abortions	Living Children
Jean Sanchez	2	1	0	1	1
Tracy Hopkins	4	1	2	1	2

Figure 33-24 » The **G TPAL** approach provides detailed information about a woman's pregnancy history.

first day of the last menstrual period (LMP), subtracts 3 months, and adds 7 days. For example:

First day of LMP	November 21
Subtract 3 months	<u>-3 months</u>
	August 21
Add 7 days	<u>+7 days</u>
EDB	August 28

It is simpler to change the months to numeric terms:

November 21 becomes	11-21
Subtract 3 months	<u>-3</u>
	8-21
Add 7 days	<u>+7</u>
EDB	8-28

A gestation calculator or wheel permits the caregiver to calculate the EDB even more quickly (**Figure 33-25** ▶).

If a woman with a history of menses every 28 days remembers her last menstrual period and was not taking oral contraceptives before becoming pregnant, the Nägele rule may be a fairly accurate determiner of the EDB. However, ovulation usually occurs 14 days before the onset of the next menses, not 14 days after the previous menses. Consequently, if the woman's cycle is irregular or is more than 28 days long, the time of ovulation may be delayed. If she has been using oral contraceptives, ovulation may be delayed for several weeks following her last menses. Then, too, a postpartum woman who is breastfeeding may resume ovulating but be amenorrheic for a time, making calculation impossible. Thus, the Nägele rule, although helpful, is not foolproof.

Source: George Dodson/Pearson Education, Inc.

Figure 33-25 ▶ The EDB wheel can be used to calculate the due date. To use it, place the arrow labeled “1st day of last period” on the date of the woman’s last menstrual period (LMP). Then read the EDB at the arrow labeled “40.” In this case, the LMP is September 8 and the EDB is June 16.

It is important to determine the EDB as accurately as possible, as the gestational age at which many prenatal screenings are done is extremely important. The most common reason for false-positive results on aneuploidy and neural tube defect screening is inaccurate calculation of gestational age (Messerlian, Farina, & Palomaki, 2016). It is also essential for evaluating fetal growth and deciding on the timing of intervention for postterm pregnancies. The most accurate estimation of gestational age is a 7–10 week crown–rump length (CRL) measurement consistent with LMP dating. If there is a discrepancy of more than 3 days between early ultrasound and LMP, the pregnancy is dated by the ultrasound (MacKenzie, Stephenson, & Funai, 2016).

Physical Examination

The physical examination begins with assessment of vital signs; then the woman’s body is examined. The pelvic examination is performed last. Before the examination, the woman should provide a clean urine specimen. When her bladder is empty, the woman is more comfortable during the pelvic examination and the examiner can palpate the pelvic organs more easily. After the woman has emptied her bladder, the nurse asks her to disrobe and gives her a gown and sheet or some other protective covering.

Increasing numbers of nurses (e.g., CNMs and other nurses in advanced practice) are prepared to perform complete physical examinations. The nurse who does not yet possess advanced assessment skills can assess the woman’s vital signs, explain the procedures to allay apprehension, position her for examination, and assist the examiner as necessary. Each nurse is responsible for operating at the expected standard for his or her skill and knowledge base.

Thoroughness and a systematic procedure are the most important considerations when performing the physical portion of a prenatal examination. To promote completeness, the Prenatal Assessment feature is organized in three columns that address the areas to be assessed and the normal findings, the variations or alterations that may be observed and their possible causes, and nursing responses to the data. The nurse should be aware that certain organs and systems are assessed concurrently with others during the physical portion of the examination.

Uterine Assessment

Physical Examination

When a woman is examined in the first 10–12 weeks of pregnancy and her uterine size is compatible with her menstrual history, uterine size may be the single most important clinical method for dating her pregnancy. In many cases, however, women do not seek prenatal care until well into their second trimester, when it becomes more difficult to evaluate specific uterine size. In women with obesity, it is difficult to determine uterine size early in a pregnancy because the uterus is more difficult to palpate.

Fundal Height

Fundal height may be used as an indicator of uterine size, although this method is less accurate late in pregnancy. A centimeter tape measure is used to measure the distance abdominally from the top of the symphysis pubis to the top of the

Prenatal Assessment

PHYSICAL ASSESSMENT/ NORMAL FINDINGS

ALTERATIONS AND POSSIBLE CAUSES*

NURSING RESPONSES TO DATA†

Vital Signs

Blood pressure (BP): less than or equal to 140/90 mmHg	High BP (essential hypertension; renal disease; gestational hypertension, apprehension or anxiety associated with pregnancy diagnosis, exam, or other crises; preeclampsia if initial assessment not done until after 20 weeks' gestation)	BP greater than 140/90 mmHg requires immediate consideration; establish woman's BP; refer to healthcare provider if necessary. Assess woman's knowledge about high BP; counsel on self-care and medical management.
Pulse: 60–100 beats/min; rate may increase 10 beats/min during pregnancy	Increased pulse rate (excitement or anxiety, cardiac disorders)	Count for 1 full minute; note irregularities.
Respirations: 12–20 breaths/min (or pulse rate divided by 4); pregnancy may induce a degree of hyperventilation; thoracic breathing predominant	Marked tachypnea or abnormal patterns	Assess for respiratory disease.
Temperature: 36.0°–38.5°C (96.8°–101.3°F)	Elevated temperature (infection)	Assess for infection process of disease state, or ruptured membranes, if temperature is elevated; refer to healthcare provider.

Body Mass Index (BMI)

Between 18.5 and 24.9 based on prepregnant weight or weight on presentation to care if prepregnant weight is unknown	Less than 18.5 or greater than 30	Evaluate need for nutritional counseling; obtain information on eating habits, cooking practices, food regularly eaten, income limitations, need for food supplements, pica and other abnormal food habits. Note initial weight to establish baseline for weight gain throughout pregnancy.
--	-----------------------------------	---

Skin

Color: consistent with racial background; pink nail beds	Pallor (anemia); bronze, yellow (hepatic disease; other causes of jaundice) Bluish, reddish, mottled; dusky appearance or pallor of palms and nail beds in dark-skinned women (anemia)	The following tests should be performed: complete blood count (CBC), bilirubin level, urinalysis, and blood urea nitrogen (BUN). If abnormal, refer to healthcare provider.
Condition: absence of edema (slight edema of lower extremities is normal during pregnancy)	Edema (possible preeclampsia); rashes, dermatitis (allergic response)	Counsel on relief measures for slight edema. Initiate preeclampsia assessment; refer to healthcare provider.
Lesions: absence of lesions	Ulceration (varicose veins, decreased circulation)	Further assess circulatory status; refer to healthcare provider if lesion is severe.
Spider nevi common in pregnancy	Petechiae, multiple bruises, ecchymosis (hemorrhagic disorders; abuse) Change in size or color (carcinoma)	Evaluate for bleeding or clotting disorder. Provide opportunities to discuss abuse if suspected. Refer to healthcare provider.
Pigmentation: pigmentation changes of pregnancy include linea nigra, striae gravidarum, melasma		Assure woman that these are normal manifestations of pregnancy and explain the physiologic basis for the changes.
Café-au-lait spots	Six or more (Albright syndrome or neurofibromatosis)	Consult with healthcare provider.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

(continued on next page)

Prenatal Assessment *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS

ALTERATIONS AND POSSIBLE CAUSES*

NURSING RESPONSES TO DATA†

Nose

Character of mucosa: redder than oral mucosa; in pregnancy, nasal mucosa is edematous in response to increased estrogen, resulting in nasal stuffiness (rhinitis of pregnancy) and nosebleeds (epistaxis)

Olfactory loss (first cranial nerve deficit)

Counsel woman about possible relief measures for nasal stuffiness and nosebleeds; refer to healthcare provider for olfactory loss.

Mouth

May note hypertrophy of gingival tissue because of estrogen

Edema, inflammation (infection); pale in color (anemia)

Assess hematocrit for anemia; counsel regarding dental hygiene habits. Refer to healthcare provider or dentist if necessary. Routine dental care is appropriate during pregnancy (no epinephrine, no nitrous anesthesia). Dental x-rays can be done during the second trimester if needed.

Neck

Nodes: small, mobile, nontender nodes

Tender, hard, fixed, or prominent nodes (infection, carcinoma)

Examine for local infection; refer to healthcare provider.

Thyroid: small, smooth, lateral lobes palpable on either side of trachea; slight hyperplasia by third month of pregnancy

Enlargement or nodule tenderness (hyperthyroidism)

Listen over thyroid for bruits, which may indicate hyperthyroidism. Question woman about dietary habits (iodine intake). Ascertain history of thyroid problems; refer to healthcare provider.

Chest and Lungs

Chest: symmetric, elliptic, smaller AP than transverse diameter

Increased AP diameter, funnel chest, pigeon chest (emphysema, asthma, chronic obstructive pulmonary disease [COPD])

Evaluate for emphysema, asthma, COPD.

Ribs: slope downward from nipple line

More horizontal (COPD) angular bumps (rachitic rosary) (vitamin C deficiency)

Evaluate for COPD. Evaluate for fractures. Consult healthcare provider. Consult nutritionist.

Inspection and palpation: no retraction or bulging of intercostal spaces (ICS) during inspiration or expiration; symmetric expansion

ICS retractions with inspirations, bulging with expiration; unequal expansion (respiratory disease)

Do thorough initial assessment. Refer to healthcare provider.

Tactile fremitus

Tachypnea, hyperpnea, Cheyne-Stokes respirations (respiratory disease)

Refer to healthcare provider.

Percussion: bilateral symmetry in tone

Flatness of percussion, which may be affected by chest wall thickness

Evaluate for pleural effusions, consolidations, or tumor.

Low-pitched resonance of moderate intensity

High diaphragm (atelectasis or paralysis), pleural effusion

Refer to healthcare provider.

Auscultation: upper lobes: bronchovesicular sounds above sternum and scapulas; equal expiratory and inspiratory phases

Abnormal if heard over any other area of chest

Refer to healthcare provider.

Remainder of chest: vesicular breath sounds heard; inspiratory phase longer (3:1)

Rales, rhonchi, wheezes; pleural friction rub; absence of breath sounds; bronchophony, egophony, whispered pectoriloquy

Refer to healthcare provider.

*Possible causes of alterations are identified in parentheses.

†This column provides guidelines for further assessment and initial nursing intervention.

Prenatal Assessment *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS

ALTERATIONS AND POSSIBLE CAUSES*

NURSING RESPONSES TO DATA†

Breasts

Supple: symmetric in size and contour; darker pigmentation of nipple and areola; may have supernumerary nipples.
Axillary nodes unpalpable or pellet-sized

“Pigskin” or orange-peel appearance, nipple retractions, swelling, hardness (carcinoma); redness, heat, tenderness, cracked or fissured nipple (infection)
Tenderness, enlargement, hard node (carcinoma); may be visible bump (infection)

Encourage monthly self-examination; instruct woman how to examine her breasts.
Refer to healthcare provider if evidence of inflammation.

Pregnancy changes:

1. Size increase noted primarily in first 20 weeks.
2. Become nodular.
3. Tingling sensation may be felt during first and third trimester; woman may report feeling of heaviness.
4. Pigmentation of nipples and areolae darkens.
5. Superficial veins dilate and become more prominent.
6. Striae seen in multiparas.
7. Tubercles of Montgomery enlarge.
8. Colostrum may be present after 12th week.
9. Secondary areola appears at 20 weeks, characterized by series of washed-out spots surrounding primary areola.
10. Breasts less firm, old striae may be present in multiparas.

Discuss normalcy of changes and their meaning. Teach and/or institute appropriate relief measures. Encourage use of supportive, well-fitting brassiere.

Heart

Normal rate, rhythm, and heart sounds

Enlargement, thrills, thrusts, gross irregularity or skipped beats, gallop rhythm or extra sounds (cardiac disease)

Complete an initial assessment. Explain normal pregnancy-induced changes.
Refer to healthcare provider if indicated.

Pregnancy changes:

1. Palpitations may occur due to sympathetic nervous system disturbance
2. Short systolic murmurs that increase in held expiration are normal due to increased volume

Abdomen

Normal appearance, skin texture, and hair distribution; liver nonpalpable; abdomen nontender

Muscle guarding (anxiety, acute tenderness); tenderness, mass (ectopic pregnancy, inflammation, carcinoma)

Assure woman of normalcy of diastasis. Provide initial information about appropriate prenatal and postpartum exercises. Evaluate woman's anxiety level. Refer to healthcare provider if indicated.

*Possible causes of alterations are identified in parentheses.

†This column provides guidelines for further assessment and initial nursing intervention.

(continued on next page)

Prenatal Assessment *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
<p>Pregnancy changes:</p> <ol style="list-style-type: none"> 1. Purple striae may be present (or silver striae on a multipara) as well as linea nigra. 2. Diastasis of the rectus muscles late in pregnancy. 3. Size: flat or rotund abdomen; progressive enlargement of uterus due to pregnancy. 10–12 weeks: fundus slightly above symphysis pubis. 16 weeks: fundus halfway between symphysis and umbilicus. 20–22 weeks: fundus at umbilicus. 28 weeks: fundus three finger breadths above umbilicus. 36 weeks: fundus just below ensiform cartilage. 4. Fetal heart rate: 110–160 beats/min may be heard with Doppler at 10–12 weeks' gestation; may be heard with fetoscope at 17–20 weeks. 5. Fetal movement palpable by a trained examiner after 18th week. 6. Ballottement: during fourth to fifth month, fetus rises and then rebounds to original position when uterus is tapped sharply. 	<p>Size of uterus inconsistent with length of gestation (IUGR, multiple pregnancy, fetal demise, hydatidiform mole, polyhydramnios, inaccurate dating)</p> <p>Failure to hear fetal heartbeat with Doppler (fetal demise, hydatidiform mole)</p> <p>Failure to feel fetal movements after 20 weeks' gestation (fetal demise, hydatidiform mole)</p> <p>No ballottement (oligohydramnios)</p>	<p>Reassess menstrual history regarding pregnancy dating. Use ultrasound to establish diagnosis.</p> <p>Refer to healthcare provider. Administer pregnancy tests. Use ultrasound to establish diagnosis.</p> <p>Refer to healthcare provider for evaluation of fetal status. Refer to healthcare provider for evaluation of fetal status.</p>
Extremities		
Skin warm, pulses palpable, full range of motion; may be some edema of hands and ankles in late pregnancy; varicose veins may become more pronounced; palmar erythema may be present	Unpalpable or diminished pulses (arterial insufficiency); marked edema (preeclampsia)	Evaluate for other symptoms of heart disease; initiate follow-up if woman mentions that her rings feel tight. Discuss prevention and self-treatment measures for varicose veins; refer to healthcare provider if indicated.
Spine		
Normal spinal curves: concave cervical, convex thoracic, concave lumbar	Abnormal spinal curves; flatness, kyphosis, lordosis	Refer to healthcare provider for assessment of cephalopelvic disproportion.
In pregnancy, lumbar spinal curve may be accentuated	Backache	May have implications for administration of spinal anesthetics.
Shoulders and iliac crests should be even	Uneven shoulders and iliac crests (scoliosis)	Refer very young women to healthcare provider; discuss back-stretching exercise with older women.
Reflexes		
Normal and symmetric	Hyperactivity, clonus (preeclampsia)	Evaluate for other symptoms of preeclampsia.
Pelvic Area		
External female genitals: normally formed with female hair distribution; in multiparas, labia majora loose and pigmented; urinary and vaginal orifices visible and appropriately located	Lesions, hematomas, varicosities, inflammation of the Bartholin glands; clitoral hypertrophy	Explain pelvic examination procedure. Encourage woman to minimize her discomfort by relaxing her hips. Provide privacy.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

Prenatal Assessment *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
Vagina: pink or dark pink, vaginal discharge odorless, nonirritating; in multiparas, vaginal folds smooth and flattened; may have episiotomy scar	Abnormal discharge associated with vaginal infections	Obtain vaginal smear. Provide understandable verbal and written instructions about treatment for woman and partner if indicated.
Cervix: pink color; os closed except in multiparas, in whom os admits fingertip	Eversion, reddish erosion, nabothian or retention cysts, cervical polyp; granular area that bleeds (carcinoma of cervix); lesions (herpes, human papilloma virus [HPV]); presence of string or plastic tip from cervix (intrauterine device [IUD] in uterus)	Provide woman with a hand mirror and identify genital structures for her; encourage her to view her cervix if she wishes. Refer to healthcare provider if indicated. Advise woman of potential serious risks of leaving an IUD in place during pregnancy; refer to healthcare provider for removal.
Pregnancy changes: <i>1–4 weeks' gestation:</i> enlargement in AP diameter <i>4–6 weeks' gestation:</i> softening of cervix (Goodell sign); softening of isthmus of uterus (Hegar sign); cervix takes on bluish coloring (Chadwick sign) <i>8–12 weeks' gestation:</i> vagina and cervix appear bluish violet in color (Chadwick sign) Uterus: pear-shaped, mobile; smooth surface	Absence of Goodell sign (inflammatory conditions, carcinoma) Fixed (pelvic inflammatory disease [PID]); nodular surface (fibromas)	Refer to healthcare provider. Refer to healthcare provider.
Ovaries: small, walnut-shaped, nontender (ovaries and fallopian tubes are located in adnexal areas)	Pain on movement of cervix (PID); enlarged or nodular ovaries (cyst, tumor, tubal pregnancy, corpus luteum of pregnancy)	Evaluate adnexal areas; refer to healthcare provider.

Pelvic Measurements

Internal measurements: 1. Diagonal conjugate is at least 11.5 cm. 2. Obstetric conjugate is estimated by subtracting 1.5–2.0 cm from diagonal conjugate. 3. Inclination of sacrum. 4. Motility of coccyx; external intertubular diameter is greater than 8 cm.	Measurement below normal Disproportion of pubic arch Abnormal curvature of sacrum Fixed or malposition of coccyx	May be considered as a factor in protraction or arrest of labor.
--	---	--

Anus and Rectum

No lumps, rashes, excoriation, tenderness; cervix may be felt through rectal wall	Hemorrhoids, rectal prolapse; nodular lesion (carcinoma)	Counsel about appropriate prevention and relief measures; refer to healthcare provider for further evaluation.
---	--	--

Laboratory Evaluation

Hemoglobin: 12–16 g/dL; women residing in areas of high altitude may have higher levels of hemoglobin	Less than 11 g/dL (anemia)	<i>Note:</i> Wear nonlatex gloves when drawing blood. Hemoglobin less than 12 g/dL requires nutritional counseling; less than 11 g/dL requires iron supplementation.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

(continued on next page)

Prenatal Assessment *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
ABO and Rh typing: normal distribution of blood types	Rh negative	If Rh negative, check for presence of anti-Rh antibodies. Discuss the need for measurement of antibody titers during pregnancy, management during the intrapartum period, and possible need for Rh immune globulin. Determine the father's Rh status if possible.
CBC: Hematocrit: 38–47% physiologic anemia (pseudoanemia) may occur	Marked anemia or blood dyscrasias	Perform CBC and Schilling differential cell count. Consider iron studies and hemoglobin electrophoresis
RBCs: 4.2–5.4 million/microliter		
White blood cells (WBCs): 5000–12,000/microliter	Presence of infection; may be elevated in pregnancy and with labor	Evaluate for other signs of infection.
Differential Neutrophils: 40–60% Bands: up to 5% Eosinophils: 1–3% Basophils: up to 1% Lymphocytes: 20–40% Monocytes: 4–8%		
Syphilis tests: serologic tests for syphilis (STS), complement fixation test, Venereal Disease Research Laboratory (VDRL) test—nonreactive	Positive reaction STS—tests may have 25–45% incidence of biologic false-positive results; false results may occur in individuals who have acute viral or bacterial infections, hypersensitivity reactions, recent vaccinations, collagen disease, malaria, or tuberculosis	Positive results may be confirmed with the fluorescent treponemal antibody-absorption (FTA-ABS) test; all tests for syphilis give positive results in the secondary stage of the disease; antibiotic tests may cause negative test results.
First trimester integrated screen	Abnormal fetal nasal bone and/or nuchal fold on ultrasound combined with abnormal lab values as the quad screen.	Offered to all pregnant women at the gestational age appropriate for each test. If abnormal, further testing such as ultrasound or amniocentesis is offered.
Noninvasive prenatal testing (NIPT)/cell-free fetal DNA (cffDNA)	Detection of abnormal fetal alleles in maternal serum	Refer to healthcare provider
Quad screen (Evaluates four factors—maternal serum alpha-fetoprotein [MSAFP], unconjugated estriol [UE], human chorionic gonadotropin [hCG], and inhibin-A: normal levels)	Elevated MSAFP (neural tube defect, underestimated gestational age, multiple gestation). Lower than normal MSAFP (Down syndrome, trisomy 18). Higher than normal hCG and inhibin-A (Down syndrome). Lower than normal UE (Down syndrome)	Refer to healthcare provider for possible amniocentesis.
Indirect Coombs Test: done on all pregnant women at the initial prenatal visit and repeated at 28 weeks for Rh negative women	Red blood cell (RBC) antibodies present (either Rhesus or non-Rhesus)	A number of RBC antigens may cause isoimmunization and fetal and newborn hemolytic disease. The most common of these is the D antigen, which may occur when an Rh-negative mother carries an Rh-positive fetus. This may be prevented through prenatal administration of Rh immune globulin (RhoGAM).
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

Prenatal Assessment *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
Screening for Group B Streptococcus (GBS): Rectal and vaginal swabs obtained at 35–37 weeks' gestation for all pregnant women	Positive culture (maternal colonization)	Antibiotics administered during labor for infection prophylaxis in the neonate.
Glucose Tolerance Test: 50-g 1-hour glucose screen (done between 24 and 28 weeks' gestation)	Plasma glucose level greater than 130–140 mg/dL is considered abnormal, depending on provider preference. Be aware of your institution's guidelines.	Refer for a diagnostic 3-hour glucose tolerance test.
Urinalysis: normal color; specific gravity; pH 4.6–8.0	Abnormal color (porphyria, hemoglobinuria, bilirubinemia); alkaline urine (metabolic alkalemia, <i>Proteus</i> infection, old specimen)	Repeat urinalysis; refer to healthcare provider.
Urinalysis: negative for protein, RBCs, WBCs, casts	Positive findings (contaminated specimen, kidney disease)	Repeat urinalysis; refer to healthcare provider.
Urinalysis: glucose: negative (a small degree of glycosuria may occur in pregnancy)	Glycosuria (physiologic secondary to increased glomerular filtration of pregnancy for glucose, diabetes mellitus)	Assess blood glucose level; test urine for ketones.
Rubella titer: hemagglutination-inhibition (HAI) test — 1:10 or above indicates woman is immune	HAI titer less than 1:10	Immunization will be given postpartum or within 6 weeks after childbirth. Instruct woman whose titers are less than 1:10 to avoid children who have rubella.
Hepatitis B screen for hepatitis B surface antigen (HbsAg): negative	Positive	If negative, consider referral for hepatitis B vaccine postpartum. If positive, refer to physician. Babies born to women who test positive are given hepatitis B immune globulin soon after birth, followed by first dose of hepatitis B vaccine.
HIV screen: offered to all women; encouraged for those at risk; negative	Positive	Refer to healthcare provider.
Illicit drug screen: offered to all women; negative	Positive	Refer to healthcare provider.
Hemoglobin screen for patients of African, Mediterranean, or south Asian descent: negative	Positive; test results would include a description of cells	Refer to healthcare provider.
Pap smear: negative	Test results that show atypical cells	Refer to healthcare provider. Discuss with the woman the meaning of the findings and the importance of follow-up.
Gonorrhea culture: negative	Positive	Refer for treatment.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

(continued on next page)

Prenatal Assessment *(continued)*

CULTURAL ASSESSMENT [§]	VARIATIONS TO CONSIDER	NURSING RESPONSE TO DATA ^{§§}
Determine the woman's fluency in written and oral English	Woman may be fluent in language other than English	Work with a knowledgeable translator to provide information and answer questions.
Ask the woman how she prefers to be addressed	Some women prefer informality; others prefer to use titles	Address the woman according to her preference. Maintain formality in introducing oneself if that seems preferred.
Determine customs and practices regarding prenatal care:	Practices are influenced by individual preference, cultural expectations, or religious beliefs	Honor a woman's practices and provide for specific preferences unless they are contraindicated for safety reasons.
■ Ask the woman if there are certain practices she expects to follow when she is pregnant	Some women believe they should perform certain acts related to sleep, activity, or clothing	Have information printed in the language of different cultural groups that live in the area.
■ Ask the woman if there are any activities she cannot do while she is pregnant	Some women have restrictions or taboos they follow related to work, activity, sexual, environmental, or emotional factors	Provide alternate activities if needed.
■ Ask the woman whether there are certain foods she is expected to eat or avoid while she is pregnant. Determine whether she has lactose intolerance	Foods are an important cultural factor. Some women may have certain foods they must eat or avoid; many women have lactose intolerance and have difficulty consuming sufficient calcium	Respect the woman's food preferences, help her plan an adequate prenatal diet within the framework of her preferences, and refer to a dietitian if necessary.
■ Ask the woman whether the gender of her caregiver is of concern	Some women are comfortable only with a female caregiver	Arrange for a female caregiver if it is the woman's preference.
■ Ask the woman about the degree of involvement in her pregnancy that she expects or wants from her support person, mother, and other significant people	A woman may not want her partner involved in the pregnancy. The role may fall to the woman's mother or a female relative or friend	Respect the woman's preferences about her partner's involvement; avoid imposing personal values or expectations.
■ Ask the woman about her sources of support and counseling during pregnancy	Some women seek advice from a family member or traditional healer	Respect and honor the woman's sources of support.
Psychologic Status		
Excitement and/or apprehension, ambivalence	Marked anxiety (fear of pregnancy diagnosis, fear of medical facility)	Establish lines of communication. Active listening is useful. Establish trusting relationship. Encourage woman to take active part in her care.
	Apathy; display of anger with pregnancy diagnosis	Establish communication and begin counseling. Use active listening techniques.
Educational Needs		
May have questions about pregnancy or may need time to adjust to reality of pregnancy		Establish educational, supporting environment that can be expanded throughout pregnancy.
Support System		
Can identify at least two or three individuals with whom she is emotionally intimate (partner, parent, sibling, friend)	Isolated (no telephone, unlisted number); cannot name a neighbor or friend whom she can call on in an emergency; does not perceive parents as part of her support system	Institute support system through community groups. Help woman to develop trusting relationship with healthcare professionals.
[§] These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.		^{§§} This column provides guidelines for further assessment and initial nursing intervention.

Prenatal Assessment *(continued)*

CULTURAL ASSESSMENT[§]

VARIATIONS TO CONSIDER

NURSING RESPONSE TO DATA^{§§}

Family Functioning

Emotionally supportive
Adequate communication
Mutually satisfying
Cohesiveness in times of trouble

Long-term problems or specific problems related to this pregnancy, potential stressors within the family, pessimistic attitudes, unilateral decision making, unrealistic expectations of this pregnancy or child

Help identify the problems and stressors, encourage communication, and discuss role changes and adaptations.

Economic Status

Source of income is stable and sufficient to meet basic needs of daily living and medical needs

Limited prenatal care; poor physical health; limited use of healthcare system; unstable economic status

Discuss available resources for health maintenance and the birth. Institute appropriate referral for meeting expanding family's needs (e.g., food stamps).

Stability of Living Conditions

Adequate, stable housing for expanding family's needs

Crowded living conditions; questionable supportive environment for newborn

Refer to appropriate community agency. Work with family on self-help ways to improve situation.

[§]These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.

^{§§}This column provides guidelines for further assessment and initial nursing intervention.

uterine fundus (the McDonald method) (**Figure 33-26** ). Fundal height in centimeters correlates well with weeks of gestation after 20 weeks. The normal variation is gestational weeks plus or minus 2 cm. Thus, at 26 weeks' gestation, fundal height is 24–28 cm depending on fetal position and maternal body habitus. The woman should have voided within 30 minutes of the exam and should lie in the same

position each time. In the third trimester, variations in fetal weight decrease the accuracy of fundal height measurements. A lag in progression of measurements of fundal height from month to month and from week to week may signal a fetus that is small for gestational age (SGA). A sudden increase in fundal height may indicate twins or hydramnios.

Small for gestational age is defined as a fetal weight estimated by ultrasound or a baby's actual birth weight that is less than the 10th percentile for gestational age. When no cause for this can be identified and the fetus or newborn shows no evidence of compromise, it may be concluded that it is constitutionally small. When a fetus is SGA in the setting of some pathology, this is called *intrauterine growth restriction (IUGR)*. Causes include congenital anomalies, exposure to teratogens, maternal smoking and substance abuse, malnutrition, abnormal formation of the placenta, and decreased placental perfusion (King et al., 2013).

Leopold Maneuvers

Leopold maneuvers are a system of palpating the uterus externally, starting at the fundus and moving downward, to assess the baby's position and orientation. In the first maneuver, the examiner grips the fundus with both hands and identifies the fetal parts in the fundus. The second maneuver consists of palpating the sides of the uterus to locate the fetal back and legs. The third maneuver consists of grasping the lower portion of the uterus to identify the fetal part that is lowest in the pelvis, called the presenting part. It should be the head in the third trimester. The fourth maneuver consists of identifying the position of the fetal brow or occiput to determine the degree of flexion or extension of the head (Gabbe et al., 2012).

Figure 33-26  A cross-sectional view of fetal position when the McDonald method is used to assess the fundal height.

Assessment of Fetal Development

Fetal assessment occurs at various points in gestation to determine fetal development and well-being. Methods include subjective and objective findings, such as fetal movement, fetal heartbeat, and ultrasound. Healthcare providers compare findings to gestational age and expected developmental milestones. Providers use findings to develop a plan of care to promote positive pregnancy outcomes.

Quickening

The first perception of fetal movement by the mother is termed quickening. Quickening may indicate that the fetus is nearing 20 weeks' gestation. However, quickening may be experienced between 16 and 22 weeks' gestation, so this method is not completely accurate.

Fetal Heartbeat

An ultrasonic Doppler device (**Figure 33-27** ») is the primary tool for assessing fetal heartbeat. It can detect fetal heartbeat, on average, at 8–12 weeks' gestation. If such a device is not available, a fetoscope may be used, although in current practice it is seldom necessary. The fetal heartbeat can be detected by fetoscope as early as week 16 and usually by 19 or 20 weeks' gestation.

Ultrasound

In the first trimester, ultrasound scanning can detect a gestational sac as early as 5–6 weeks after the LMP, fetal heart activity by 6–7 weeks, and fetal breathing movement by 10–11 weeks of pregnancy. Crown-to-rump measurements can be made to assess fetal age until the fetal head can be visualized clearly. Biparietal diameter (BPD) can then be used. The BPD measures the diameter across the fetus's skull from one parietal bone to the other. BPD measurements can be made by approximately 12–13 weeks and are most accurate between 20 and 30 weeks, when rapid growth in the BPD occurs. Measurements and visualization of structures in the fetal body are used to determine appropriate growth, development, and function.

Figure 33-27 » Listening to the fetal heartbeat with a Doppler device.

Assessment of Pelvic Adequacy (Clinical Pelvimetry)

The pelvis can be assessed vaginally by a process called *clinical pelvimetry*. It is performed by physicians or by advanced practice nurses such as CNMs or nurse practitioners. Some caregivers assess the pelvis as part of the initial physical examination. Others wait until later in the pregnancy, when hormonal effects are greatest and it is possible to make some determination of fetal size. However, pelvic adequacy can be reliably determined only by a trial of labor. Both radiographic and physical assessments of pelvic adequacy are poor predictors of the course of labor and birth.

Prenatal Tests

A number of tests may be used to detect hCG during pregnancy. In addition, a number of diagnostic and screening tests allow healthcare professionals (and the pregnant woman) to monitor the safety of both mother and child. These tests are summarized in **Table 33-1** »; some of them are discussed in greater detail in Exemplar 33.A.

Nursing care for the woman who is undergoing prenatal testing focuses on outcomes to ensure that she understands the reasons for the test, understands the test results, and has support during the test. In addition, other objectives include completing the tests without complication and ensuring that the safety of the mother and her unborn child has been maintained.

Case Study » Part 2

When Mrs. Halleck returns to the clinic at 32 weeks' gestation, she says, "I feel like I need to pee all the time." Mrs. Halleck also states that she doesn't feel like exercising as much as she used to. She used to go to the gym three or four times a week, but now she only goes on the weekend, saying "I just don't feel like it. I keep getting these dull headaches, and all I seem to be able to do is sit on the sofa and eat and go to the bathroom." On examination, Mrs. Halleck has gained 12 pounds since her last appointment and her current weight is 150 lb. Her vital signs are T_O 98.6°F, BP 139/90 mmHg, P 84 beats/min, R 21/min. Otherwise her examination is normal. When the nurse asks Mrs. Halleck how her family has responded to her pregnancy, Mrs. Halleck replies, "Everyone's been great except my mother. She's only 45. She says she's too young to have a grandchild, and that I'm too young to have a baby." Mrs. Halleck looks away as she says this, adding, "I really wish I had her support."

Clinical Reasoning Questions Level I

1. How should the nurse respond to Mrs. Halleck's statements about her mother?
2. What interventions can the nurse recommend to help Mrs. Halleck with her nausea?
3. What interventions can the nurse recommend to Mrs. Halleck in response to her complaint about urinary frequency?

Clinical Reasoning Questions Level II

4. Which findings should concern the nurse caring for Mrs. Halleck?
5. Referring to Exemplar 16.H, *Hypertensive Disorders in Pregnancy*: What other signs and symptoms of preeclampsia should the nurse assess in Mrs. Halleck?
6. Referring to Exemplar 16.H, *Hypertensive Disorders in Pregnancy*: What clinical therapies would be appropriate for Mrs. Halleck if the nurse observes edema in her extremities in addition to her high blood pressure?

TABLE 33–1 Summary of Selected Antenatal Surveillance and Screening

Goal	Test	Timing
To confirm intrauterine pregnancy and viability	Ultrasound: gestational sac volume	5 or 6 weeks after LMP by transvaginal ultrasound
To determine gestational age	Ultrasound: crown/rump length	6–10 weeks' gestation
	Ultrasound: BPD and fetal body measurement ratios	Greater than or equal to 14 weeks
To evaluate fetal growth	Ultrasound: BPD	
	Ultrasound: fetal body measurement ratios	Greater than or equal to 14 weeks
	Ultrasound: estimated fetal weight	About 23–42 weeks' gestation
To detect congenital anomalies and problems	Nuchal translucency testing	11–13 weeks' gestation
	Ultrasound	Greater than or equal to 18 weeks
	Chorionic villus sampling	10–12 weeks' gestation
	Amniocentesis	After 15 weeks' gestation
	First trimester integrated screen	10–13 weeks' gestation
	Cell-free fetal DNA (cffDNA)	From 9 weeks onward
To determine placental location	Ultrasound	18–20 weeks initially. Repeated at 28–32 weeks for re-evaluation if needed
To assess fetal status	Biophysical profile	Approximately 23 weeks to birth
	Maternal assessment of fetal activity	Approximately 28 weeks to birth
	Nonstress test	Approximately 28 weeks to birth
To diagnose cardiac problems	Fetal echocardiography	Second and third trimesters
To assess fetal lung maturity with amniocentesis or vaginal pool sampled amniotic fluid	L/S ratio	32–39 weeks
	Phosphatidylglycerol	32–39 weeks
	Phosphatidylcholine	32–39 weeks
	Lamellar body counts	32–39 weeks
To determine fetal presentation	Ultrasound	At term or on admission for labor and birth

Source: LONDON, MARCIA L; LADEWIG, PATRICIA W; DAVIDSON, MICHELE; BALL, JANE W; BINDLER, RUTH C; COWEN, KAY, MATERNAL & CHILD NURSING CARE, 5th Ed., ©2017. Reprinted and Electronically reproduced by permission of Pearson Education, Inc., New York, NY.

Independent Interventions

Caring interventions for the pregnant woman are focused on teaching the patient appropriate self-care techniques, especially with regard to protecting the fetus and relieving discomfort. Many of these interventions are discussed in Exemplars 33.A and 33.B on antepartum and intrapartum care, respectively. Those that are covered here are related to fetal safety and to some of the most common discomforts experienced by the pregnant woman.

It is important to recognize that pregnancy is usually a normal process that ends with the delivery of a healthy newborn. The nurse's role in these cases is health promotion and patient teaching. However, alterations can result in injury to either the fetus or the woman or both. The nurse assesses patients at each encounter in order to rapidly intervene, to minimize complications, and promote expected outcomes. Holistic, culturally appropriate care is important to make the experience as positive as possible for the woman and her family.

Prenatal Education

Prenatal education programs provide important opportunities to share information about pregnancy and childbirth

and to enhance the parents' decision-making skills. The content of each class is generally directed by the overall goals of the program. For example, in classes that aim to provide pre-conceptional information, preparations for becoming pregnant and optimizing the woman's health status are the major topics. Other classes may be directed toward childbirth choices available today, preparation of the mother and her partner for pregnancy and birth, preparation for a vaginal birth after a previous cesarean (VBAC) birth, and preparation for the birth by specific people such as grandparents or siblings. The nurse who knows the types of prenatal programs available in the community can direct expectant parents to programs that meet their special needs and learning goals.

From the expectant parents' point of view, class content is best presented in chronology with the pregnancy. It is important to begin the classes by finding out what each parent wants to learn and including a discussion of related choices. Classes that provide an environment supportive of practicing newly learned techniques and the freedom to ask questions and receive explanations are beneficial in helping class participants obtain these goals (Davidson et al., 2017).

Relief of the Common Discomforts of Pregnancy

The common discomforts of pregnancy result from physiologic and anatomic changes and are fairly specific to each of the three trimesters. See Table 33–2 in Exemplar 33.A for a summary of the common discomforts of pregnancy, their possible causes, and the self-care measures that might relieve discomfort. Health professionals often refer to these discomforts as minor, but they are not minor to the pregnant woman. They can make her quite uncomfortable and, if they are unexpected, anxious.

Nausea and Vomiting

Nausea and vomiting are early, very common symptoms occurring in up to 80% of pregnant women (Fantasia, 2014). These symptoms appear sometime after the first missed menstrual period and usually cease by the fourth missed menstrual period. Some women develop an aversion to specific foods, many experience nausea on arising in the morning, and others experience nausea throughout the day or in the evening.

The exact cause of nausea and vomiting in pregnancy (NVP) is unknown, but it is thought to be multifactorial. An elevated hCG level is believed to be a major factor, but changes in carbohydrate metabolism, fatigue, and emotional factors also may play a role. Research suggests that pregnant women should start taking a multivitamin before reaching 6 weeks' gestation to reduce the effects of NVP (ACOG, 2015a).

In addition to the self-care measures identified in Table 33–2, certain complementary therapies may be useful. For example, many women find that acupressure applied to pressure points in the wrists is helpful. Ginger also may relieve NVP (see Focus on Integrative Health: Ginger for Morning Sickness). Pyridoxine (vitamin B₆) or vitamin B₆ plus doxylamine (Unisom), an OTC antihistamine, is considered a first-line treatment. This is now available by prescription as a combined tablet under the brand name Diclegis. Antihistamine H₁-receptor blockers, phenothiazines, and antinausea medications such as promethazine (Phenergan), metoclopramide (Reglan), and ondansetron (Zofran) are considered safe and effective for treating refractory cases. In severe cases, methylprednisolone, a steroid, may be used, but as a last resort because it poses a potential risk to the fetus (ACOG, 2015a).

Focus on Integrative Health Ginger for Morning Sickness

Women who experience NVP often try alternative approaches to relieve their symptoms because they are reluctant to take medication for fear of harming their fetus. Ginger has long been used as a traditional remedy for treating nausea and vomiting associated with early pregnancy (Tiran, 2012). It has few side effects when taken in small doses (National Center for Complementary and Integrative Health [NCCIH], 2012). Ginger is available in a variety of forms, including the fresh root, capsules, tea, candy, cookies, crystals, inhaled powdered ginger, and sugared ginger.

The nurse should advise a woman to contact her health-care provider if she vomits more than once a day or shows signs of dehydration such as dry mouth and concentrated urine. In such cases, the healthcare provider might order an antiemetic such as promethazine (Phenergan).

Urinary Frequency

Urinary frequency, a common discomfort of pregnancy, occurs early in pregnancy and again during the third trimester because of pressure of the enlarging uterus on the bladder. Although frequency is considered normal during the first and third trimesters, the woman is advised to report to her healthcare provider signs of bladder infection such as pain, burning with voiding, or blood in the urine. Fluid intake should never be decreased to prevent frequency. The woman needs to maintain an adequate fluid intake—at least 2000 mL (eight to ten 8-oz glasses) per day. The nurse should also encourage her to empty her bladder frequently (about every 2 hours while awake).

Backache

Nearly 70% of women experience backache during pregnancy (King et al., 2013). Backache is due primarily to exaggeration of the lumbosacral curve that occurs as the uterus enlarges and becomes heavier. Maintaining good posture and using proper body mechanics throughout pregnancy can help prevent backache. The pregnant woman is advised to avoid bending over at the waist to pick up objects and should bend from the knees instead. She should place her feet 12–18 inches apart to maintain body balance. If the woman uses work surfaces that require her to bend, the nurse can advise her to adjust the height of the surfaces.

Collaborative Therapies

According to the American Association of Colleges of Nursing (AACN, 2016), “Collaboration emanates from an understanding and appreciation of the roles and contributions that each discipline brings to the care delivery experience.” A diversity of disciplines, as well as treatment team members, enhances care by broadening available expertise and innovative ideas.

Members of the interprofessional team collaborate to coordinate high-quality, safe, and evidence-based care. Team members may include perinatologists, neonatologists, certified nurse-midwives, women's health practitioners, obstetricians, pediatricians, dietitians, social workers, mental healthcare providers, pharmacists, endocrinologists, cardiologists, lactation consultants, and registered nurses.

Pharmacologic Therapy

A number of pharmacologic therapies may be safely used to protect the health and safety of the mother and fetus. A pregnant woman who lives with chronic illness or disease needs to discuss the treatment of her illness during her pregnancy with both her obstetrician and her treating physician. The nurse's responsibility is to elicit information about any preexisting illness when obtaining the patient's health history. Particular consideration should be given to women with existing respiratory or cardiac

disease, diabetes mellitus, or HIV. Pregnant women living with a chronic disease require additional teaching regarding management of their disease during pregnancy. Collaboration among all of the healthcare professionals working with these patients is essential to promoting patient self-care and fetal well-being.

Medications

The use of medications during pregnancy, including prescriptions, OTC drugs, and herbal remedies, is of great concern because maternal drug exposure is associated with birth defects. Many pregnant women need medication for therapeutic purposes, such as the treatment of infections, allergies, or other pathologic processes. In these situations, the problem can be complex. Known teratogenic agents are not prescribed and usually can be replaced with medications that are considered safe. Even when a woman is highly motivated to avoid taking any medications, she may have taken potentially teratogenic medications before her pregnancy was confirmed, especially if she has an irregular menstrual cycle.

The greatest potential for gross abnormalities in the fetus occurs during the first trimester of pregnancy, when fetal organs are first developing. Many factors influence teratogenic effects, including the specific type of teratogen and the dose, the stage of embryonic development, and the genetic sensitivity of the mother and fetus. For example, the commonly prescribed acne medication isotretinoin (Accutane) is associated with a high incidence of spontaneous abortion and congenital malformations if taken early in pregnancy.

To provide information for caregivers and patients, the FDA has developed a labeling system for medications administered during pregnancy. Medications were previously listed under a five-category system (Categories A, B, C, D, and X) to assist patients and caregivers to make informed decisions about the safety of medication to treat conditions during pregnancy. In 2014, the FDA amended its regulations governing the labeling to prescription drugs and biologic products for women who are pregnant or lactating. These regulations became effective in June 2015. According to the new requirements, three categories have been specified (U.S. Food and Drug Administration [FDA], 2014):

- **Pregnancy.** If the drug is absorbed systemically, labeling must include a risk summary of adverse developmental outcomes that includes data from all relevant sources, including human, animal, and/or pharmacologic information. The labeling must also contain relevant information to help healthcare providers counsel women about the use of the drug during pregnancy. In addition, if there is a pregnancy exposure registry for the drug, the labeling should include a specific statement to that effect followed by contact information needed to obtain information about the registry or to enroll.
- **Lactation.** For drugs that are absorbed systemically, labeling must include a summary of the risks of using a drug when the woman is lactating. To the extent that information is available, the summary should include relevant information about the drug's presence in human

milk, the effects of the drug on milk production, and the effects of the drug on the breastfed child.

- **Females and Males of Reproductive Potential.** This section must include information when human or animal data suggests drug-associated effects on fertility. It should also specify when contraception or pregnancy testing is required or recommended, such as before, during, or after the drug therapy.

Although the first trimester is the critical period for teratogenesis, some medications are known to have a teratogenic effect when taken in the second and third trimesters. For example, tetracycline taken in late pregnancy is commonly associated with staining of teeth in children and has been shown to depress skeletal growth, especially in premature babies. Sulfonamides taken in the last few weeks of pregnancy are known to compete with bilirubin attachment of protein-binding sites, increasing the risk of jaundice in the newborn (Niebyl & Simpson, 2012).

Pregnant women need to avoid all medications—prescribed, homeopathic, or OTC—if possible. If no alternative exists, it is wisest to select a well-known medication rather than a newer drug whose potential teratogenic effects may not be known. When possible, the oral form of a drug should be used, and it should be prescribed in the lowest possible therapeutic dose for the shortest time possible. The advantage of using a particular medication must outweigh the risk. Any medication with possible teratogenic effects is best avoided.

Nonpharmacologic Therapy and Complementary Health Approaches

Nonpharmacologic therapies are considered safe and effective for use during pregnancy for women with depression, chronic headaches, sleep disturbances, back pain, and nausea and vomiting of pregnancy. Examples include relaxation therapy, physical therapy, massage therapy, cognitive-behavioral therapy, and hydrotherapy. Many women use complementary and alternative medicine (CAM), such as homeopathy, herbal therapy, acupressure, acupuncture, biofeedback, therapeutic touch, massage, and chiropractic, as part of a holistic approach to their healthcare regimen. Nurses are in a unique position to bridge the gap between conventional therapies and CAM therapies. As patient advocates, nurses are able to provide patients with information needed to make informed decisions about their health and healthcare. Using a nonjudgmental approach, the nurse should inquire about the use of CAM as part of a routine antepartum assessment. It is important that nurses working with pregnant women and their families develop a general understanding of the more commonly used therapies to be able to answer questions and provide resources as needed.

It is important for the pregnant woman to understand that herbs are considered to be dietary supplements and are not regulated as prescription or OTC drugs by the FDA. In general, it is best to advise pregnant women not to ingest any herbs, except ginger, during the first trimester of pregnancy. The website of the National Center for Complementary and Integrative Health is a reliable source for information about herbs, homeopathic remedies, and other alternative options.

Lifespan Considerations

Although pregnancy is a normal process for many women, it can carry increased risk for adolescents and women over age 35. These special populations require additional considerations throughout the childbearing process. Considerations may include additional testing, monitoring, and the assessment of psychosocial needs.

Adolescent Pregnancy

Over the past decade, U.S. adolescent birth rates have steadily decreased; however, the rate is substantially higher than in other Western industrialized countries (CDC, 2016). As recently as 2014, a total of 249,078 babies were born to females age 15–19 years, for a birth rate of 24.2 per 1000 women in this age group (CDC, 2016).

Adolescent pregnancy is a health and social issue with no single cause or cure. For the adolescent, pregnancy comes at a time when her physical development and the developmental tasks of adolescence are incomplete. She may not be prepared physically, psychologically, or economically for parenthood. Thus both she and her child are at high risk for a number of adverse outcomes. Compared with women of similar socioeconomic status who postpone childbearing, teen mothers are less likely to finish high school, less likely to go to college, more likely to be single, less likely to receive child support, and more likely to require public assistance. Babies of adolescent mothers are at an increased risk for preterm birth, low birth weight, and newborn/infant mortality. In addition, children of teen mothers tend to score lower on assessments of knowledge, language development, and cognition. They are also more likely to grow up without a father. In addition, children of adolescent mothers are at an increased risk for abuse and neglect (Born, 2012).

Pregnancy Over Age 35

An increasing number of women are choosing to have their first baby after age 35. Many factors contribute to this trend, including the following:

- The availability of effective birth control methods
- The expanded roles and career options available to women
- The increased number of women obtaining advanced education, pursuing careers, and delaying parenthood until they are established professionally
- The increased incidence of later marriage and second marriage
- The high cost of living, which causes some young couples to delay childbearing until they are more secure financially
- The increased availability of specialized fertilization procedures, which offers opportunities for women who had previously been considered infertile.

There are advantages to having a first baby after the age of 35. Single women or couples who delay childbearing until they are older tend to be well educated and financially secure. Usually their decision to have a baby was deliberately and thoughtfully made. Because of their life experiences,

they are also more aware of the realities of having a child than younger women, and they recognize what it means to have a baby at their age. This delay in family allows for women to pursue advanced educational degrees and prepare financially for the impact children will have on their lives. Some women are ready to make a change in their lives, desiring to stay home with a new baby. Those who plan to continue working outside the home are typically able to afford good child care.

Special Concerns of the Expectant Couple Over Age 35

No matter what their age, most expectant couples have concerns regarding the well-being of the fetus and their ability to parent. The older couple has additional concerns related to their age, especially if they are over 40. Some couples are concerned about whether they will have enough energy to care for a new baby. Of greater concern is their ability to deal with the needs of the older child as they themselves age.

The financial concerns of an older couple are usually different from those of a younger couple. The older couple is generally more financially secure than the younger couple. However, when their “baby” is ready for college, the older couple may be near retirement and might not have the means to provide for their child.

While considering their financial future and future retirement, the older couple may be forced to face their own mortality. Certainly this is not uncommon in midlife, but instead of confronting this issue at 40–45 years of age or later, the older expectant couple may confront the issue several years earlier as they consider what will happen as their child grows.

The older couple facing pregnancy following a late or second marriage or after therapy for infertility may find themselves somewhat isolated socially. They may feel “different” because they are often the only couple in their peer group expecting their first baby. In fact, many of their peers are likely to be parents of adolescents or young adults and may be grandparents as well.

The response of older couples who already have children to learning that the woman is pregnant may vary greatly depending on whether the pregnancy was planned or unexpected. Other factors influencing their response include the attitudes of the couple’s children, family, and friends to the pregnancy; the impact on their lifestyle; and the financial implications of having another child. Sometimes couples who had previously been married to other mates will choose to have a child together. The concept of blended family applies to situations in which “her” children, “his” children, and “their” children come together as a new family group.

The woman who has delayed pregnancy may be concerned about the limited amount of time that she has to bear children. When pregnancy does not occur as quickly as she hoped, the older woman may become increasingly anxious as time slips away on her “biological clock.” When an older woman becomes pregnant but experiences a spontaneous abortion, her grief for the loss of her unborn child is exacerbated by her anxiety about her ability to conceive again in the time remaining to her.

Healthcare professionals may treat the older expectant couple differently than they would a younger couple. Older women may be offered more medical procedures, such as amniocentesis and ultrasound, than younger women. An older woman may be prevented from using a birthing room or birthing center even if she is healthy, because her age is considered to put her at risk.

Medical risks for the pregnant woman over age 35 are discussed in Exemplar 33.A, Antepartum Care.

Case Study » Part 3

Mrs. Halleck is at the clinic for a weekly follow-up appointment. She reports that she has been taking her blood pressure at home, and her readings during the past 2 weeks have been consistently around 130/85 mmHg. On examination, her weight is 151 lb, T_O 98.5°F, BP 131/84 mmHg, P 85 beats/min, R 20/min. Mrs. Halleck reports that is very stressed about her blood pressure. She has already lost a baby and she is afraid she may lose this one. In addition, as a relatively young teacher, she does not have a lot of sick time built up and if she cannot return to work, she doesn't know how she and her husband will be able to pay their bills. "My parents won't help," she says, "My mother is still more worried about her image than she is about me." Mrs. Halleck begins to cry and states, "I cry all the time now. I can't sleep. My husband says he doesn't know what to do

with me. I knew we should've waited before we tried to have another baby!"

Clinical Thinking Questions Level I

1. What is the priority for care for Mrs. Halleck at this time?
2. Based on the history of her pregnancy and the findings at this visit, what screenings do you anticipate the healthcare provider will order for Mrs. Halleck?
3. What do you think the nurse's responsibility to Mr. Halleck is at this time?

Clinical Thinking Questions Level II

4. What independent nursing interventions can the nurse implement to assist Mrs. Halleck at this time?
5. *Referring to Exemplar 28.C, Postpartum Depression:* What risk factors does Mrs. Halleck have for postpartum depression?
6. *Referring to Exemplar 28.C, Postpartum Depression:* What could the nurse do to assess Mrs. Halleck for possible depression with peripartum onset? The Edinburgh Postnatal Depression Scale and the Postpartum Depression Predictors Inventory may provide additional information to aid the nurse and the healthcare provider in determining if Mrs. Halleck needs further intervention at this time.

REVIEW The Concept of Reproduction

RELATE Link the Concepts

Linking the concept of reproduction with the concept of family:

1. Identify specific examples that demonstrate how the childbearing family is meeting developmental tasks of pregnancy.
2. Discuss family adaptation to pregnancy.
3. Describe the impact of family stressors on pregnancy.

Linking the concept of reproduction with the concept of nutrition:

4. Develop health promotion strategies to promote optimal nutrition during pregnancy, postpartum, and throughout the first year of life.
5. Analyze the impact of nutritional deficits on birth outcomes.
6. Identify motivational strategies to improve nutritional status throughout the childbearing period.

Linking the concept of reproduction with the concept of perfusion:

7. Analyze fetal assessments to determine placental perfusion and fetal well-being.
8. Discuss the impact of poor perfusion on maternal-fetal outcomes.
9. Prioritize nursing care according to severity of postpartum hemorrhage.

REFLECT Apply Your Knowledge

Mrs. Patterson, 41, is a G1P0 with a history of infertility. She currently works as an account manager for a pharmaceutical company and has been promoted to International Sales Director. She typically works long hours and must travel on occasion. She and her husband, 43, married for 15 years, are anticipating the arrival of their first child, but have expressed some concerns. Mrs. Patterson's height is 167.6 cm (5 ft, 6 in.); weight, 64.9 kg (143 lb); fundal height, 26 cm; ultrasound results show an intrauterine pregnancy at 25 weeks' gestation. No

fetal abnormalities were noted. She has no existing medical diagnoses. Mrs. Patterson voices concerns about balancing motherhood with her career. She states that her husband is supportive, but recognizes that a new child may alter their routine and lifestyle. Mrs. Patterson also states that she is worried that her busy schedule may compromise the pregnancy.

1. What are the priority concerns for Mrs. Patterson?
2. Given the current findings, what interventions would be most therapeutic?
3. What resources might be appropriate for this patient?
4. What independent nursing interventions can the nurse implement to assist Mrs. Patterson at this time?

Exemplar 33.A Antepartum Care

Exemplar Learning Outcomes

33.A Summarize antepartum care of the pregnant woman.

- Summarize relief of the common discomforts of pregnancy.
- Describe commonly occurring alterations related to pregnancy.
- Summarize maternal and fetal risk factors related to pregnancy.
- Compare diagnostic tests used to assess fetal well-being.
- Describe factors that influence maternal nutrition and weight gain.
- Differentiate considerations related to the assessment and care of pregnant adolescents and women over 35.
- Illustrate the nursing process in providing culturally competent care to the pregnant woman and her family.

Overview

From the moment a woman finds out she is pregnant, she faces a future marked by dramatic changes. Her appearance will alter. Her relationships will change. Even her psychologic state will be affected. She will need to make adjustments in her daily life to cope with these changes. So, too, will her family. The roles and responsibilities of family members, for example, may alter as the woman's ability to perform certain activities changes. The family also must adapt psychologically to the expected arrival of a new member.

The expectant woman and her family will probably have many questions about the pregnancy and its impact on all of them, especially if this is a first pregnancy. Their daily activities and healthcare practices may affect the well-being of the unborn child. Addressing self-care and discomforts related to pregnancy, performing ongoing assessment to ensure fetal and maternal health and safety, and preparing for childbirth are the nursing priorities for the woman experiencing a normal pregnancy.

Relief of the Common Discomforts of Pregnancy

The common discomforts of pregnancy result from physiologic and anatomic changes and are fairly specific to each of the three trimesters (**Table 33-2**). Health professionals often refer to these discomforts as minor, but they are not minor to the pregnant woman. In fact, they can make her quite uncomfortable and, if they are unexpected, anxious.

At each prenatal visit, focus patient teaching on changes or possible discomforts the pregnant woman might encounter during the coming month and the next trimester. If the pregnancy is progressing normally, spend a few minutes describing her baby at that particular stage of development. In regard to culture and diversity, discuss potential self-care techniques to promote safe practices and encourage incorporation of traditions supportive of patient needs. See Focus on Diversity and Culture: Self-Care Techniques During Pregnancy.

TABLE 33–2 Self-care Measures for Common Discomforts of Pregnancy

Discomfort	Influencing Factors	Self-Care Measures
First Trimester		
Nausea and vomiting	Increased levels of hCG Changes in carbohydrate metabolism Emotional factors Fatigue	Avoid odors or causative factors. Eat dry crackers or toast before arising in morning. Have small but frequent meals. Avoid greasy or highly seasoned foods. Take dry meals with fluids between meals. Drink carbonated beverages.
Urinary frequency	Pressure of uterus on bladder in both first and third trimesters	Void when urge is felt. Increase fluid intake during the day. Decrease fluid intake <i>only</i> in the evening to decrease nocturia.
Fatigue	Specific causative factors unknown May be aggravated by nocturia due to urinary frequency	Plan time for a nap or rest period daily. Go to bed early. Seek family support and assistance with responsibilities so that more time is available to rest.
Breast tenderness	Increased levels of estrogen and progesterone	Wear well-fitting, supportive bra.
Increased vaginal discharge	Hyperplasia of vaginal mucosa and increased production of mucus by the endocervical glands due to the increase in estrogen levels	Promote cleanliness by daily bathing. Avoid douching, nylon underpants, and pantyhose; cotton underpants are more absorbent.
Nasal stuffiness and nosebleed (epistaxis)	Elevated estrogen levels	May be unresponsive, but cool-air vaporizer may help; avoid use of nasal sprays and decongestants.
Ptyalism (excessive, often bitter salivation)	Specific causative factors unknown	Use astringent mouthwashes, chew gum, or suck hard candy. Carry tissues or a small towel to spit into when necessary.
Second and Third Trimesters		
Heartburn (pyrosis)	Increased production of progesterone, decreasing gastrointestinal motility and increasing relaxation of cardiac sphincter, displacement of stomach by enlarging uterus, thus regurgitation of acidic gastric contents into the esophagus	Eat small and more frequent meals. Use low-sodium antacids if approved by healthcare provider. Avoid overeating, fatty and fried foods, lying down after eating, and sodium bicarbonate.
Ankle edema	Prolonged standing or sitting Increased levels of sodium due to hormonal influences Circulatory congestion of lower extremities Increased capillary permeability Varicose veins	Practice frequent dorsiflexion of feet when prolonged sitting or standing is necessary. Elevate legs when sitting or resting. Avoid tight garters or restrictive bands around legs.
Varicose veins	Venous congestion in the lower veins that increases with pregnancy Hereditary factors (weakening of walls of veins, faulty valves) Increased age and weight gain	Elevate legs frequently. Wear supportive hose. Avoid crossing legs at the knees, standing for long periods, garters, and hosiery with constrictive bands.
Hemorrhoids	Constipation (see following discussion) Increased pressure from gravid uterus on hemorrhoidal veins	Avoid constipation. Apply ice packs, topical ointments, anesthetic agents, warm soaks, or sitz baths; gently reinsert hemorrhoid into rectum as necessary.
Constipation	Increased levels of progesterone, which cause general bowel sluggishness Pressure of enlarging uterus on intestine Iron supplements Diet, lack of exercise, and decreased fluids	Increase fluid intake, fiber in the diet, and exercise. Develop regular bowel habits. Use stool softeners as recommended by healthcare provider.
Backache	Increased curvature of the lumbosacral vertebrae as the uterus enlarges Increased levels of hormones, which cause softening of cartilage in body joints Fatigue Poor body mechanics	Use proper body mechanics. Practice the pelvic-tilt exercise. Avoid uncomfortable working heights, high-heeled shoes, lifting of heavy loads, and fatigue.
Leg cramps	Imbalance of calcium/phosphorus ratio Increased pressure of uterus on nerves Fatigue Poor circulation to lower extremities Pointing the toes	Practice dorsiflexion of feet to stretch affected muscle. Evaluate diet. Apply heat to affected muscles. Arise slowly from resting position.

(continued on next page)

TABLE 33-2 Self-care Measures for Common Discomforts of Pregnancy (*continued*)

Discomfort	Influencing Factors	Self-Care Measures
Faintness	Postural hypotension Sudden change of position causing venous pooling in dependent veins Standing for long periods in warm area Anemia	Avoid prolonged standing in warm or stuffy environments. Evaluate hematocrit and hemoglobin.
Dyspnea	Decreased vital capacity from pressure of enlarging uterus on the diaphragm	Use proper posture when sitting and standing. Sleep propped up with pillows for relief if problem occurs at night.
Flatulence	Decreased gastrointestinal motility leading to delayed emptying time Pressure of growing uterus on large intestine Air swallowing	Avoid gas-forming foods. Chew food thoroughly. Get regular daily exercise. Maintain normal bowel habits.
Carpal tunnel syndrome	Compression of median nerve in carpal tunnel of wrist Aggravated by repetitive hand movements	Avoid aggravating hand movements. Use splint as prescribed. Elevate affected arm.

Source: Davidson, M., London, M., & Ladewig, P. (2017). *Olds' maternal-newborn nursing & women's health across the lifespan* (10th ed.). Key Points: Health Promotion Education: Self-Care Measures for Common Discomforts of Pregnancy, pp. 289–290. Hoboken, NJ: Pearson.

Alterations of Pregnancy

Even though pregnancy is a normal process, for some women it may become a life-threatening event because of potential or existing complications. These complications can result from factors such as age, parity, blood type, socioeconomic status, psychologic health, or preexisting chronic illnesses. Alterations or complications may involve pregestational factors related to a variety of concepts, such as metabolism, perfusion, oxygenation, immunity, nutrition, and coping. Some alterations arise during pregnancy and potentially result in additional complications related to an increased risk for preterm delivery or perinatal loss. Effective prenatal care is directed toward identifying factors that increase a pregnant woman's risk and developing supportive therapies that promote optimal health of the mother and her fetus.

Anemia During Pregnancy

Anemia indicates inadequate levels of hemoglobin (Hb) in the blood. Anemia is defined as hemoglobin less than 12 g/dL in nonpregnant women and less than 11 g/dL in pregnant women (ACOG, 2015b). Ethnicity, altitude, smoking, nutrition, and medications can affect the normal limits of hemoglobin. The lower limit of normal tends to be higher for women who smoke and those who live at higher altitudes because their bodies require a greater quantity of red blood cells to maintain their tissue oxygen levels. The common anemias of pregnancy are due either to insufficient hemoglobin production related to nutritional deficiency in iron or folic acid during pregnancy, or to hemoglobin destruction in inherited disorders, specifically sickle cell disease and thalassemia.

Iron Deficiency Anemia

Iron deficiency anemia is the most common medical complication of pregnancy. Low iron stores in the body may result in diminished red blood cell production (Short & Domagal-ski, 2014). This is primarily a consequence of expansion of plasma volume without normal expansion of maternal

hemoglobin mass (ACOG, 2015b). The greatest need for increased iron intake occurs in the second half of pregnancy. When the iron needs of pregnancy are not met, maternal hemoglobin falls below 11 g/dL. Serum ferritin levels, indicating iron stores, are below 12 mg/L.

The woman with iron deficiency anemia may be asymptomatic, but she is more susceptible to perinatal infection and has an increased chance preeclampsia and bleeding. There is evidence of increased risk of low birth weight, prematurity, stillbirth, and neonatal death in babies of women with severe iron deficiency (maternal Hb less than 6 g/dL). The newborn is not iron deficient at birth because of active transport of iron across the placenta, even when maternal iron stores are low. However, these babies do have lower iron stores and are at increased risk for developing iron deficiency during the newborn period and infancy (Abu-Ouf & Jan, 2015).

The first goal of healthcare is to prevent iron deficiency anemia. To prevent anemia, the AAP and ACOG (2012) recommend that pregnant women supplement their diet with at least 30 mg of iron daily. This amount is contained in most prenatal vitamins. In addition, the woman should be encouraged to eat an iron-rich diet. If anemia is diagnosed, the dosage should be increased to 60–120 mg/day of iron. If the woman remains anemic after 1 month of therapy, further evaluation is indicated.

Folic Acid Deficiency Anemia

Folate deficiency is the most common cause of megaloblastic anemia during pregnancy. **Folic acid** is needed for deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) synthesis and cell duplication. In its absence, immature red blood cells fail to divide, become enlarged (megaloblastic), and are fewer in number. Even more significantly, an inadequate intake of folic acid has been associated with neural tube defects (NTDs) (spina bifida, anencephaly, myelomeningocele) in the fetus or newborn. With the tremendous cell multiplication that occurs

Focus on Diversity and Culture

Self-care Techniques During Pregnancy*

Belief or Practice	Nursing Considerations
Home Remedies	
<ul style="list-style-type: none"> Pregnant women of Native American background may use herbal remedies. An example is the dandelion, which contains a milky juice in its stem believed to increase breast milk flow in mothers who choose to breastfeed (Spector, 2017). Patients of Chinese descent may drink ginseng tea for faintness after childbirth or as a sedative when mixed with bamboo leaves. Some individuals of African heritage may use self-medication for pregnancy discomforts—for example, laxatives to prevent or treat constipation (Purnell, 2014). 	Find out what medications and home remedies your patient is using, and counsel her regarding their overall effects. It is common for individuals to avoid telling healthcare workers about home remedies, because the patient may feel the use of such remedies will be judged unfavorably. Phrase your questions in a sensitive, accepting way.
Nutrition	
<ul style="list-style-type: none"> Some women of Italian background may believe it is necessary to satisfy desires for certain foods in order to prevent congenital anomalies. Also, they may believe they must eat food that they smell, or else the fetus will move “inside,” which will result in a miscarriage. Some pregnant women of African descent may continue the tradition of eating clay, dirt, or starch, which they believe will benefit the mother and fetus (Carmonney, 2014). 	Discuss the woman’s beliefs and practices in regard to nutrition during pregnancy. Obtain a diet history from the patient. Discuss the importance of a well-balanced diet during pregnancy, with consideration of the woman’s cultural beliefs and practices. In some cases, you might want to suggest remedies that may be more effective—for example, eating high-fiber foods to reduce constipation. If the home remedy is not harmful, there is no reason to ask a patient to discontinue this practice.
Alternative Healthcare Providers	
<ul style="list-style-type: none"> Some pregnant women of Mexican background may choose to seek out the care of a <i>partera</i> (midwife) for prenatal and intrapartum care. A <i>partera</i> speaks their language, shares a similar culture, and can care for pregnant women at home or in a birthing center instead of a hospital. Some individuals in Hispanic-American communities may use a <i>curandero</i> (folk healer). A <i>curandero</i> frequently uses herbs, massage, and religious artifacts for treatment (Spector, 2017). 	Discuss the variety of choices for healthcare providers available to the pregnant woman. Contrast the benefits and risks of different settings for prenatal care and birth. Provide reassurance that the goal of healthcare during pregnancy and birth is a healthy outcome for mother and baby, with respect for the specific cultural beliefs and practices of the mother.
Exercise	
<ul style="list-style-type: none"> Some pregnant women of Italian descent may fear changing their body position in certain ways because they believe this may cause the fetus to develop abnormally. Some individuals of European, African, and Mexican descent believe that reaching over the head during pregnancy can harm the baby. 	Ask the woman whether she is afraid of any activities because of the pregnancy. Assure her that reaching over her head will not harm the baby, and evaluate other activities for their effect on the pregnancy.
Spirituality	
<ul style="list-style-type: none"> Native Americans are aware of the mind–soul connection and may try to follow certain practices to have a healthy pregnancy and birth. These practices could include a focus on peace and positive thoughts as well as certain types of prayers and ceremonies. A traditional healer may assist them (Ogbum et al., 2012). Some individuals of European background may tend to pay more attention to spirituality in their life to alleviate fears and ensure a safe birth. 	Encourage the use of support systems and spiritual aids that provide comfort for the pregnant woman.

*Note: This information is meant only to provide examples of the behaviors that may be found within certain cultures. Not all members of a culture practice the behaviors described.

in pregnancy, an adequate amount of folic acid is crucial. However, increased urinary excretion of folic acid and fetal uptake can rapidly result in folic acid deficiency.

Diagnosis of folic acid deficiency anemia may be difficult, and it is usually not detected until late in pregnancy or the early puerperium. This is because serum folate levels normally fall as pregnancy progresses. Even though folate levels are lower with deficiency, they will fluctuate with diet. Measurement of erythrocyte folate status is more reliable

but indicates the folate status of several weeks previously. Women with true folic acid deficiency anemia often present with nausea, vomiting, and anorexia. Hemoglobin levels as low as 3–5 g/dL may be found. Typically the blood smear reveals that the newly formed erythrocytes are macrocytic.

Folic acid deficiency during pregnancy is prevented by a daily supplement of 0.4 mg of folate. Treatment of deficiency consists of 1-mg folic acid supplements. Because iron deficiency anemia almost always coexists with folic acid

deficiency, the woman also needs iron supplements. The Food and Drug Administration (FDA) requires the addition of folic acid for all foods labeled “enriched.” Even with this addition, the U.S. Public Health Service recommends that all women of childbearing age (15–45 years) consume 0.4 mg of folic acid daily. This recommendation is important because half of all U.S. pregnancies are unplanned and NTDs occur very early in pregnancy (3–4 weeks after conception), before most women realize they are pregnant (AAP & ACOG, 2012). Nurses can play a crucial role in helping young women become aware of this important recommendation.

Sickle Cell Disease

Sickle cell disease (SCD) is an autosomal recessive disorder in which the normal adult hemoglobin, hemoglobin A (HbA), is abnormally formed. This abnormal hemoglobin is called hemoglobin S (HbS). Approximately 1 in 12 African Americans has sickle cell trait and 1 in every 300 African American newborns has some form of sickle cell disease (ACOG, 2015b). Diagnosis is confirmed by hemoglobin electrophoresis or a test to induce sickling in a blood sample. Prenatal diagnosis and newborn screening for sickle cell disease are important components of perinatal care (ACOG, 2015b).

Women with sickle cell trait have a good prognosis for pregnancy if they have adequate nutrition and prenatal care. Maternal mortality due to sickle cell disease is rare. Women with sickle cell disease may have experienced severe complications by the time they reach childbearing age (James, 2014). Complications include anemia requiring blood transfusion, infections, and emergency cesarean births. Acute chest syndrome, congestive heart failure, or acute renal failure may also occur. Prematurity and intrauterine growth restriction (IUGR) are also associated with sickle cell disease. Fetal death is believed to be due to sickling attacks in the placenta.

Because the woman with sickle cell disease maintains her hemoglobin levels by intense erythropoiesis, additional folic acid supplements (4 mg/day) are required. Maternal infection should be treated promptly because dehydration and fever can trigger sickling and crisis. Vaso-occlusive crisis is best treated by a perinatal team in a medical center. Proper management requires close observation and evaluation of all symptoms. Women with sickle cell disease are at higher risk of developing *sickle cell crisis*, which may increase rates of maternal morbidity and mortality (Alayed et al., 2014).

Diabetes During Pregnancy

Carbohydrate metabolism is affected early in pregnancy by a rise in serum levels of estrogen, progesterone, and other hormones. These hormones stimulate maternal insulin production and increase tissue response to insulin; therefore, anabolism (building up) of glycogen stores in the liver and other tissues occurs.

In the second half of pregnancy, the woman demonstrates prolonged hyperglycemia and hyperinsulinemia (increased secretion of insulin) following a meal. Although the mother is producing more insulin, placental secretion of hPL and prolactin (from the decidua), as well as elevated levels of

cortisol (an adrenal hormone) and glycogen, causes increased maternal peripheral resistance to insulin. This resistance helps ensure that a sustained supply of glucose is available for the fetus. This glucose is transported across the placenta to the fetus, which uses it as a major source of fuel. Maternal amino acids are also actively transported by the placenta from the mother to her fetus. The fetus uses these amino acids for protein synthesis and as a source of energy. In addition to ensuring that glucose is available to the fetus, the increased maternal resistance to insulin means that the pregnant woman has a lower peripheral uptake of glucose to meet her own needs. This results in a catabolic (destructive) state during fasting periods (e.g., during the night and after meal absorption). Because increasing amounts of circulating maternal glucose are being diverted to the fetus, maternal fat is metabolized (lipolysis) during fasting periods much more readily than in a nonpregnant individual. This process is called *accelerated starvation*. Ketones may be present in the urine as a result of lipolysis.

The delicate system of checks and balances that exists between glucose production and glucose use is stressed by the growing fetus, who derives energy from glucose taken from the mother, and by maternal resistance to the insulin her body produces. This stress is referred to as the *diabetogenic effect of pregnancy*. Thus any preexisting disruption in carbohydrate metabolism is augmented by pregnancy, and any diabetic potential may precipitate gestational diabetes mellitus.

Gestational Diabetes Mellitus

Gestational diabetes mellitus (GDM) is defined as a carbohydrate intolerance of variable severity with onset or first recognition during pregnancy. It results from (1) an unidentified preexisting disease or (2) the unmasking of a compensated metabolic abnormality by the added stress of pregnancy, or (3) it is a direct consequence of the altered maternal metabolism stemming from changing hormonal levels. Diagnosis of GDM is important because even mild diabetes increases the risk of perinatal morbidity and mortality. Many women with GDM progress over time to overt type 2 diabetes mellitus (T2D).

Influence of Preexisting and Gestational Diabetes During Pregnancy

Pregnancy can affect diabetes significantly. First, the physiologic changes of pregnancy can drastically alter insulin requirements. Second, pregnancy may accelerate the progress of vascular disease secondary to diabetes.

The disease may be more difficult to control during pregnancy because insulin requirements are changeable. Insulin needs frequently decrease early in the first trimester. Levels of hPL, an insulin antagonist, are low; energy demands of the embryo/fetus are minimal; and the woman may be consuming less food because of nausea and vomiting. Nausea and vomiting may also cause dietary fluctuations, which can increase the risk of hypoglycemia or insulin shock. Insulin requirements usually begin to rise late in the first trimester as glucose use and glycogen storage by the woman and fetus increase. As a result of placental maturation and production of hPL and other hormones, insulin requirements may double or quadruple by the end of pregnancy.

Because her energy needs increase during labor, the woman with diabetes may require more insulin at that time to balance intravenous glucose. After delivery of the placenta, insulin requirements usually decrease abruptly with loss of hPL in the maternal circulation.

Other factors contribute to the difficulty in controlling the disease. As pregnancy progresses, the renal threshold for glucose decreases. There is an increased risk of ketoacidosis, which may occur at lower serum glucose levels in the pregnant woman with diabetes than in the nonpregnant woman with diabetes. The vascular disease that accompanies diabetes may progress during pregnancy. Hypertension may occur. Nephropathy may result from renal blood vessel impairment, and retinopathy may develop (from occlusion of the microscopic blood vessels of the eye).

Influence of Preexisting Diabetes and Gestational Diabetes on Pregnancy Outcome

The pregnancy of a woman who has diabetes carries a higher risk of complications than a normal pregnancy, especially perinatal mortality and congenital anomalies. The risk has been reduced by the recent recognition of the importance of tight metabolic control (fasting, premeal, and bedtime blood glucose levels of 60–95 mg/dL; peak postprandial blood glucose levels of 100–129 mg/dL; and glycohemoglobin less than 6%). New techniques for monitoring blood glucose, delivering insulin, and monitoring the fetus have also reduced perinatal mortality (ACOG, 2013d).

Maternal Risks

Maternal health problems in diabetic pregnancy have been greatly reduced by the team approach to preconception planning and early prenatal care and by the increased emphasis on maintaining tight control of blood glucose levels. The prognosis for the pregnant woman with gestational, type 1, or type 2 diabetes that has not resulted in significant vascular damage is positive. However, diabetic pregnancy still carries higher risks for complications than normal pregnancy.

Hydramnios, or an increase in the volume of amniotic fluid, occurs in 10–20% of pregnant women with diabetes. It is thought to be a result of excessive fetal urination because of fetal hyperglycemia (ACOG, 2013d). *Preeclampsia-eclampsia* occurs more often in diabetic pregnancies, especially when diabetes-related vascular changes already exist.

Hyperglycemia due to insufficient amounts of insulin can lead to *ketoacidosis* as a result of the increase in ketone bodies (which are acidic) in the blood released when fatty acids are metabolized. Ketoacidosis usually develops slowly, but it may develop more rapidly in the pregnant woman because of the hyperketonemia associated with accelerated starvation in the fasting state. The tendency for higher postprandial glucose levels because of decreased gastric motility and the contrainsulin effects of hPL also predispose the woman to ketoacidosis. If the ketoacidosis is not treated, it can lead to coma and death of both mother and fetus.

Another risk to the pregnant woman with diabetes is a difficult labor (*dystocia*), caused by fetopelvic disproportion if fetal macrosomia (>4000 g) exists. The pregnant woman with diabetes is also at increased risk for recurrent monilial vaginitis (yeast infection) and urinary tract infections because of increased glycosuria, which contributes to a favorable environment for bacterial growth. If untreated, asymptomatic bacteriuria can lead to pyelonephritis, a serious kidney infection.

Several studies have demonstrated that pregnancy worsens *retinopathy* in women with diabetes. Most investigators agree that during a diabetic pregnancy, good control of blood glucose levels and the use of laser photocoagulation (a treatment used to prevent retinal hemorrhage when the retina shows changes in the blood vessels) when indicated minimize the risk of the negative effects of pregnancy. Hence, women with preexisting diabetes should be referred to an ophthalmologist for evaluation during pregnancy.

Fetal-Neonatal Risks

Many of the problems of the newborn result directly from high maternal plasma glucose levels. The incidence of *congenital anomalies* in diabetic pregnancies is 6–12% and is the major cause of death for babies of mothers with diabetes. Research suggests that this increased incidence of congenital anomalies is related to multiple factors, including high glucose levels in early pregnancy (ACOG, 2013d). The anomalies often involve the heart, central nervous system (CNS), and skeletal system. Septal defects, coarctation of the aorta, and transposition of the great vessels are the most common heart lesions seen. CNS anomalies include hydrocephalus, meningomyelocele, and anencephaly. One anomaly, *sacral agenesis*, appears only in babies of mothers with diabetes. In sacral agenesis, the sacrum and lumbar spine fail to develop and the lower extremities develop incompletely. To reduce the incidence of congenital anomalies, preconception counseling and strict diabetes control before conception and in the early weeks of pregnancy are indicated.

Approximately 18% of newborns of mothers with diabetes are large for gestational age (LGA) as a result of high levels of fetal insulin production stimulated by the high levels of glucose crossing the placenta from the mother. Sustained fetal hyperinsulinism and hyperglycemia ultimately lead to *macrosomia* and deposition of fat. If born vaginally, the macrosomic newborn is at increased risk for birth trauma such as fractured clavicle or brachial plexus injuries due to shoulder dystocia. Shoulder dystocia occurs when, following birth of the head, the anterior shoulder of the macrosomic fetus does not emerge either spontaneously or with gentle traction (ACOG, 2013d). Macrosomia can be significantly reduced by tight maternal blood glucose control.

After birth, the umbilical cord is severed and, thus, the generous maternal blood glucose supply is eliminated. However, continued islet cell hyperactivity leads to excessive insulin levels and depleted blood glucose (hypoglycemia) within 2–4 hours after birth in the neonate. Babies of mothers with diabetes with vascular involvement (see the

module on Metabolism) may demonstrate IUGR. This occurs because vascular changes in the mother decrease the efficiency of placental perfusion, and the fetus is not as well sustained in utero. *Respiratory distress syndrome* appears to result from inhibition, by high levels of fetal insulin, of some fetal enzymes necessary for surfactant production. Polycythemia in the newborn is due primarily to the diminished ability of glycosylated hemoglobin in the mother's blood to release oxygen. *Hyperbilirubinemia* is a result of the inability of immature liver enzymes to metabolize the increased bilirubin resulting from the polycythemia. Hypocalcemia, characterized by signs of irritability or even tetany, may occur. The cause of these low calcium levels in newborns of mothers with diabetes is not known.

Clinical Therapy

Gestational diabetes is more common than preexisting diabetes. It is estimated to occur in from 6 to 7% of pregnancies, depending on the population studied (ACOG, 2013d). Therefore, screening for its detection is a standard part of prenatal care. If diabetes is suspected, further testing is undertaken for diagnosis.

All pregnant women should have their risk of diabetes assessed at the first prenatal visit (see Exemplar 12.A, Type 1 Diabetes Mellitus, in the module on Metabolism). Women at high risk (prior history of GDM or birth of an LGA baby, marked obesity, diagnosis of polycystic ovarian syndrome, presence of glycosuria, or a strong family history of type 2 diabetes mellitus [T2D]) should be screened for diabetes as soon as possible. In early pregnancy, the screening criteria for nonpregnant individuals is used: Hb A1C equal to or greater than 6.5% would be considered diagnostic as would a fasting plasma glucose level equal to or greater than 126 mg/dL (American Diabetes Association [ADA], 2014).

If there is no preexisting diabetes, screening for GDM is done using one of two approaches performed at 24 to 28 weeks' gestation (ADA, 2014). In the two-step approach, the first step is to give the woman a non-fasting, 50-g, 1-hour oral glucose tolerance test (OGTT). The oral glucose load can be given at any time of the day with no requirement for fasting. One hour later, plasma glucose is measured. If plasma glucose levels are elevated (equal to or greater than 140 mg/dL, depending on the laboratory used), a 100-g, 3-hour glucose test is done. In the second step, a 100-g, 3-hour OGTT is administered. The woman eats an unrestricted diet, consuming at least 150 g of carbohydrates per day for at least 3 days before her scheduled test. She then ingests a 100-g oral glucose solution in the morning after an overnight fast. Plasma glucose is measured fasting and at 1, 2, and 3 hours. A diagnosis of GDM occurs if two or more of the following values are met or exceeded:

Fasting	95 mg/dL
1 hour	180 mg/dL
2 hours	155 mg/dL
3 hours	140 mg/dL

In the one-step approach, the woman ingests a 75-g oral glucose solution in the morning after an overnight fast. Plasma glucose levels are determined fasting and at 1 and 2 hours. A

diagnosis of GDM occurs if any one of the following values are equaled or exceeded:

Fasting	92 mg/dL
1 hour	180 mg/dL
2 hours	153 mg/dL

Laboratory Assessment of Long-term Glucose Control

Glycosylated hemoglobin (hemoglobin A1C) is a laboratory test that loosely reflects glucose control over the previous 4–8 weeks. It measures the percentage of glycohemoglobin in the blood. Glycohemoglobin is the hemoglobin to which a glucose molecule is attached. The test is not reliable for screening for gestational diabetes and is not recommended at this time.

In women with known pregestational diabetes, however, abnormal hemoglobin A1C values correlate directly with the frequency of spontaneous abortion and fetal congenital anomalies. Consequently, women with preexisting diabetes who plan to become pregnant should work to achieve hemoglobin A1C levels at target levels (less than 6%) without significant hypoglycemia (ADA, 2014). Once the woman is pregnant, her hemoglobin A1C levels should be tested at the initial prenatal visit and every 2–3 months if target levels have been achieved (ADA, 2014).

Diet therapy and regular exercise form the cornerstone of intervention for GDM. Insulin therapy is indicated when dietary management is unable to achieve a 1-hour postprandial blood glucose value of less than 130–140 mg/dL, a 2-hour postprandial level of less than 120 mg/dL, or a fasting glucose of less than 95 mg/dL. In most instances, the overt diabetic manifestation disappears postpartum, though subtle manifestations of impaired insulin secretory capacity may remain.

Oral hypoglycemics are used during pregnancy when needed, with Glyburide being the most common.

Evaluation of Fetal Status

Information about the well-being, maturation, and size of the fetus is important for planning the course of the pregnancy and the timing of birth. Because pregnancies complicated by preexisting diabetes are at increased risk of neural tube defects, a quadruple screen, which includes testing for maternal serum α -fetoprotein (AFP), is offered at weeks 16–20 of gestation. Daily maternal evaluation of fetal activity, begun at about 28 weeks, is effective and simple to do. The woman is taught a particular method for counting fetal movements.

Nonstress testing (NST) may be started at about 28 weeks. If evidence of IUGR, preeclampsia, oligohydramnios, or poorly controlled blood glucose exists, testing may begin as early as 23 weeks and may be done more often. NSTs are increased to twice weekly at 32 weeks' gestation. If the NST is nonreactive, a fetal biophysical profile is performed. If the woman requires hospitalization (for example, to control glycemia or for complications), NSTs may be done daily.

Ultrasound at 18 weeks confirms gestational age and diagnoses multiple pregnancy or congenital anomalies. It is repeated at 28 weeks to monitor fetal growth for IUGR or macrosomia. Some physicians order fetal biophysical profiles (ultrasound evaluation of fetal well-being in which fetal breathing movements, fetal activity, reactivity, muscle tone, and amniotic fluid volume are assessed) as part of an ongoing evaluation of fetal status.

Alterations and Therapies

Pregnancy

ALTERATION	DESCRIPTION	THERAPY
Pregestational Factors		
Prenatal substance abuse	Use of tobacco, alcohol, or illegal substances, including cocaine, methamphetamines, narcotics, or abuse of prescription medications. Such use can be profoundly harmful to the fetus.	<ul style="list-style-type: none"> Nursing care is focused on motivating the patient to abstain from substance use and on supporting the patient through the withdrawal-and-recovery period. For more information, see Exemplar 22.C, Substance Abuse, in the module on Addiction.
Diabetes mellitus	An endocrine disorder of carbohydrate metabolism resulting from inadequate production or use of insulin. The patient may be diagnosed with diabetes before becoming pregnant or develop gestational diabetes during pregnancy.	<ul style="list-style-type: none"> Patient teaching is important to promote self-care focused on stable glucose levels using a balance of diet, exercise, medications, and frequent monitoring. For more information, see Exemplar 12.A, Type 1 Diabetes Mellitus, in the module on Metabolism.
Anemia	Inadequate levels of hemoglobin in the blood, defined as levels of <11 g/dL during pregnancy (ACOG, 2015b) caused by either insufficient hemoglobin production related to nutritional deficiency in iron or folic acid or to hemoglobin destruction in inherited disorders, such as sickle cell disease.	<ul style="list-style-type: none"> Monitor patients for symptoms of anemia (fatigue, pallor, shortness of breath, and alterations in level of consciousness). Promote good nutrition in order to meet the body's metabolic needs. For more information, see Exemplar 2.B, Anemia, in the module on Cellular Regulation.
HIV/AIDS	Viral infection caused by the human immunodeficiency virus (HIV); called AIDS (acquired immunodeficiency syndrome) when symptoms of the disease appear.	<ul style="list-style-type: none"> Reassure the pregnant woman that risk of transmission to the fetus can be reduced by use of antiretroviral medication, that pregnancy is not believed to accelerate progression of the disease, and that most medications used to treat HIV can be safely taken during pregnancy. Cesarean birth and abstaining from breastfeeding are recommended to reduce the risk of transmission to the baby. For more information, see Exemplar 8.A, HIV and AIDS, in the module on Immunity.
Heart disease	Pregnancy increases cardiac output, heart rate, and blood volume, which the normal heart can adapt to but which may put stress on the heart of a patient with decreased cardiac reserve. Women in Class I or II usually experience a normal pregnancy; those in Class III or IV are at risk for more severe complications.	<ul style="list-style-type: none"> Assess the stress of pregnancy on functional capacity of the heart during all antepartum visits. This includes monitoring vital signs and comparing them with prepregnancy levels, activity level, and factors that increase strain on the heart, such as anemia, infection, anxiety, lack of a support system, and lifestyle demands (career, home life, and other children to care for). For more information, see the module on Perfusion.
Asthma	An obstructive lung condition that can improve symptoms in some pregnant women and worsen symptoms in others. Asthma has also been linked with higher rates of hyperemesis gravidarum, preeclampsia, uterine hemorrhage, and perinatal mortality.	<ul style="list-style-type: none"> Promote oxygenation to prevent hypoxia in both the mother and the fetus. Teach the woman how to recognize signs of preterm labor, because the rate of premature birth is higher in patients with asthma. The goal of therapy is to prevent maternal exacerbations, because even a mild exacerbation can cause severe hypoxia-related complications in the fetus. If an exacerbation occurs, inhaled albuterol may be recommended by the healthcare provider. For more information, see Exemplar 15.B, Asthma, in the module on Oxygenation.

(continued on next page)

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPY
Epilepsy	Chronic disorder characterized by seizures. Many women have uneventful pregnancies with excellent outcomes. Those with more frequent seizures before pregnancy may have exacerbations during pregnancy. Encourage patients to consult with their neurologists before and during pregnancy.	<ul style="list-style-type: none"> Teach the patient to continue taking recommended antiseizure medication as well as supplementing with folic acid and vitamin K throughout the pregnancy to improve fetal outcome. For more information, see Exemplar 11.B, Seizure Disorders, in the module on Intracranial Regulation.
Hyperthyroidism	Enlarged, overactive thyroid gland. This can increase the risk for preeclampsia and postpartum hemorrhage in the mother and for abortion, intrauterine death, and stillbirth in the fetus if not well controlled. Even low doses of antithyroid drug in the mother may produce a mild fetal/neonatal hypothyroidism; higher dose may produce a goiter or mental deficiencies. Fetal loss is not increased in women who are euthyroid.	<ul style="list-style-type: none"> Nursing care is focused on early identification and treatment. For more information, see Exemplar 12.F, Thyroid Disease, in the module on Metabolism.
Hypothyroidism	Characterized by inadequate thyroid secretions (decreased thyroxine [T_4]:thyroxine-binding globulin [TBG] ratio), elevated thyroid-stimulating hormone (TSH), lowered basal metabolic rate, and enlarged thyroid gland (goiter). Long-term replacement therapy usually continues during pregnancy at the same dosage as before. If the mother is untreated, the rate of fetal loss is 50%, with a high risk for congenital goiter or true cretinism. Therefore, newborns are screened for T_4 level. Mild TSH elevations present little risk because TSH does not cross the placenta.	<ul style="list-style-type: none"> Nursing care is focused on early identification and treatment to prevent potential complications. Teach the patient the importance of taking a thyroid hormone supplement regularly to maintain stable levels. For more information, see Exemplar 12.F, Thyroid Disease, in the module on Metabolism.
Multiple sclerosis	Neurologic disorder that destroys the myelin sheath of nerve fibers and affects primarily young women. Pregnancy is associated with remission and slightly increased relapse rates postpartum. Uterine contraction strength is not diminished, but labor may be almost painless because of diminished sensation.	<ul style="list-style-type: none"> Nursing care is focused on promoting rest and nutrition. For more information, see Exemplar 13.D, Multiple Sclerosis, in the module on Mobility.
Rheumatoid arthritis	Chronic inflammatory disease believed to have a genetic component. Remission of symptoms is common during the antepartum period, with relapse in the postpartum period. Heavy salicylate use may prolong gestation and lengthen labor. Salicylates may have possible teratogenic effects.	<ul style="list-style-type: none"> Monitor for anemia secondary to blood loss from salicylate therapy. Encourage rest to relieve weight-bearing joints, but the patient needs to continue range-of-motion exercises. The patient in remission may be advised to stop medications during pregnancy. For more information, see Exemplar 8.C, Rheumatoid Arthritis, in the module on Immunity.
Systemic lupus erythematosus (SLE)	Autoimmune collagen disease characterized by exacerbations and remissions. Women who conceive when the disease is in remission appear to have little risk for adverse outcomes. Those with active disease have less favorable outcomes, although pregnancy does not appear to alter the long-term prognosis (Nili et al., 2013). Increased incidence of spontaneous abortion, stillbirth, prematurity, and intrauterine growth restriction (IUGR). Babies born to women with SLE may have characteristic skin rash, which usually disappears by 12 months. Neonates are at increased risk for complete congenital heart block, a condition that can be diagnosed prenatally (Nili et al., 2013). When diagnosed, the mother is given corticosteroids that cross the placenta and decrease fetal heart inflammation (Davidson et al., 2017).	<ul style="list-style-type: none"> Nursing care is focused on providing emotional support throughout the pregnancy and monitoring fetal well-being. Women with SLE have often experienced prenatal loss and may be very fearful about the outcome of pregnancy. For more information, see Exemplar 8.D, Systemic Lupus Erythematosus, in the module on Immunity.

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPY
Tuberculosis (TB)	An infection caused by <i>Mycobacterium tuberculosis</i> , which often affects the lungs. There has been a significant increase in diagnosis of TB, often associated with HIV infection, living in homeless shelters, and illicit drug use (Cunningham et al., 2014). Eighty percent of new cases are found in developing countries, primarily in Africa and Asia. In the United States, the majority of cases occur in foreign-born people (CDC, 2013). The relapse rate does not increase if TB is inactive because of prior treatment. Isoniazid crosses the placenta, but most studies show no teratogenic effects. Rifampin also crosses the placenta, and the possibility of harmful effects is still being studied.	<ul style="list-style-type: none"> When isoniazid is used during pregnancy, the woman should take supplemental pyridoxine (vitamin B₆). Extra rest and limited contact with others are required until the disease becomes inactive. If maternal TB is inactive, the mother may breastfeed and care for her baby. If TB is active, the newborn should not have direct contact with the mother until she is noninfectious. For more information, see Exemplar 9.G, Tuberculosis, in the module on Infection.
Gestational Onset		
Vaginal bleeding	Primarily the result of abortion (miscarriage) during the first and second trimesters. Bleeding can also result from complications, such as ectopic pregnancy or gestational trophoblastic disease. In the second half of pregnancy, bleeding is often caused by placenta previa and abruptio placentae.	<ul style="list-style-type: none"> Monitor blood pressure and pulse frequently. Observe the woman for behaviors indicative of shock, such as pallor, clammy skin, perspiration, dyspnea, or restlessness. Count and weigh pads to assess amount of bleeding over a given time period; save any tissue or clots expelled. If at 12 weeks' gestation or beyond, assess fetal heart tones with a Doppler. Prepare the woman for intravenous (IV) therapy. There may be standing orders to begin IV therapy on patients who are bleeding. Prepare equipment for examination. For more information, see Exemplar 16.L, Shock, in the module on Perfusion; and Exemplar 19.D, Menstrual Dysfunction, in the module on Sexuality.
Spontaneous abortion (miscarriage)	Many pregnancies end in the first trimester by spontaneous abortion, often without the woman's awareness that she was even pregnant. Most miscarriages result from chromosomal abnormalities. Other causes include teratogens, faulty implantation because of an abnormal reproductive tract, weakened cervix, placental abnormalities, chronic maternal diseases, endocrine imbalances, and maternal infections.	<ul style="list-style-type: none"> Miscarriage during the first trimester can rarely be reversed, so nursing care is focused on providing emotional support and preventing complications. Discourage use of hot tubs, because hyperthermia increases risk.
Ectopic pregnancy	Implantation of the fertilized ovum in a site other than the endometrial lining of the uterus. Ectopic pregnancy has many associated risk factors, including tubal damage caused by pelvic inflammatory disease, previous tubal surgery, congenital anomalies of the tube, endometriosis, previous ectopic pregnancy, presence of an intrauterine device, and in utero exposure to diethylstilbestrol.	<ul style="list-style-type: none"> Nursing care is focused on early identification, providing emotional support, and preventing complications secondary to blood loss. Pain management is an important nursing intervention. Assess human chorionic gonadotropin (hCG) levels (often lower with ectopic pregnancy and do not increase normally). Prepare the patient for surgery. Provide postoperative reassurance that pregnancy is still possible with one remaining fallopian tube.
Gestational trophoblastic disease (GTD)	Pathologic proliferation of trophoblastic cells (the trophoblast is the outermost layer of embryonic cells). This includes hydatidiform mole, invasive mole (chorioadenoma destruens), and choriocarcinoma.	<ul style="list-style-type: none"> Teach the woman about the need for regular screening for choriocarcinoma. Assess all pregnant women for symptoms of GTD, including vaginal bleeding that is brown with greater uterine enlargement than expected for gestational age. Follow quantitative hCG levels (discussed in greater detail in the Concept section of the module on Sexuality).

(continued on next page)

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPY
Hyperemesis gravidarum	Excessive vomiting during pregnancy that progress to a point at which the woman not only vomits everything she swallows but also retches between meals. Increased hCG levels may play a role.	<ul style="list-style-type: none"> Assess hydration. Administer IV fluids. Assess nutritional status. Total parenteral nutrition may be administered to prevent malnutrition. Keep patient away from food odors that may increase nausea and vomiting. Maintain oral hygiene. For more information on treating dehydration, see Exemplar 9.A, Fluid and Electrolyte Imbalance, in the module on Fluids and Electrolytes.
Hypertensive disorders	Preeclampsia, eclampsia, chronic hypertension, and gestational hypertension.	<ul style="list-style-type: none"> Nursing care focuses on prevention and early detection. For more information, see Exemplar 16.H, Hypertensive Disorders in Pregnancy, in the module on Perfusion.
Alloimmunization	Destruction of fetal hemoglobin. When the mother is Rh negative and the fetus is Rh positive, alloimmunization may occur in second and successive pregnancies if maternal-fetal blood mixture occurs, whether the pregnancy was carried to term or not. Alloimmunization causes fetal anemia, resulting in marked fetal edema (hydrops fetalis). Congestive heart failure may result. Marked jaundice leading to neurologic damage is also a risk.	<ul style="list-style-type: none"> Administer Rh immunoglobulin at 28 weeks of gestation if the pregnancy continues, or immediately following a spontaneous miscarriage if the mother is Rh negative and the father is Rh positive, or within 72 hours after delivery if the mother is Rh negative and the baby is Rh positive. Assess lab results for positive Coombs test, indicating sensitization, in which case Rh immunoglobulin is not administered.
ABO incompatibility	When a woman who has type O blood becomes pregnant with a type A, B, or AB fetus, causing interaction of antibodies present in maternal serum and the antigen sites on the fetal red blood cells. ABO incompatibility does not normally cause the severity of hemolysis seen with Rh incompatibility.	<ul style="list-style-type: none"> Assess blood type during prenatal care, and document so that the newborn can be followed after birth for potential hyperbilirubinemia if ABO incompatibility is likely.
Herpes simplex virus	Viral infection causing painful lesions in the genital area; may also occur on the cervix. This infection can profoundly affect the fetus. Primary infection has been associated with spontaneous abortion, low birth weight, and preterm birth. Transmission to the fetus usually occurs with membrane rupture and rarely via transplacental infection. If the fetus is infected, symptoms may include fever or hypothermia, jaundice, seizures, and poor feeding.	<ul style="list-style-type: none"> Prepare the mother for the need for cesarean birth if active lesions are present when she goes into labor.
Group B streptococcal (GBS) infection	Bacterial infection is found in the lower gastrointestinal or urogenital tracts of 10–40% of pregnant women (AAP & ACOG, 2012). Women may transmit GBS infection to their fetus in utero or during childbirth. GBS is one of the major causes of early-onset neonatal infection. Newborns become infected by vertical transmission from the mother during birth or by horizontal transmission from colonized nursing personnel or colonized babies. GBS causes severe, invasive disease in newborns.	<ul style="list-style-type: none"> Nursing care is focused on detection and early intervention during pregnancy in order to resolve the infection before delivery and, if not resolved prior, through prescribed IV antibiotics during labor.

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPY
Urinary tract infections	Dysuria, urgency, frequency; low-grade fever and hematuria. If not treated, infection may ascend and lead to acute pyelonephritis, which is associated with increased risk of premature birth and IUGR.	<ul style="list-style-type: none"> Nursing care is focused on teaching the woman the signs to report in order to allow quick intervention and to prevent potential complications. Oral sulfonamides taken in the last few weeks of pregnancy may lead to neonatal hyperbilirubinemia and kernicterus.
Vulvovaginal candidiasis	Fungal infection manifested by thick, white, curdy discharge as well as by severe itching, dysuria, and dyspareunia. If the infection is present at birth and the fetus is born vaginally, the fetus may contract thrush.	<ul style="list-style-type: none"> Nursing care is focused on teaching the woman the signs and symptoms of infection, preventive measures, and rapid recognition so that treatment can be initiated quickly.
Syphilis	Sexually transmitted infection manifested by chancre lasting 3–6 weeks, then often asymptomatic until Stage III. Syphilis can be passed transplacentally to the fetus. If untreated, one of the following can occur: second trimester abortion, stillborn baby at term, congenitally infected baby, or uninfected live newborn. (For more information, see Exemplar 19.E, Sexually Transmitted Infections, in the module on Sexuality.)	<ul style="list-style-type: none"> Screening for infections should be part of prenatal care in order to treat and eliminate the infection before delivery.

Assessment of Fetal Well-being

A number of tests are used to obtain accurate and helpful data about the developing fetus. At times, just one test is done; in other circumstances, a combination of testing is necessary. Some of these assessment techniques pose risks to the fetus and, possibly, to the pregnant woman; the risk to both should be considered before deciding to perform the test. The healthcare provider must be certain that the advantages outweigh the potential risks and added expense. In addition, the diagnostic accuracy and applicability of these tests may vary. Although some tests are for *screening* purposes, meaning that they indicate the fetus may be at risk for a certain disorder or anomaly, others are *diagnostic*, meaning that they can diagnose the abnormality. Not all high-risk pregnancies require the same tests.

Before administration of any screening or diagnostic test, the nurse should use the following guide to ensure that the patient knows the reason for performing the procedure:

- Assess whether the woman knows the reason why the screening or diagnostic test is being recommended:
 - “Has your physician or nurse-midwife told you why this test is necessary?”
 - “Sometimes tests are done for many different reasons. Can you tell me why you are having this test?”
 - “What is your understanding about what the test will show?”
- Provide an opportunity for questions:
 - “Do you have any questions about the test?”
 - “Is there anything that is not clear to you?”

- Explain* the test procedure, paying particular attention to any preparation the woman needs before the test:
 - “The test that has been ordered for you is designed to _____.” (*Add specific information about the particular test. Give the explanation in simple language.*)
- Validate the woman’s understanding of the preparation:
 - “Tell me what you will have to do to get ready for this test.”
- Give permission for the woman to continue to ask questions if needed:
 - “I’ll be with you during the test. If you have any questions at any time, please don’t hesitate to ask.”

Selected conditions that indicate a pregnancy is at risk include the following:

- Maternal age less than 16 or more than 35 years
- Chronic maternal hypertension, preeclampsia, diabetes mellitus, or heart disease
- Presence of Rh isoimmunization (immune response to foreign antigen Rh-positive cells)
- Maternal history of fetal demise (stillbirth)
- Suspected IUGR
- Pregnancy prolonged past 42 weeks of gestation
- Multiple gestation
- Prior preterm birth
- Previous pregnancy losses before 20 weeks’ gestation or diagnosed cervical insufficiency.

*For any procedure that requires consent, the healthcare provider should explain the procedure, not the nurse.

Maternal Assessment of Fetal Activity

Clinicians now generally agree that vigorous fetal activity provides reassurance of fetal well-being and that a marked decrease in activity or cessation of movement may indicate possible fetal compromise (or even death), requiring immediate follow-up (Blackburn, 2013). Maternal assessment is typically used to monitor fetal well-being beginning at approximately 28 weeks of gestation. It provides a low-technology, inexpensive means to evaluate fetal well-being. A reduction of fetal movement has been associated with fetal hypoxia, fetal growth restriction, and fetal death (Malm et al., 2014).

Although there is no standard definition of how many movements should occur within a specified time, if there are fewer than 10 movements in a 12-hour period, or fewer than three in a 1-hour period, or if the amount of movement is significantly less than normal, the woman should immediately notify her healthcare provider. A maternal perception

of decreased movement occurring during a 24-hour period should cause concern and warrant antepartum fetal testing.

Fetuses spend approximately 25% of their time making gross body movements. Fetal movements are directly related to the fetus's sleep-wake cycle and vary from the maternal sleep-wake cycle (Blackburn, 2013; O'Neill & Thorp, 2012). Fetuses may react to maternal hypoglycemia by decreasing their activity level. In women with a multiple gestation, daily fetal movements are significantly higher. After 38 weeks, fetuses spend 75% of their time in a quiet-sleep or active-sleep state. Other factors affecting fetal movement include sound, cigarette smoking, and drugs.

A variety of methods for tracking fetal activity have been developed. These methods focus on having the pregnant woman keep a fetal movement record, such as the Cardiff Count-to-Ten method (**Figure 33-28** ) or the Daily Fetal Movement Record (DFMR). A **fetal movement record** is a

Patient Teaching

Maternal Assessment of Fetal Activity

- Explain that fetal movements are first felt around 18 weeks of gestation. This is called *quickening*. From that time, the fetal movements get stronger and easier to detect. A slowing or stopping of fetal movement may be an indication that the fetus needs some attention and evaluation. The mother's perception of decreased fetal movement is sufficient in most cases. Formal tracking of fetal movement does not lead to improved outcomes in low-risk pregnancies but may have value in high-risk situations.
- Describe the procedures, and demonstrate how to assess fetal movement. Sit beside the woman and show her how to place her hand on the fundus to feel fetal movement. Advise the woman to keep a daily record of fetal movements beginning at about 28 weeks of gestation.
- Explain the procedure for the Cardiff Count-to-Ten method:
 - a. Beginning at the same time each day, have the woman place an X on the Cardiff card (Figure 33-28) for each fetal movement she perceives during normal everyday activity until she has recorded 10 of them.
 - b. Movement varies considerably, but the woman should feel fetal movement at least 10 times in 12 hours, and many women will feel 10 fetal movements in much less time, possibly 2 hours or less.
- Explain the procedure for the Daily Fetal Movement Record (DFMR) method:
 - a. The woman should begin counting at about the same time each day, after taking food.
 - b. She should lie quietly in a side-lying position.
 - c. The woman should feel at least three fetal movements within 1 hour.
- Instruct the woman to contact her care provider in the following situations:
 - a. Using the Cardiff method: If there are fewer than 10 movements in 12 hours.
 - b. Using the DFMR method: If there are fewer than three movements in 1 hour.
 - c. Both methods: If overall the fetus's movements are slowing, and it takes much longer each day to note the minimum number of movements in the specified time period, and if there are no movements in the morning.
 - d. If there are fewer than three movements in 8 hours.
- Whichever method she is using, encourage the woman to complete her fetal movement record daily and to bring it with her during each prenatal visit. Assure her that the record will be discussed at each prenatal visit and that questions may be addressed at that time if desired.
- Provide the woman with a name and phone number in case she has further questions.

noninvasive technique that enables the pregnant woman to monitor and record movements easily and without expense. See Patient Teaching: Maternal Assessment of Fetal Activity.

The expectant mother's perception of fetal movements and her commitment to completing a fetal movement record may vary. When a woman understands the purpose of the assessment, how to complete the form, whom to call with questions, and what to report—and has the opportunity for follow-up during each visit—she generally views completing the fetal movement record as an important activity. The nurse should be available to answer questions and clarify areas of concern.

Figure 33-29 » Ultrasound scanning permits visualization of the fetus in utero.

Ultrasound

Valuable information about the fetus may be obtained from **ultrasound** testing, in which intermittent ultrasonic waves (high-frequency sound waves) are transmitted by an alternating current to a transducer, which is applied to the woman's abdomen. The ultrasonic waves are deflected by tissues within the patient's abdomen, showing structures of varying densities (**Figures 33-29** » and **33-30** »).

Diagnostic ultrasound has several advantages. It is noninvasive, painless, and nonradiating to both the woman and the fetus. Serial studies (several ultrasound tests done over a span of time) may be done for assessment and comparison.

Figure 33-30 » Ultrasound of fetal face.

Soft-tissue masses (e.g., tumors) can be differentiated, the fetus can be visualized, fetal growth can be followed (especially in the presence of multiple gestation), cervical length and impending cervical insufficiency can be detected, and a number of other potential problems can be averted. In addition, the results are immediately available to the ultrasonographer and physician.

The use of four-dimensional ultrasound may eventually be able to generate future research regarding fetal well-being. Four-dimensional ultrasound combines the components of three-dimensional ultrasound with a fourth dimension, time, because it monitors live action. The technology produces images of photo-like quality, allowing healthcare providers to better visualize fetal structures and producing better guidance during invasive intrauterine procedures, such as amniocentesis and chorionic villus sampling. However, advanced 3D/4D techniques can increase the incidence of artifacts, or distortions, which could increase the need for additional scanning and increase parental anxiety (Malhotra et al., 2014).

Although ultrasound is believed to serve as a useful tool in monitoring the fetus throughout pregnancy, it does have limitations. Ultrasound is limited by maternal body habitus, fetal positioning, and technician or physician skill. Another limitation is that ultrasound cannot guarantee that a fetus does not have certain disorders or defects. Even though certain fetal problems can be diagnosed via the technology, sometimes abnormalities go unrecognized. A “normal” ultrasound is reassuring for the parents and the healthcare team, but it is important for parents to realize that a normal sonogram is not 100% reliable.

The two most common methods of ultrasound scanning are transabdominal and transvaginal.

Transabdominal Ultrasound

In the transabdominal approach, a transducer is moved across the patient’s abdomen. The woman is often scanned with a full bladder, because when the bladder is full, the examiner can assess other structures, especially the vagina and cervix, in relation to the bladder. The ability to see the lower portion of the uterus and cervix is particularly important when vaginal bleeding is noted and placenta previa is the suspected cause. The patient is directed to drink 1–1.5 quarts of water approximately 2 hours before the examination and to refrain from emptying her bladder. If the bladder is not sufficiently filled, she is asked to drink three to four 8-oz glasses of water and is rescanned 30–45 minutes later.

A water-based transmission gel is generously spread over the woman’s abdomen, and the sonographer slowly moves a transducer over the abdomen to obtain a picture of the uterine contents and surrounding structures. Ultrasound testing takes 20–30 minutes. The patient may feel discomfort caused by pressure applied over a full bladder. In addition, if the woman lies on her back during the test, she may develop shortness of breath. This may be relieved by elevating her upper body during the test.

Transvaginal Ultrasound

The transvaginal approach uses a probe inserted into the vagina. Once inserted, the transvaginal probe is close to the structures being imaged; therefore, it produces a clearer, more defined image. The improved images obtained by transvaginal ultrasound have enabled sonographers to identify struc-

tures and fetal characteristics earlier in pregnancy. Internal visualization can also be used as a predictor for preterm birth in high-risk patients (Cunningham et al., 2014). Use of the ultrasound technique to detect shortened cervical length or funneling (a cone-shaped indentation in the cervical os) is helpful in predicting preterm labor, especially in patients who have a history of preterm birth (Cunningham et al., 2014).

After the procedure is fully explained to the woman, she is prepared in the same manner as for a pelvic examination: in the lithotomy position, with appropriate drapes to provide privacy, and a female attendant in the room. It is important that her buttocks be at the end of the table so that, once inserted, the probe can be moved in various directions. A small, lightweight vaginal transducer is covered with a specially fitted sterile sheath, a condom, or one finger of a glove. Ultrasound gel is then applied to both the inside and outside of the covering, making insertion into the vagina easier and providing a medium for enhancing the ultrasound image. The transvaginal procedure can be accomplished with an empty bladder, and most women do not feel discomfort during the exam. The probe is smaller than a speculum, so insertion is usually completed with ease. The woman may feel the movement of the probe during the exam as various structures are imaged. Some patients may want to insert the probe themselves to enhance their comfort, whereas others would feel embarrassed even to be asked. The CNM, physician, or ultrasonographer offers the choice based on personal rapport with the patient.

Ultrasound testing can be of benefit in the following ways:

- **Early identification of pregnancy.** Pregnancy may be detected as early as the fifth or sixth week after the last menstrual period by assessing the gestational sac and the presence of a fetal heart rate (FHR) after 6 weeks of gestation.
- **Observation of fetal heartbeat and fetal breathing movements.** Fetal breathing movements have been observed as early as 11 weeks of gestation.
- **Identification of more than one embryo or fetus.**
- **Comparison of the biparietal diameter of the fetal head, head circumference, abdominal circumference, and femur length to assess growth patterns.** These measurements help determine the gestational age of the fetus and identify IUGR.
- **Clinical estimations of birth weight.** This assessment helps identify macrosomia (newborns > 4000 g at birth) and low-birth-weight newborns (babies < 2500 g at birth). Macrosomia has been identified as a predictor of birth-related trauma and is a risk factor for both maternal and fetal morbidity (Jazayeri, 2012). It is used only as a guideline in clinical decision making. Antenatal estimates of fetal weight are poor predictors of both actual fetal weight and outcomes in labor and birth.
- **Detection of fetal anomalies such as anencephaly and hydrocephalus.**
- **Examination of nuchal translucency in the first trimester to assess for Down syndrome and other fetal structural anomalies** (Sahota et al., 2012). Nuchal translucency describes an area in the back of the fetal neck that is measured via ultrasound during the first trimester of pregnancy. Nuchal translucency testing (NTT), also known as nuchal testing or nuchal fold testing, is performed at 11–13 weeks of gestation to screen for trisomies 13, 18, and 21 (Migueluez et al., 2012).

- **Examination of fetal cardiac structures (echocardiography).**
- **Length of fetal nasal bone.** The length of the fetal nasal bone during the NTT is used to indicate a risk factor for Down syndrome. Fetuses with a nonvisualized or shortened nasal bone are more likely to have trisomy 21 than are those with a normal-length nasal bone (Sonek et al., 2012).
- **Identification of amniotic fluid index (AFI).** Ultrasound can provide a rough measurement of the amount of amniotic fluid, which is an indicator of fetal well-being. The maternal abdomen is divided into quadrants using the umbilicus as the center point. The vertical diameter of the largest amniotic fluid pocket in each quadrant is measured. All measurements are totaled to obtain the AFI in centimeters. Women with an AFI of more than 24 cm are considered to have polyhydramnios (an excessive amount of amniotic fluid in the amniotic sac), and women with an AFI of less than 5 cm at term are considered to have oligohydramnios (not enough amniotic fluid). An AFI of between 5 and 24 cm is considered to be normal. After 39 weeks of gestation, the amniotic fluid volume begins to decline (Magann & Ross, 2014). Both polyhydramnios and oligohydramnios are associated with increased risk to the fetus, including nonreassuring fetal status, IUGR, meconium-stained amniotic fluid, and an increase in admissions to the neonatal intensive care unit.
- **Location of the placenta.** The placenta is located before amniocentesis to avoid puncturing it during the procedure. Ultrasound is valuable in identifying and evaluating placenta previa (Cunningham et al., 2014).
- **Placental grading.** As the fetus matures, the placenta calcifies. These changes can be detected by ultrasound and graded according to the degree of calcification. Placental grading can be used to identify internal placental vasculature, in which abnormalities can be associated with preeclampsia and chronic hypertension.
- **Detection of fetal death.** Inability to visualize the fetal heart beating and the separation of the bones in the fetal head are signs of fetal death.
- **Determination of fetal position and presentation.**
- **Accompanying procedures.** Ultrasound guidance is used in a variety of intrauterine procedures, including amniocentesis and chorionic villus sampling.

Nonstress Test

The **nonstress test (NST)**, a widely used method of evaluating fetal status, may be used alone or as part of a more comprehensive diagnostic assessment called a biophysical profile. The NST is based on the knowledge that when the fetus has adequate oxygenation and an intact CNS, accelerations of the FHR occur with fetal movement. An NST requires an external electronic fetal monitor to observe and record these FHR accelerations. A nonreactive NST is fairly consistent in identifying at-risk fetuses (Cunningham et al., 2014).

The advantages of the NST include the following:

- It is quick to perform, permits easy interpretation, and is inexpensive.

- It can be done in an office or clinic setting.
- It is a noninvasive procedure.
- There are no known side effects.

The disadvantages of the NST include the following:

- It is sometimes difficult to obtain a suitable tracing.
- The woman has to remain relatively still for at least 20 minutes.

Procedure for NST

The test can be done with the patient in a reclining chair or in bed with the patient in a left-tilted semi-Fowler or side-lying position. Research has shown that certain maternal positions can help produce more favorable results. Patients in left-tilted semi-Fowler, sitting, and left lateral positions are more likely to have a reactive tracing. Patients should not be placed in a supine position, because it decreases cardiac output and uterine perfusion, maternal back pain, and maternal shortness of breath (Cunningham et al., 2014). An electronic fetal monitor is used to obtain a tracing of the FHR and fetal movement. The nurse places the monitor under the woman's clothing. Privacy should be provided. The examiner puts two elastic belts on the patient's abdomen. One belt holds a device that detects uterine or fetal movement; the other belt holds a device that detects the FHR. As the NST is done, each fetal movement is documented so that associated or simultaneous FHR changes can be evaluated.

Interpretation of NST Results

An NST is indicated after 32 weeks at any time fetal well-being needs to be established. It may be used between 26 and 32 weeks with modified criteria for interpretation. The results of the NST are interpreted as follows:

- **Reactive test.** A reactive NST shows at least two accelerations of FHR with fetal movements of 15 beats/min, lasting 15 seconds or more, over 20 minutes (**Figure 33-31** »).
- **Nonreactive test.** In a nonreactive test, the reactive criteria are not met. For example, the accelerations do not meet the requirements of 15 beats/min or do not last 15 seconds (**Figure 33-32** »).
- **Unsatisfactory test.** An NST is unsatisfactory if the data cannot be interpreted or there was inadequate fetal activity.

It is important that anyone who performs the NST understand the significance of any decelerations of the FHR during testing. If decelerations are noted, the healthcare provider should be notified for further evaluation of fetal status.

Fetal Acoustic and Vibroacoustic Stimulation Tests

Acoustic (sound) and vibroacoustic (vibration and sound) stimulation of the fetus can be used as an adjunct to the NST. A handheld, battery-operated device is applied to the woman's abdomen over the area of the fetal head. This device generates a low-frequency vibration and a buzzing sound. These are intended to induce movement and associated accelerations of

Figure 33-31 » Example of a reactive nonstress test: accelerations of 15 beats/min lasting 15 seconds with each fetal movement (FM). Top of strip shows fetal heart rate (FHR); bottom of strip shows uterine activity tracing. Note that FHR increases (above the baseline) at least 15 beats and remains at that rate for at least 15 seconds before returning to the former baseline.

the FHR in fetuses with a nonreactive NST and in fetuses with decreased variability of the FHR during labor. The sound stimulus persists for 1 second; if no accelerations occur, it is then repeated at 1-minute intervals up to two times and then progresses to 2 seconds waiting 1 minute if no accelerations occur after the stimulus. Whether the fetus responds more to the vibration or to the sound is not known. Two FHR accelerations of 15 beats/min, lasting 15 seconds, in a 20-minute period indicate a reactive test (Cunningham et al., 2014).

Advantages of the fetal acoustic stimulation test and the vibroacoustic stimulation test include the following:

- Both are noninvasive techniques and are easy to perform.
- Results are rapidly available.
- Time for the NST is shortened.

Biophysical Profile

Use of the biophysical profile is indicated when there is risk of placental insufficiency or fetal compromise. The biophysical profile is a comprehensive assessment of five biophysical variables over a 30-minute period:

1. Fetal breathing movement
2. Fetal movements of body or limbs
3. Fetal tone (extension and flexion of extremities)
4. Amniotic fluid volume (visualized as pockets of fluid around the fetus)
5. FHR accelerations with activity (reactive NST).

The first four variables are assessed by ultrasound scanning; FHR reactivity is assessed with the NST. By combining

Figure 33-32 » Example of a nonreactive nonstress test. There are no accelerations of the fetal heart rate (FHR) with fetal movement (FM). Baseline FHR is 130 beats/min. The tracing of uterine activity is on the bottom of the strip.

TABLE 33-3 Criteria for Biophysical Profile Scoring

Component	Normal (Score = 2)	Abnormal (Score = 0)
Fetal breathing movements	≥1 episode of rhythmic breathing lasting ≥30 seconds within 30 minutes	≤30 seconds of breathing in 30 minutes
Gross body movements	≥3 discrete body or limb movements in 30 minutes (episodes of active continuous movement considered as single movement)	≤2 movements in 30 minutes
Fetal tone	≥1 episode of extension of a fetal extremity with return to flexion or opening or closing of hand	No movements or extension/flexion
Amniotic fluid volume	Single vertical pocket >2 cm AFI >5 cm	Largest single vertical pocket ≤2 cm AFI <5 cm
Nonstress test	≥2 accelerations of ≥15 beats/min for ≥15 seconds in 20–40 minutes	0 or 1 acceleration in 20–40 minutes

these five assessments, the biophysical profile helps to identify the compromised fetus or to confirm the healthy fetus and also provides an assessment of placental functioning.

Specific criteria for normal and abnormal assessments are presented in **Table 33-3** ». A score of 2 is assigned to each normal finding, and a score of 0 to each abnormal one, for a maximum score of 10. Scores of 8 and 10 are considered to be normal. Such scores have the least chance of being associated with a compromised fetus unless oligohydramnios is noted, in which case delivery of the fetus may be indicated (Thompson, Kuller, & Rhee, 2012).

Use of the biophysical profile may be indicated in the following conditions when there is risk of placental insufficiency or fetal compromise:

- IUGR
- Maternal diabetes mellitus
- Maternal heart disease
- Maternal chronic hypertension
- Maternal preeclampsia or eclampsia
- Maternal sickle cell disease
- Suspected fetal postmaturity (>42 weeks of gestation)
- History of previous stillbirths
- Rh sensitization
- Abnormal estriol excretion
- Hyperthyroidism
- Renal disease
- Nonreactive NST.

Contraction Stress Test

The **contraction stress test (CST)** is a means of evaluating the respiratory function (oxygen and carbon dioxide

exchange) of the placenta. It enables the healthcare team to identify the fetus at risk for intrauterine asphyxia by observing the response of the FHR to the stress of uterine contractions (spontaneous or induced). During contractions, intrauterine pressure increases, and blood flow to the intervillous space of the placenta is momentarily reduced, thereby decreasing oxygen transport to the fetus. A healthy fetus usually tolerates this reduction well and maintains moderate variability. If the placental reserve is insufficient, however, then fetal hypoxia, depression of the myocardium, and a decrease in variability to minimal or absent may occur, indicating an altered state in fetal oxygen reserve.

In many areas, the CST has given way to the biophysical profile. It is still used, however, in areas where the availability of other technology is reduced (e.g., during night shifts) or limited (e.g., at small community hospitals or birthing centers). It may also be used as an adjunct to other forms of fetal assessment.

The CST is contraindicated in the patient with third-trimester bleeding from placenta previa, marginal abruptio placentae or unexplained vaginal bleeding, previous cesarean section with classic incision (vertical incision in the fundus of the uterus), premature rupture of the membranes, cervical insufficiency, cerclage in place (gathering stitch around cervix), anomalies of the maternal reproductive organs, history of preterm labor (if being done before term), or multiple gestation.

The critical component of the CST is the presence of uterine contractions. These contractions may occur spontaneously, which is unusual before the onset of labor, or they may be induced (stimulated) with oxytocin (Pitocin) administered intravenously (also known as an oxytocin challenge test). A natural method of obtaining oxytocin is through the use of breast stimulation (either via nipple self-stimulation or application of an electric breast pump); the posterior pituitary produces oxytocin in response to stimulation of the breasts or nipples.

An electronic fetal monitor is used to provide continuous data about the FHR and uterine contractions. After a 15-minute baseline recording of uterine activity and FHR, the tracing is evaluated for evidence of spontaneous contractions. If three spontaneous contractions of good quality and lasting 40–60 seconds occur in a 10-minute window, the results are evaluated, and the test is concluded. If no contractions occur, or if the contractions that do occur are insufficient for interpretation, then intravenous administration of oxytocin, breast self-stimulation, or application of an electric breast pump is done to produce contractions of good quality. The CST should be conducted only in a setting where tocolytic medications are available if a tachysystole pattern occurs or if labor is stimulated from the test.

The CST is classified as follows:

- **Negative.** A negative CST shows three contractions of good quality lasting 40 seconds or longer in a 10-minute period without evidence of late decelerations. This is the desired result and implies that the fetus can handle the hypoxic stress of uterine contractions.
- **Positive.** A positive CST shows repetitive, persistent, late decelerations, in which the fetal heart rate decreases after

Figure 33-33 » Example of a positive contraction stress test. Repetitive late decelerations occur with each contraction. Note that there are no accelerations of fetal heart rate (FHR) with three fetal movements (FM). The baseline FHR is 120 beats/min. Uterine contractions (bottom half of strip) occurred four times in 12 minutes.

the onset of a contraction and recovers after the completion of a contraction, with more than 50% of the contractions (**Figure 33-33** »). This is not a desired result. The hypoxic stress of the uterine contraction causes a slowing of the FHR. The pattern will not improve, and will most likely get worse with additional contractions.

- **Equivocal.** An equivocal–suspicious test has non-persistent late decelerations associated with tachysystole (contraction frequency of every 2 minutes or duration lasting longer than 90 seconds). When this test result occurs, more information is needed (Davidson et al., 2017).
- **Unsatisfactory.** In an unsatisfactory CST, the quality of the tracing is too poor to accurately interpret FHR with contractions or the frequency of three contractions lasting 40–60 seconds occurring in a 10-minute window of time cannot be obtained for the end point of the test.

A negative CST implies that the placenta is functioning normally, fetal oxygenation is adequate, and the fetus will probably be able to withstand the stress of labor. If labor does not occur in the ensuing week, further testing is done.

A positive CST with a nonreactive NST presents evidence that the fetus will not likely withstand the stress of labor. A positive CST may be able to identify a compromised fetus earlier than a nonreactive NST because of the stimulated interruption of intervillous blood flow (Blackburn, 2013). Although a negative CST is reliable in predicting fetal status, a positive result needs to be verified, such as with a biophysical profile.

Amniotic Fluid Analysis

Amniocentesis is a procedure used to obtain amniotic fluid for genetic testing to determine fetal abnormalities or fetal lung maturity in the third trimester of pregnancy. During an amniocentesis, the physician scans the uterus using ultrasound to identify the fetal and placental positions and to identify adequate pockets of amniotic fluid. The skin is then

cleaned with a Betadine solution. The use of a local anesthesia at the needle insertion site is optional. A 22-gauge needle is then inserted into the uterine cavity to withdraw amniotic fluid (**Figure 33-34** »). After 15–20 mL of fluid has been removed, the needle is withdrawn, and the site is assessed for streaming (movement of fluid), which is an indication of bleeding. The FHR and maternal vital signs are then assessed. Rh immune globulin is given to all Rh-negative women. The analysis of amniotic fluid provides valuable information about fetal status. Amniocentesis is a fairly simple procedure, although complications do occur on rare occasions (<1% of cases).

A number of studies can be performed on amniotic fluid. These tests can provide information about genetic disorders, fetal health, and fetal lung maturity. Concentrations of certain substances in amniotic fluid provide information about the health status of the fetus. An amniocentesis is 99% accurate in diagnosing genetic abnormalities. Because gestational age, birth weight, and the rate of development of organ systems do not necessarily correspond, amniotic fluid may also be analyzed to determine the maturity of the fetal lungs. Determination of fetal lung maturity is important when making clinical decisions regarding the timing of birth for women who may have complications, such as preeclampsia or diabetes.

Lecithin/Sphingomyelin Ratio

The alveoli of the lungs are lined with a substance called **surfactant**, which is composed of phospholipids. Surfactant lowers the surface tension of the alveoli when the newborn exhales. When a neonate with mature pulmonary function takes its first breath, a tremendously high pressure is needed to open the lungs. By lowering the alveolar surface tension, surfactant stabilizes the alveoli, and a certain amount of air always remains in the alveoli during expiration. Thus, when the neonate exhales, the lungs do not collapse. A baby born before synthesis of surfactant is complete, however, is unable

Figure 33-34 » Amniocentesis. The woman is scanned by ultrasound to determine the placenta site and to locate a pocket of amniotic fluid. The needle is then inserted into the uterine cavity to withdraw amniotic fluid.

to maintain lung stability. Each breath requires the same effort as the first. This results in underinflation of the lungs and the development of respiratory distress syndrome.

Fetal lung maturity can be ascertained by determining the **lecithin/sphingomyelin (L/S) ratio**. Lecithin and sphingomyelin are two components of surfactant. Early in pregnancy, the sphingomyelin concentration in amniotic fluid is greater than the concentration of lecithin, and so the L/S ratio is low (i.e., lecithin levels are low, and sphingomyelin levels are high). At approximately 32 weeks of gestation, sphingomyelin levels begin to fall, and the amount of lecithin begins to increase. By 35 weeks of gestation, an L/S ratio of 4:1 is usually achieved in the normal fetus. An L/S ratio of 2:1 indicates that the risk of respiratory distress syndrome is very low. Under certain conditions of stress, such as a physiologic problem in the mother, placenta, and/or fetus (e.g., hypertension or placental insufficiency), the fetal lungs mature more rapidly (Angelini & Lafontaine, 2012).

Phosphatidylglycerol

Phosphatidylglycerol (PG) is another phospholipid in surfactant. PG is not present in the fetal lung fluid early in gestation. It appears when fetal lung maturity has been attained, at approximately 34 weeks of gestation. Because the presence of PG is associated with fetal lung maturity, when it is present, the risk of respiratory distress syndrome is low. Determination of PG is also useful in blood-contaminated

specimens. Because PG is not present in blood or vaginal fluids, its presence is reliable in predicting fetal lung maturity.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) involves obtaining a small sample of chorionic villi from the developing placenta.

The advantages of this procedure are early diagnosis and a short waiting time for results. Whereas amniocentesis is not done until at least 14 weeks of gestation, CVS is typically performed between 10 and 12 weeks of gestation. Previous studies that evaluated the use of CVS at 9 weeks of gestation found a possible association between limb-reduction birth defects and early CVS. Based on these findings, most practitioners do not recommend early CVS before 10 weeks of gestation (Cunningham et al., 2014). Risks of CVS include failure to obtain tissue, rupture of membranes, leakage of amniotic fluid, bleeding, intrauterine infection, maternal tissue contamination of the specimen, and Rh immunization.

Because CVS testing is performed so early in the pregnancy, it cannot detect neural tube defects. Patients who desire screening for neural tube defects would need a quadruple screening or the AFP component of first trimester integrated screening at 15–20 weeks of gestation.

The **quadruple screen** is a widely used test to screen for Down syndrome (trisomy 21), trisomy 18, and neural tube defects. The serum test assesses for appropriate levels of alpha-fetoprotein, human chorionic gonadotropin,

unconjugated estriol, and dimeric inhibin-A. A newer **penta screen** tests for all that the quadruple screen tests for and also tests for ventral abdominal wall defects. In recent years integrated screening for aneuploidy (chromosome abnormality) has been offered to pregnant women between 11 and 13 weeks' gestation. It consists of an early ultrasound which evaluates markers on the fetus (nasal bone and nuchal fold) and combines these with hCG, estriol, and inhibin A values to generate a more accurate risk profile for trisomy 13, 18, and 21 earlier in the pregnancy. A serum AFP and ultrasound for fetal anatomy are added between 18 and 20 weeks to determine risk or presence of a neural tube defect. Abnormal values on quadruple, penta, and integrated screens are indicators of increased risk only. They must be followed by a diagnostic amniocentesis from which a fetal karyotype is done (Messerlian et al., 2016). Another new development in the diagnosis of fetal aneuploidy is noninvasive prenatal testing (NIPT), also called cell free fetal DNA (cffDNA). This process detects fetal alleles in maternal serum and can provide accurate information on chromosomal abnormalities without the invasiveness and, albeit small, risk of amniocentesis from 9 weeks gestation onward (Wolfberg, 2016). Aneuploidy detection rates are similar for NIPT, CVS, and amniocentesis (King et al., 2013).

SAFETY ALERT When explaining options for genetic testing to expectant parents, inform them that even if a CVS shows no chromosomal abnormality, it cannot screen for neural tube defects. Patients who have a normal CVS and an abnormal quadruple screen test are to be offered amniocentesis. Patients with risk factors for neural tube defects may want to consider amniocentesis instead of CVS because amniocentesis screens for both types of disorders.

The nurse assists the physician during the amniocentesis or CVS and supports the woman undergoing the procedure. Although the physician has explained the procedure in advance so that the patient can give informed consent, the woman is likely to be apprehensive, both about the procedure itself and about the information it may reveal. She may become anxious during the procedure and need additional emotional support. The nurse can provide support by further clarifying the physician's instructions or explanations, by relieving the patient's physical discomfort when possible, and by responding verbally and physically to the woman's need for reassurance.

Factors Affecting Maternal Nutrition

A woman's nutritional status before and during pregnancy can significantly influence her health and that of her fetus. In most prenatal clinics and offices, nurses offer nutritional counseling directly or work closely with a nutritionist to provide nutritional assessment and teaching.

The following factors influence the pregnant woman's ability to achieve good prenatal nutrition:

- **General nutritional status before pregnancy.** Nutritional deficits, such as folic acid deficiency, present at the

time of conception and during the early prenatal period may influence the outcome of the pregnancy.

- **Maternal age.** An expectant adolescent must meet her own growth needs in addition to the nutritional needs of pregnancy.
- **Maternal parity.** The mother's nutritional needs and the outcome of the pregnancy are influenced by the number of pregnancies she has had and by the interval between them.

Fetal growth occurs in three overlapping stages:

1. Growth by increase in cell number
2. Growth by increases in cell number and cell size
3. Growth by increase in cell size alone.

Nutritional problems that interfere with cell division may have permanent consequences. If the nutritional insult occurs when cells are mainly enlarging, the changes are usually reversible when normal nutrition resumes.

Growth of fetal and maternal tissues requires increased quantities of essential dietary components. These are listed in the federal government's **Dietary Reference Intakes (DRIs)** as specific allowances for pregnant and lactating women (**Table 33-4** »). The DRIs are subdivided into the recommended dietary allowance (RDA) and adequate intake (AI). An RDA is the daily dietary intake that is considered to be sufficient to meet the nutritional requirements of nearly all individuals in a specific life stage and gender group. An AI is the value cited for a nutrient when the data are not sufficient to calculate an estimated average requirement. Most of the recommended nutrients can be obtained by eating a well-balanced diet each day. **Table 33-5** » is a sample daily food plan for pregnancy and lactation.

It is important to consider the many factors that affect a woman's nutrition. What environmental risks should the woman consider? What are her age, lifestyle, and culture? What food beliefs and habits does she have? What an individual eats is determined by availability, economics, and symbolism. These factors and others influence the expectant mother's acceptance of the nurse's intervention. For more information, see the module on Nutrition.

Socioeconomic Influences

Socioeconomic level may be a determinant of nutritional status. Families living at the poverty level cannot afford the same foods that higher-income families can. Thus, pregnant women with low incomes are frequently at risk for poor nutrition. Because access to healthy proteins and fresh fruits and vegetables is critical for pregnant women and very young children, federal, state, and local programs exist to provide at-risk women and their children with nutritional support. The largest program assisting low-income families and individuals is the Supplemental Nutrition Assistance Program (SNAP). This program works with state agencies, communities, educators, and faith-based organizations to provide nutrition assistance to those who qualify for benefits (U.S. Department of Agriculture, 2016). The largest program available for women and children is the Special Supplemental Nutrition

TABLE 33–4 Dietary Reference Intakes (DRIs) for Nonpregnant, Pregnant, and Lactating Females, Vitamins and Elements

	Age	Vitamin A (mcg/day)	Vitamin C (mg/day)	Vitamin D (mcg/day)	Vitamin E (mg/day)
Females	9–13 yr	600	45	15	11

Program for Women, Infants and Children (WIC) program, a federal program administered at the state level. WIC provides food vouchers and nutrition education to low-income and at-risk pregnant and postpartum women and for at-risk newborns/infants and children up to 5 years old.

» **Stay Current:** More information about the WIC program can be found at the program’s website, www.fns.usda.gov/wic.

Cultural, Ethnic, and Religious Influences

Cultural, ethnic, and religious backgrounds determine an individual’s experiences with food and influence that individual’s food preferences and habits (**Figure 33–35** »). Individuals of different nationalities are accustomed to

Figure 33–35 » Cultural factors affect food preferences and habits.

eating different foods because of the kinds of foodstuffs available in their countries of origin. The way food is prepared varies depending on the customs and traditions of the ethnic and cultural group. In addition, the laws of certain religions sanction particular foods, prohibit others, and direct the preparation and serving of meals. For an example, see the accompanying Focus on Diversity and Culture feature.

In each culture, certain foods have symbolic significance. Generally these symbolic foods are related to major life experiences such as birth and death. Although generalizations have been made about the food practices of ethnic and religious groups, there are many variations. The extent to which individuals continue to consume traditional ethnic foods and follow food-related ethnic customs

Focus on Diversity and Culture
The Kosher Diet

The kosher diet followed by many Jewish individuals forbids the eating of pork products and shellfish. Certain cuts of meat from sheep and cattle are allowed, as are fish with fins and scales. In addition, many Jews believe that meat and dairy products should not be mixed and eaten at the same meal. Findings from a study of Jewish women in southern Israel indicate that iron deficiency anemia is the most prevalent type of anemia among Jewish women (Treister-Goltzman, Peleg, & Biderman, 2015). Those who follow a kosher diet acknowledge the need for increased protein, vitamins, and other nutrients during pregnancy. The Jewish community encourages intake of healthy sources of nutrients in alignment with the practices defined in kosher dietary guidelines. Acceptable food choices include protein from fish, eggs, and some meat and poultry, as well as legumes combined with whole grains. Additional recommendations include the consumption of at least one serving of leafy green vegetables and one serving of orange vegetables each day.

TABLE 33–5 Daily Food Plan for Pregnancy and Lactation

Food Group	Nutrients Provided	Food Source	Recommended Daily Amount During Pregnancy	Recommended Daily Amount During Lactation
Dairy products	Protein; riboflavin; vitamins A, D, and others; calcium; phosphorus; zinc; magnesium	Milk—whole, 2%, skim, dry, buttermilk Cheeses—hard, semisoft, cottage Yogurt—plain, low-fat Soybean milk	Four 8-oz cups (five for teenagers) used plain or with flavoring, in shakes, soups, puddings, custards, cocoa Calcium in 1 cup of milk equivalent to 1 1/2 cups of cottage cheese; 1 1/2 oz of hard or semisoft cheese; 1 cup of yogurt; 1 1/2 cups of ice cream (high in fat and sugar)	Four 8-oz cups (five for teenagers); equivalent amount of cheese, yogurt, and so forth
Meat and meat alternatives	Protein; iron; thiamine, niacin, and other vitamins; minerals	Beef, pork, veal, lamb, poultry, animal organ meats, fish, eggs; legumes; nuts, seeds, peanut butter, grains in proper vegetarian combination (vitamin B ₁₂ supplement needed)	Three servings (one serving = 2 oz), combination in amounts necessary for same nutrient equivalent (varies greatly)	Two servings
Grain products, whole grain or enriched	B vitamins; iron; whole grain also has zinc, magnesium, and other trace elements; provides fiber	Breads and bread products such as cornbread, muffins, waffles, hotcakes, biscuits, dumplings, cereals, pastas, and rice	6–11 servings daily: one serving = one slice bread, 3/4 cup or 1 oz of dry cereal; 1/2 cup of rice or pasta	Same as for pregnancy
Fruits and fruit juices	Vitamins A and C; minerals; raw fruits for roughage	Citrus fruits and juices, melons, berries, all other fruits and juices	Two to four servings (one serving for vitamin C): one serving = one medium fruit, 1/2–1 cup of fruit; 4 oz of orange or grapefruit juice	Same as for pregnancy
Vegetables and vegetable juices	Vitamins A and C; minerals; provides roughage	Leafy green vegetables; deep yellow or orange vegetables such as carrots, sweet potatoes, squash, tomatoes; green vegetables, such as peas, green beans, and broccoli; other vegetables, such as beets, cabbage, potatoes, corn, and lima beans	Three to five servings (one serving of dark green or deep yellow vegetable for vitamin A): one serving = 1/2 – 1 cup of vegetables; two tomatoes; one medium potato	Same as for pregnancy
Fats	Vitamins A and D; linoleic acid	Butter, cream cheese, fortified table spreads; cream, whipped cream, whipped toppings; avocado, mayonnaise, oil, nuts	As desired in moderation (high in calories): one serving = 1 tbsp butter or enriched margarine	Same as for pregnancy
Sugar and sweets		Sugar, brown sugar, honey, molasses, agave syrup	Occasionally, if desired	Same as for pregnancy
Desserts		Nutritious desserts such as fruits, puddings, custards, fruit whips, and crisps; other rich, sweet desserts and pastries	Occasionally, if desired	Same as for pregnancy
Beverages	Fluid	Coffee, decaffeinated beverages, tea, bouillon, carbonated drinks	As desired, in moderation	Same as for pregnancy
Miscellaneous		Iodized salt, herbs, spices, condiments	As desired	Same as for pregnancy

Note: The pregnant woman should eat regularly, three meals a day, with nutritious snacks of fruit, cheese, milk, or other foods between meals if desired. (More frequent but smaller meals are also recommended.) Between four and six 8-oz glasses of water, and a total of between eight and ten 8-oz cups of total fluid intake, should be consumed daily. Water is an essential nutrient.

is affected by the extent of their exposure to other cultures and by the availability, quality, and cost of traditional foods.

When working with pregnant women from any ethnic background, the nurse should understand the impact of the woman's cultural and spiritual beliefs on her eating habits and identify any beliefs she may have about food and pregnancy. Talking with the woman can help the nurse determine the level of influence that traditional food customs exert. The nurse can then provide dietary advice that is meaningful to the woman and her family.

Psychosocial Influences

The nurse should be aware of the various psychosocial factors that influence a woman's food choices. The sharing of food has long been a symbol of friendliness, warmth, and social acceptance in many cultures. Some foods and food practices are associated with status. Some foods are prepared "just for company"; others are served only on special occasions or holidays.

Knowledge about the basic components of a balanced diet is essential. Often, educational level is related to economic status, but even individuals with very limited incomes

can prepare well-balanced meals if their knowledge of nutrition is adequate.

The expectant woman's attitudes and feelings about her pregnancy influence her nutritional status. For example, foods may be used as a substitute for expressing emotions, such as anger or frustration, or as a way of expressing feelings of joy. The woman who is depressed or does not wish to be pregnant may manifest these feelings through loss of appetite or overindulgence in certain foods.

Eating Disorders

Two serious eating disorders, anorexia nervosa and bulimia nervosa, develop most commonly in adolescent girls and young women. These conditions are described fully in Exemplar 29.A, Feeding and Eating Disorders, in the module on Self.

Women with eating disorders who become pregnant are at risk for a variety of complications. The consequences of the restricting, bingeing, and purging behaviors characteristic of eating disorders can result in a lack of nutrients being available for the fetus. These patients are at increased risk for miscarriage, hyperemesis gravidarum, preeclampsia, and birth complications, whereas their babies have an increased incidence of preterm birth, low birth weight, low Apgar scores (see Exemplar 33.D, Newborn Care, for a discussion of Apgar scores), and intrauterine death (Micali et al., 2012).

Pregnancy can be an especially difficult time for the woman with an eating disorder, even if she has long desired a child. The consumption of additional food and the expectations that she will gain additional weight can result in feelings of fear, anxiety, depression, and guilt. Women with eating disorders also have high rates of postpartum depression (Micali et al., 2012).

When a pregnant woman has an eating disorder, education and individualized meal plans can help the patient increase her dietary intake while maintaining a sense of control. A multidisciplinary approach to treatment, involving medical, nursing, psychiatric, and dietetic practitioners, is indicated. Pregnant women with eating disorders need to be closely monitored and supported throughout their pregnancies.

Pica

Pica is the craving for and persistent eating of nonnutritive substances not ordinarily considered to be edible or nutritionally valuable, such as soil, clay, and soap. Pica appears to occur worldwide but is underreported because women are often embarrassed to discuss it. In the United States, pica is more common among women who are economically disadvantaged, are of African American descent, live in rural areas, practiced pica before pregnancy, belong to a culture that encourages pica as important for fertility, and have family members who also practice pica (Ellis & Schnoes, 2012).

Iron deficiency anemia is the most common concern in pica. The connection of ice pica to iron deficiency is well known, but it is unclear if ingestion of large amounts of ice is a sign of iron deficiency or a contributing factor. However, the pica often resolves with iron supplementation (King et al., 2013). The ingestion of laundry starch or certain types of clay may contribute to iron deficiency because they interfere

with iron absorption. The ingestion of large quantities of clay could fill the intestine and cause fecal impaction, and the ingestion of starch may be associated with excessive weight gain. Lead poisoning, one of the most serious complications that can result from *geophagia* (eating soil or clay), may affect both the mother and her fetus. Geophagia may produce soil-borne parasitic infections, such as toxoplasmosis and toxocariasis. Gastrointestinal (GI) tract complications resulting from pica can be mechanical bowel problems, constipation, ulcerations, perforations, and intestinal obstructions. It also can result in impaired cognitive functioning, kidney damage, and encephalopathy. Consequently, blood lead levels should be determined in cases of diagnosed or suspected geophagia.

The nurse should be aware of pica and its implications for the woman and fetus. Assessment for pica is an important part of a nutritional history. However, a patient may be embarrassed about her cravings or reluctant to discuss them for fear of criticism. Using a nonjudgmental approach, the nurse can provide the woman with information that is useful in decreasing or eliminating this practice.

Vegetarianism

Vegetarianism is the dietary choice of many individuals for religious, health, or ethical reasons. There are several types of vegetarians. **Lacto-ovovegetarians** include milk, dairy products, and eggs in their diets. **Lactovegetarians** include dairy products but no eggs in their diets. **Vegans** will not eat any food from animal sources.

The expectant woman who is vegetarian must eat the proper combination of foods to obtain adequate nutrients. If her diet allows, the woman can obtain ample and complete proteins from dairy products and eggs. Plant protein quality can be improved if it is consumed with these animal proteins.

If the woman follows a vegan diet, careful planning is necessary to obtain complete proteins and sufficient calories. An adequate, pure vegan diet contains protein from unrefined grains (brown rice, whole wheat), legumes (beans, split peas, lentils), nuts in large quantities, and a variety of cooked and fresh vegetables and fruits. Adequate dietary protein can be obtained by consuming a varied diet with complementary amino acids, which together provide complete proteins. Complete proteins can be obtained by eating different types of plant-based proteins, such as beans and rice, peanut butter on whole-grain bread, and whole-grain cereal with soy milk, either in the same meal or over a day. Seeds may provide adequate protein in the vegetarian diet if the quantity is large enough. Obtaining sufficient calories to ensure adequate weight gain can be difficult, however, because vegan diets tend to be high in fiber and therefore filling. **Figure 33-36** » depicts a vegetarian food pyramid with suggestions for daily servings.

Both lacto-ovovegetarians and vegans should eat four servings of vitamin B₁₂-fortified foods (meat substitutes, tofu, cereals, soy milk, and nutritional yeast) daily. A daily supplement of vitamin B₁₂ is also recommended during pregnancy and while breastfeeding (London et al., 2017).

The best sources of iron and zinc are animal products; consequently, vegan diets may also be low in these minerals. In addition, a high fiber intake may reduce mineral (calcium,

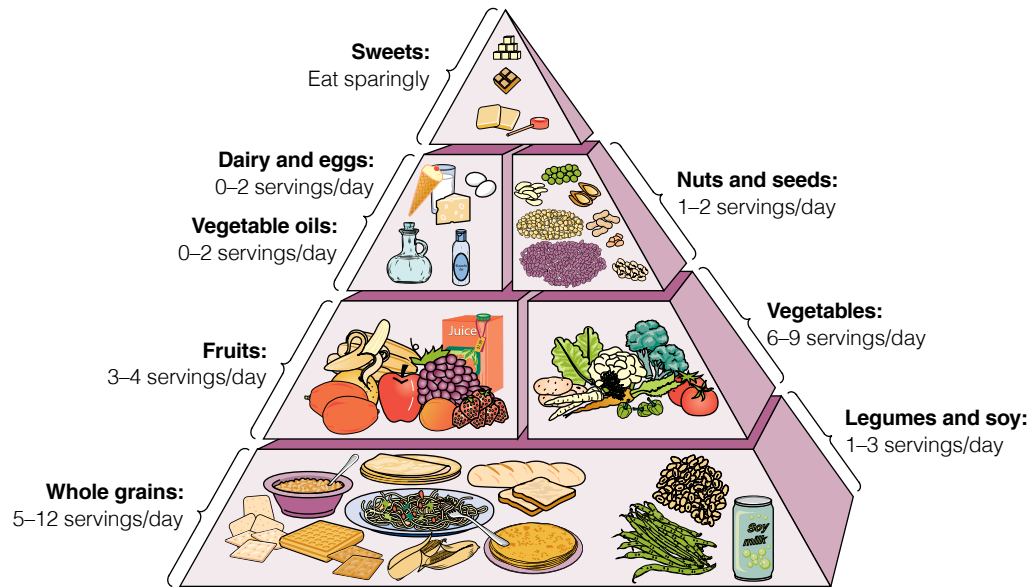

Figure 33–36 » The vegetarian food pyramid.

iron, and zinc) bioavailability. Thus, pregnant women who are vegetarians should be advised to have approximately 1200–1500 mg/day of calcium, which is higher than the recommended levels for patients who are omnivores. Vitamin D supplements may be indicated for women who do not have adequate exposure to sunlight (Baggerly et al., 2015).

To achieve optimal nutrition, the nurse should emphasize the use of foods that are nutrient dense and that provide a balanced diet. A vegetarian food group guide appears in **Table 33–6** ».

Special Dietary Considerations

The pregnant woman must carefully consider choices regarding foods and food additives. These include maintaining adequate levels of folic acid, use of artificial sweeteners, mercury levels in fish, and lactose intolerance.

Folic Acid

Folic acid, or folate, is required for normal growth, reproduction, and lactation and prevents the macrocytic, megaloblastic anemia of pregnancy. Megaloblastic anemia caused by folate deficiency is rarely found in the United States, but it does occur.

Even more significantly, an inadequate intake of folic acid has been associated with fetal neural tube defects (spina bifida, meningomyelocele). Although these defects are considered to be multifactorial, research indicates that 50–70% of spina bifida and anencephaly cases could be prevented by adequate intake of folic acid (ACOG, 2014; CDC, 2015a). Experts recommend that all women of childbearing age (15–45 years) consume 400 mcg of folic acid daily because half of all U.S. pregnancies are unplanned and neural tube defects occur very early in pregnancy (3–4 weeks after conception), before most women realize they are pregnant (CDC, 2015a). The best food sources of folate are fresh green leafy vegetables, liver, peanuts, and whole-grain breads and cereals. Folic acid can be made inactive by oxidation, ultra-violet light, and heating. It can easily be lost during improper storage and cooking. To prevent unnecessary loss, foods should be stored covered to protect them from light, cooked with only a small amount of water, and not overcooked.

Use of Artificial Sweeteners

Sweeteners classified as *Generally Recognized as Safe* (GRAS) by the FDA are acceptable for use during pregnancy. As with other foods, moderation should be exercised when using artificial sweeteners, such as saccharin, which can cross the

TABLE 33–6 Vegetarian Food Groups

Food Group	Mixed Diet	Lacto-Ovovegetarian	Lactovegetarian	Vegan
Grain	Bread, cereal, rice, pasta	Bread, cereal, rice, pasta	Bread, cereal, rice, pasta	Bread, cereal, rice, pasta
Fruit	Fruit, fruit juices	Fruit, fruit juices	Fruit, fruit juices	Fruit, fruit juices
Vegetable	Vegetables, vegetable juices	Vegetables, vegetable juices	Vegetables, vegetable juices	Vegetables, vegetable juices
Dairy and dairy alternatives	Milk, yogurt, cheese	Milk, yogurt, cheese	Milk, yogurt, cheese	Fortified soy milk, rice milk, almond milk
Meat and meat alternatives	Meat, fish, poultry, eggs, legumes, tofu, nuts, nut butters	Eggs, legumes, tofu, nuts, nut butters	Legumes, tofu, nuts, nut butters	Legumes, tofu, nuts, nut butters

placenta and may remain in fetal tissues. Aspartame also appears to be safe if used within FDA guidelines. Women affected by phenylketonuria should avoid aspartame because it contains phenylalanine. Splenda, or sucralose, is another artificial sweetener that is available to the public. The manufacturers of Splenda and Truvia (stevia) claim that they have no effects on fetal or neonatal development and are therefore safe for use by pregnant or lactating women.

Mercury in Fish

Seafood is an important source of omega-3 fatty acids, which are essential for neural development in the fetus. Of particular interest are the omega-3 fatty acids and their derivative, docosahexaenoic acid (DHA). Maternal dietary intake of DHA during pregnancy may reduce the risk of preterm birth and low birth weight and may enhance fetal and newborn/infant brain development (Carlson et al., 2013). Although the omega-3 in fish is beneficial, pregnant women need to be aware that fish can also contain mercury. Nearly all fish and shellfish contain traces of mercury. Although this is not a concern for most individuals, some fish and shellfish contain higher levels of mercury than others, and mercury can pose a threat to the developing nervous system of a fetus or young child. Mercury exposure also can have a negative effect on cognitive functioning, resulting in deficiencies in language, attention, motor function, memory, and visual-spatial abilities (Solan & Lindow, 2014). Consequently, pregnant women need information about the importance of seafood in their diet, but also need to know that they should consume seafood that is low in mercury. The U.S. government has issued the following guidelines for women who are pregnant or may become pregnant, breastfeeding mothers, and young children (Agency for Toxic Substance and Disease Registry [ATSDR], 2013):

- Do not eat swordfish, shark, tilefish, or king mackerel, because these fish contain high levels of mercury.
- Eat up to 12 oz/week (two average meals) of a variety of shellfish and fish that are lower in mercury. Commonly eaten fish that are lower in mercury include canned light tuna, shrimp, salmon, catfish, and pollack. Albacore (white) tuna has more mercury than canned light tuna; therefore, only 6 oz/week of albacore tuna is recommended.
- Check local advisories about the mercury content of fish caught by family and friends. If no information is available, limit fish caught in local areas to 6 oz/week, and avoid consuming additional fish that week.

Lactase Deficiency (Lactose Intolerance)

Some individuals have difficulty digesting milk and milk products. This condition, known as **lactase deficiency** or **lactose intolerance**, results from an inadequate amount of the enzyme lactase, which breaks down the milk sugar lactose into smaller, digestible substances.

Lactase deficiency is found in many adults of African, Mexican, Native American, Ashkenazi Jewish, and Asian descent and, indeed, in many other adults worldwide. Individuals who are not affected are mainly of northern European heritage. Symptoms include abdominal distention, discomfort, nausea, vomiting, loose stools, and cramps.

When counseling pregnant women who might be intolerant of milk and milk products, the nurse should be aware that even one glass of milk can produce symptoms. Milk in cooked form, such as custards, is sometimes tolerated, as are cultured or fermented dairy products, such as buttermilk, some cheeses, and yogurt. Lactase deficiency need not be a problem for pregnant women, because the enzyme is available over the counter in tablets or drops. Lactase-treated milk is also available commercially in most large grocery stores. For more information about lactase deficiency, see Exemplar 4.C, Malabsorption Disorders, in the module on Digestion.

Foodborne Illnesses

Foodborne illnesses should be avoided by any individual, but especially by the pregnant woman because they pose a threat to both fetus and mother. The nurse should provide patient teaching about salmonella, listeriosis, and hepatitis E.

Salmonella

Because of the risk for *Salmonella* contamination in raw eggs, advise pregnant women to avoid eating or tasting foods that may contain raw or lightly cooked eggs. These foods include cake batter; homemade eggnog; sauces made with raw eggs, such as Caesar salad dressing; and homemade ice cream (FDA, 2013).

Listeriosis

Listeria monocytogenes is another bacterium that poses a threat to an expectant mother and her fetus. *Listeria* is especially challenging because the organism can be found in refrigerated, ready-to-eat foods, such as unpasteurized milk and dairy products, meat, poultry, and seafood. To prevent listeriosis, advise pregnant women to do the following (FDA, 2013):

- Maintain the refrigerator at a temperature of 4°C (40°F) or below and the freezer at -18°C (0°F).
- Refrigerate or freeze prepared foods, leftovers, and perishables within 2 hours after eating or preparation.
- Do not eat hot dogs, deli meats, or luncheon meats unless they are reheated until steaming hot.
- Avoid soft cheeses, such as feta, brie, Camembert, blue-veined cheeses, queso fresco, or queso blanco (a soft cheese often used in Hispanic cooking) unless the label clearly states that they are made with pasteurized milk.
- Do not eat refrigerated pâtés or meat spreads or foods that contain raw (unpasteurized) milk. Do not drink unpasteurized milk.
- Avoid eating refrigerated smoked seafood, such as salmon, trout, cod, tuna, or mackerel, unless it is in a cooked dish, such as a casserole. Canned or shelf-stable pates, meat spreads, and smoked seafood are considered safe.

Hepatitis E

Hepatitis E is a viral infection found most often in developing countries. This disease is spread through the feces of infected people or animals and is transmitted most often through unclean drinking water, but it can also be contracted by eating contaminated food. Hepatitis E is often more

severe in pregnant women, especially during the third trimester, and may lead to maternal death (Gurley et al., 2012).

To prevent hepatitis E, pregnant women should wash their hands thoroughly after using the bathroom, changing diapers, or handling raw foods. When traveling to areas where the quality of the water is uncertain, they should avoid eating raw foods, unpeeled fruit, and uncooked fish. They should also avoid drinking tap water or using ice made with tap water. Rather, they should use bottled or boiled water for drinking, tooth brushing, and formula preparation (Gurley et al., 2012).

Maternal Weight Gain

Maternal weight gain is an important factor in fetal growth and neonatal birth weight. The optimal weight gain depends on the woman's weight for height (body mass index [BMI]) and her prepregnant nutritional state. An adequate weight gain indicates an adequate caloric intake. It does not, however, ensure that the woman has a sufficient nutrient intake. The pregnant woman must maintain the nutritional quality of her diet as her weight gain progresses.

The Institute of Medicine (2009) recommends weight gains in terms of optimal ranges based on prepregnant BMI, and ACOG (2013e) supports these recommendations. The IOM recommendations are shown in **Table 33-7** ».

The pattern of weight gain is important. The ideal pattern for a normal-weight woman consists of a gain of 0.9–1.8 kg (2.0–4.0 lb) during the first trimester, followed by a gain of approximately 0.3–0.5 kg (0.8–1 lb) per week during the second and third trimesters. The rate of weight gain in the second and third trimesters needs to be slightly higher for underweight women, and slightly lower (0.5–0.7 lb/week) for overweight women and 0.4–0.6 lb/week for women with obesity (ACOG, 2013e; IOM, 2009). A normal-weight woman who is expecting twins is advised to gain approximately 0.7 kg (1.5 lb) per week during the second and third trimesters of her pregnancy. Inadequate maternal weight gain has been associated with preterm birth and its associated problems for the newborn (ACOG, 2013e; IOM, 2009).

Obesity is becoming a major health problem in many developed countries, and more and more women are entering pregnancy already overweight or obese. Pregnant women who are obese are at an increased risk for medical and pregnancy-related complications, such as spontaneous abortion, gestational diabetes, preeclampsia, labor induc-

Figure 33-37 » It is important to monitor a pregnant woman's weight over time.

tion, and cesarean birth. They also have a higher incidence of fetal anomalies. They should be considered to be at high risk and counseled accordingly (ACOG, 2013e).

Maternal obesity also has implications for children. The children of mothers who are overweight and obese are predisposed to developing obesity and its related health concerns. In fact, the child of an overweight mother is three times more likely to be overweight by the age of 7 than is a child of a normal-weight mother (Ballogh, 2015).

Because of the association between maternal weight gain and pregnancy outcome, most healthcare providers pay close attention to weight gain during pregnancy (**Figure 33-37** »). Weight gain charts can be useful in monitoring the rate and pattern of weight gain over time.

Excessive weight gain during pregnancy also has long-term implications because weight gain during pregnancy is by far the most important predictor of the amount of weight that a woman will retain following childbirth (ACOG, 2013e). Counseling the pregnant woman to eat a variety of

TABLE 33-7 Institute of Medicine Weight Gain Recommendations for Pregnancy

Prepregnancy Weight Category	Body Mass Index*	Recommended Range of Total Weight (lb)	Recommended Rates of Weight Gain† in the Second and Third Trimesters (lb) (Mean Range [lb/wk])
Underweight	<18.5	28–40	1 (1–1.3)
Normal weight	18.5–24.9	25–35	1 (0.8–1)
Overweight	25–29.9	15–25	0.6 (0.5–0.7)
Obese (includes all classes)	30+	11–20	0.5 (0.4–0.6)

*Body mass index is calculated as weight in kilograms divided by height in meters squared, or as weight in pounds multiplied by 703 divided by square of height in inches.

†Calculations assume a 1.1- to 4.4-lb weight gain in the first trimester.

Figure 33–38 » ChooseMyPlate identifies the basic food groups and provides guidance about healthful eating. Grains, vegetables, and fruits are emphasized, with slightly less emphasis on dairy and protein. MyPlate is designed to remind Americans to eat healthfully.

nutrients from each of the food groups places less emphasis on the amount of her weight gain and more on the quality of her intake. It may also be helpful to encourage the woman to begin a simple exercise program such as walking.

The federal government's newly designed food choice program, ChooseMyPlate, offers users a colorful plan that emphasizes variety, proportionality, moderation, and physical activity. It is also designed to help guide individuals to make healthier choices (**Figure 33–38** »).

» **Stay Current:** Go to www.choosemyplate.gov/pregnancy-breast-feeding.html to see the USDA's nutrition recommendations for pregnant women and to <https://www.choosemyplate.gov/MyPlate-Daily-Checklist> to see how women can get a personalized "MyPlate Daily Checklist" using ChooseMyPlate's SuperTracker.

SAFETY ALERT Weight varies with time of day, amount of clothing, inaccurate scale adjustment, or weighing error. Do not over-emphasize a single weight; rather, pay attention to the overall pattern of weight gain.

Lifespan Considerations

The adolescent and the woman over age 35 have specific physiologic, psychologic, and care concerns during their pregnancies. Some of those considerations are discussed in this section.

Considerations for Adolescent Pregnancy

Nutritional care of the pregnant adolescent is of particular concern to healthcare professionals. Many adolescents are nutritionally at risk because of a variety of complex and

interrelated emotional, social, and economic factors. Important nutrition-related factors to assess in pregnant adolescents include low prepregnant weight, low weight gain during pregnancy, young age at menarche, smoking, excessive prepregnant weight, anemia, unhealthy lifestyle (drug or alcohol use), chronic disease, and history of an eating disorder.

Estimates regarding the nutritional needs of adolescents are generally determined by using the DRIs for nonpregnant teenagers (age 11–14 or 15–18) and adding nutrient amounts recommended for all pregnant women (see Table 33–4). If the pregnant adolescent is physiologically mature (> 4 years since menarche), her nutritional needs approach those reported for pregnant adults. However, adolescents who become pregnant less than 4 years after menarche are at risk because of their physiologic and anatomic immaturity. These adolescents are more likely than older adolescents to still be growing, which can affect the fetus's development. Thus, young adolescents (age 14 and younger) need to gain more weight than older adolescents (age 18 and older) to produce babies of equal size.

In determining the optimal weight gain for the pregnant adolescent, the nurse adds the recommended weight gain for an adult pregnancy to that expected during the postmenarchal year in which the pregnancy occurs. If the teenager is underweight, additional weight gain is recommended to bring her to a normal weight for her height.

Specific Nutrient Concerns

Caloric needs of pregnant adolescents vary widely. Major factors in determining caloric needs include the physical activity level of the individual and whether her growth is complete. Figures as high as 50 kcal/kg have been suggested for young, pregnant adolescents who are very active physically. A satisfactory weight gain usually confirms an adequate caloric intake.

An inadequate iron intake is a major concern with the adolescent diet. Iron needs are high for the pregnant teen because of the requirement for iron by the enlarging maternal muscle mass and blood volume. Iron supplements—providing between 30 and 60 mg of elemental iron—are definitely indicated.

Calcium is another nutrient that demands special attention from pregnant adolescents. Inadequate intake of calcium is frequently a problem in this age group. Adequate calcium intake is necessary to support the normal growth and development of the fetus and the growth and maintenance of calcium stores in the adolescent. An extra serving of dairy products or other calcium-rich foods is usually suggested for teenagers. Calcium supplementation is indicated for teens who do not consume dairy products or other significant calcium sources in sufficient quantities.

Because folic acid plays a role in cell reproduction, it is also an important nutrient for pregnant teens. As previously indicated, a supplement is usually recommended for all pregnant women, regardless of age.

Other nutrients and vitamins must be considered when evaluating the overall nutritional quality of the teenager's diet. Nutrients that have been found to be deficient in this age group include zinc and vitamins A, D, and B₆. Inclusion of a wide variety of foods—especially fresh and lightly processed foods—is helpful in obtaining adequate amounts of trace minerals, fiber, and vitamins.

Dietary Patterns

Healthy adolescents often have irregular eating patterns. Many skip breakfast, and most tend to be frequent snackers. Teens rarely follow the traditional three-meals-a-day pattern. Their day-to-day intake often varies drastically, and many eat food combinations that may seem bizarre to adults. Despite these practices, adolescents usually achieve a better nutritional balance than most adults would expect.

In assessing the diet of the pregnant adolescent, the nurse should consider the eating pattern over time, not simply a single day's intake. Once the pattern is identified, the nurse can direct counseling toward correcting deficiencies.

Counseling Issues

Counseling about nutrition and healthy eating practices is an important element of care for pregnant teenagers that nurses can provide effectively in a community setting. This counseling may be individualized, involve other teens, or provide a combination of both approaches. If an adolescent's family member does most of the meal preparation, it may be useful to include that individual in the discussion if the adolescent agrees. Involving the expectant father in counseling may also be beneficial. Clinics and schools often offer classes and focused activities designed to address this topic.

The pregnant teenager's understanding of nutrition will influence not only her well-being but also that of her child. However, teens tend to live in the present, and counseling that stresses long-term changes may be less effective than more concrete approaches. In many cases, group classes are effective, especially those that include other teens. In a group atmosphere, adolescents often work together to plan adequate meals, including foods that are special favorites.

Risks to the Adolescent Mother

There may be physiologic, psychologic, and sociologic risks for the pregnant adolescent.

Physiologic Risks

Adolescents older than 15 years who receive early, thorough prenatal care are at no greater risk during pregnancy than women older than age 20. Unfortunately, adolescents often begin prenatal care later in pregnancy than other age groups. Thus, risks for pregnant adolescents include preterm births, low-birth-weight newborns, cephalopelvic disproportion, iron deficiency anemia, and preeclampsia and its sequelae. In the adolescent age group, prenatal care is the critical factor that most influences pregnancy outcome.

Teenagers age 15 to 19 have a high incidence of STIs, including herpes virus, syphilis, and gonorrhea (U.S. Preventive Services Task Force, 2014). The incidence of chlamydial infection is also increased in this age group. The presence of such infections during a pregnancy greatly increases the risk to the fetus. Other problems seen in adolescents are cigarette smoking and drug use. By the time pregnancy is confirmed, the fetus may already have been harmed by these substances.

Psychologic Risks

The major psychologic risk to the pregnant adolescent is the interruption of her developmental tasks. Adding the tasks of pregnancy to her own developmental tasks creates a huge amount of psychologic work, the completion of which will affect the adolescent's and her newborn's futures. **Table 33-8** suggests typical behaviors of the adolescent when she becomes aware of her pregnancy. In reviewing

TABLE 33-8 Initial Reaction to Awareness of Pregnancy

Age	Adolescent Behavior	Nursing Implications
Early adolescent (14 years and younger)	Fears rejection by family and peers. Enters healthcare system with an adult, most likely mother (parents still seen as locus of control). Value system closely reflects that of parents, so teen turns to parents for decisions or approval of decisions. Pregnancy probably not a result of intimate relationship. Is self-conscious about normal adolescent changes in body. Self-consciousness and low self-esteem likely to increase with rapid breast enlargement and abdominal enlargement of pregnancy.	Be nonjudgmental in approach to care. Focus on needs and concerns of adolescent, but if parent accompanies daughter, include parent in plan of care. Encourage both to express concerns and feelings regarding pregnancy and options: abortion, maintaining pregnancy, adoption. Be realistic and concrete in discussing implications of each option. During physical exam of adolescent, respect increased sense of modesty. Explain in simple and concrete terms physical changes that are produced by pregnancy versus puberty. Explain each step of physical exam in simple and concrete terms.
Middle adolescent (15–17 years)	Fears rejection by peers and parents. Unsure of whom to confide in. May seek confirmation of pregnancy on own with increased awareness of options and services, such as over-the-counter pregnancy kits and Planned Parenthood. If in an ongoing, caring relationship with partner (peer), may choose him as confidant. Economic dependence on parents may determine if and when parents are told. Future educational plans and perception of parental support or lack of support are significant factors in decision regarding termination or maintenance of the pregnancy. Possible conflict between parental and own developing value system.	Be nonjudgmental in approach to care. Reassure the adolescent that confidentiality will be maintained. Help adolescent identify significant individuals in whom she can confide to help make a decision about the pregnancy. Be aware of state laws regarding requirement of parental notification if abortion intended. Also be aware of state laws regarding requirements for marriage: usually, minimum age for both parties is 18; 16- and 17-year-olds are, in most states, allowed to marry only with consent of parents. Encourage adolescent to be realistic about parental response to pregnancy.
Late adolescent (18–19 years)	Most likely to confirm pregnancy on own and at an earlier date due to increased acceptance and awareness of consequences of behavior. Likely to use pregnancy kit for confirmation. Relationship with father of baby, future educational plans, and personal value system are among significant determinants of decision about pregnancy.	Be nonjudgmental in approach to care. Reassure the adolescent that confidentiality will be maintained. Encourage adolescent to identify significant individuals in whom she can confide. Refer to counseling as appropriate. Encourage adolescent to be realistic about parental response to pregnancy.

Source: London et al. (2017). *Maternal & Child Nursing Care* (5th ed.). Hoboken, NJ: Pearson Education.

these behaviors, the nurse should realize that other factors may influence individual responses.

Sociologic Risks

Being forced into adult roles before completing adolescent developmental tasks causes a series of events that may result in prolonged dependence on parents, lack of stable relationships with the opposite sex, and lack of economic and social stability. Many teenage mothers drop out of school during their pregnancy, and then are less likely to complete their schooling. Similarly, they are less likely to go to college. In fact, fewer than 2% of teenagers who give birth before age 18 attain a college degree by age 30 (Alan Guttmacher Institute [AGI], 2016). In addition, teenage mothers are more likely to have big families and more likely to be single. Lack of education in turn reduces the quality of jobs available and leads to more tenuous employment and increased poverty (Herrman & Nandakumar, 2012).

Some pregnant adolescents choose to marry the father of the baby, who may also be a teenager. Unfortunately, most teenage marriages end in divorce. This fact should not be surprising, because pregnancy and marriage interrupt the adolescents' childhood and basic education. Lack of maturity in dealing with an intimate relationship also contributes to marital breakdown.

Dating violence is often an issue for teens. When surveyed, 10.3% of adolescents report some level of physical dating violence, and 10.4% experience some form of sexual dating violence ranging from touching and kidding to forced intercourse (Kann et al., 2014). The violence increases in pregnant teens. However, research suggests that this number is significantly lower than the actual number because teens are far less likely to report domestic violence than are adults.

The increased incidence of maternal complications, preterm birth, and low-birth-weight babies among teen mothers also affects society because many of these mothers are dependent on government programs. In the United States, the results of teenage childbearing costs tax payers \$9.4 billion annually (Ventura, Hamilton, & Mathews, 2014). Much of this cost comes from Medicaid, state health department, maternal care clinics, federal monies for Aid to Families with Dependent Children, the Supplemental Nutritional Assistance Program (SNAP), and direct payments to healthcare providers. The need for increased financial support for good prenatal care and nutritional programs remains critical.

Early, middle, and late adolescents respond differently to the developmental tasks of pregnancy, reflecting their age and maturity. In addition to her maturational level, the amount of nurturing the pregnant adolescent receives is a critical factor in the way she handles pregnancy and motherhood.

The early-adolescent girl (younger than 15 years) tends to think in a more concrete manner and usually has only a minimal ability to anticipate consequences of her behavior and see herself in the future. In addition, some degree of discomfort with normal body changes and body image may exist. The middle-adolescent girl (15 to 17 years) is prone to experimentation (i.e., drugs, alcohol, and sex), seeks independence, and frequently turns to her peer group for support, information, and advice. Pregnancy at this age can force

parental dependency and interfere with attempts at independence. Middle adolescents are capable of abstract thinking but may struggle with anticipating the long-term implications of their behavior. Finally, the late adolescent (17 to 19 years) is developing individuality and can picture herself in control. More sophisticated abstract thinking and an ability to anticipate consequences contributes to the development of problem-solving and decision-making skills (Borca et al., 2015).

Considerations for the Pregnant Woman Over Age 35

In the United States and Canada the risk of death in childbirth has declined dramatically for women of all ages since 1950 because of advances in maternal health and obstetric practice. There are, however, medical risks for the pregnant woman over age 35 that must be considered.

Medical Risks

The risk of maternal death is significantly higher for women over age 35 and is even higher for women age 40 and older. These women are more likely to have chronic medical conditions that can complicate a pregnancy. Preexisting medical conditions such as hypertension or diabetes probably play a more significant role than age in maternal well-being and the outcome of pregnancy. In addition, the rate of miscarriage, still birth, preterm birth, low birth weight, and perinatal morbidity and mortality is higher in pregnant women over age 35 (Carolan, 2013). Nevertheless, while the risk of pregnancy complications is higher in women over age 35 who have a chronic condition such as hypertension or diabetes or who are in poor general health, the risks are much lower than previously believed for physically fit women without preexisting medical problems (Cunningham et al., 2014).

The incidence of low-birth-weight newborns, very preterm births, and perinatal death is higher among women age 35 and older (Kenny et al., 2013). Women over age 35 who become pregnant also have an increased risk for gestational diabetes mellitus, hypertension, placenta previa, difficult labor, and newborn complications (March of Dimes [MOD], 2016).

The cesarean birth rate is also increased in women over age 35. This practice may be related to pregnancy complications as well as to increased concern by the woman and physician about the pregnancy outcome (MOD, 2016).

The risk of conceiving a child with Down syndrome increases with maternal age, especially when the mother is over age 35. ACOG (2016a) recommends that all pregnant women, regardless of age, be offered screening for Down syndrome. Research has focused on the use of quadruple screening to detect Down syndrome and trisomy 18. First-trimester ultrasound assessment of the thickness of fetal nuchal folds (nuchal translucency, or NT) combined with serum screens of free beta-hCG and pregnancy-associated plasma protein A (PAPP-A) is increasing the detection of Down syndrome, trisomy 18, and trisomy 13. If the screening results are not in the normal range, follow-up testing using ultrasound and amniocentesis is often indicated (ACOG, 2016a).

Amniocentesis or noninvasive prenatal testing through cell free fetal DNA (cffDNA) are routinely offered to all women over age 35 to permit the early detection of several chromosomal abnormalities, including Down syndrome. Routine genetic testing has not been offered to couples when the only risk is advanced paternal age, because there is insufficient evidence to determine a specific paternal age at which to start genetic testing. Advanced paternal age is associated with adverse fetal and neonatal outcomes, including an increased risk for autism spectrum disorder (Kovac et al., 2013).

Additional Concerns of the Pregnant Woman Over Age 35

The increased medical risks that the pregnant woman over age 35 faces, combined with social, familial, and other healthcare concerns, place many of these patients and their families at risk for impaired family processes. In particular, women who are mothers of older children and who provide some level of care for their own older parents may find themselves at their wits' ends trying to find a way to juggle their many responsibilities. The arrival of a new baby in a blended family may cause jealousy among older siblings or strain relationships with in-laws or former partners. The nurse should engage in active listening with these women and their partners, help them prioritize their concerns, and provide referrals to supportive resources as appropriate.

Often, because of their established routines, couples expecting their first child require assistance in understanding how to integrate a newborn into their daily routines. Secondary to increased risk to both the fetus and the pregnant woman, the family is often anxious, and this anxiety can create stress in the household. Encourage the couple to express their fears and concerns and provide support and reassurance. Anxiety may be particularly high when they are waiting for diagnostic test results. Couples may report that they are fighting more than usual. The nurse should help these patients recognize that the role anxiety plays in disrupting their relationships is often an important step to improving the relationship.

If the couple has other children, especially if the siblings are in the teen or preteen age, they may find their older children are embarrassed by the pregnancy. Older siblings may also fear being asked to contribute to the newborn's care. It is important for the couple to take time to understand their older children's concerns and make it clear to the siblings that the newborn will be the responsibility of the parents, not the responsibility of the older children. Siblings should be welcomed to participate in newborn care but should not be placed in the position of taking on a majority of the responsibility. The nurse can provide a supportive role in this process by encouraging open family communication and trust.

NURSING PROCESS

A written care plan or clinical pathway that incorporates the prenatal record, nursing diagnoses, and patient goals is essential to ensure continuity of care. Prenatal care, especially for women with low-risk pregnancies, is community

based, typically in a clinic or a private office. The healthcare community recognizes the value of providing a primary care nurse in these settings to coordinate holistic care for each childbearing family. The nurse in a clinic or health maintenance organization may be the only source of continuity for the woman, who may see a different healthcare provider at each visit.

Assessment

The nurse can complete many areas of prenatal assessment. Advanced practice nurses, such as CNMs and certified women's health nurse practitioners, have the education and skill to perform full and complete antepartum assessments. Areas of assessment may include the following:

- The woman's physical status
- The woman's understanding of pregnancy and the changes that accompany it
- The woman or family's attitudes about the pregnancy and expectations of the impact a baby will have on their lives
- Any health teaching needs
- The degree of support the woman has available to her
- The woman's knowledge of newborn/infant care.

While gathering data, the nurse also has an opportunity to discuss important aspects of nutrition within the context of the family's needs and lifestyle. In addition, the nurse seeks information about psychologic, cultural, and socioeconomic factors that may influence food intake.

At subsequent prenatal visits, the nurse continues to gather data about the course of the pregnancy to date and the woman's responses to it. The nurse also asks about the adjustment of the support person and of other children, if any, in the family. As the pregnancy progresses, the nurse inquires about the preparations the family has made for the new baby. The nurse asks specifically whether the woman has experienced any discomfort, especially the kinds of discomfort that are often seen at specific times during a pregnancy. The nurse also inquires about physical changes that relate directly to the pregnancy, such as fetal movement, and asks about the danger signs of pregnancy (**Table 33-9** »).

SAFETY ALERT Pregnancy is a high-risk period for intimate partner violence (IPV). It is important for the nurse to assess the woman with suspicious or unexplained injuries for this possibility.

Other pertinent information includes any exposure to contagious illnesses, medical treatment and therapy prescribed for medical problems since the last visit, and any prescription or OTC medications or herbal supplements that were not prescribed as part of the woman's prenatal care.

During the antepartum period, it is essential for the nurse to begin assessing the readiness of the woman and her partner (if possible) to assume their responsibilities as parents successfully. **Box 33-2** » identifies areas for assessment of parenting ability.

TABLE 33–9 Danger Signs in Pregnancy

Danger Sign	Possible Cause
Sudden gush of fluid from vagina	Premature rupture of membranes
Vaginal bleeding	Abruptio placentae, placenta previa, lesions of cervix or vagina, “bloody show”
Abdominal pain	Premature labor, abruptio placentae
Temperature above 38.3°C (101°F) and chills	Infection
Dizziness, blurred vision, double vision, spots before eyes	Hypertension, preeclampsia
Persistent vomiting	Hyperemesis gravidarum
Severe headache	Hypertension, preeclampsia
Edema of hands, face, legs, and feet	Preeclampsia
Reflex irritability, convulsions	Preeclampsia, eclampsia
Epigastric pain	Preeclampsia, ischemia in major abdominal vessel
Oliguria	Renal impairment, decreased fluid intake, preeclampsia
Dysuria	Urinary tract infection
Absence of fetal movement	Maternal medication, obesity, fetal death

Box 33–2

Prenatal Assessment of Parenting Ability

Perception of Complexities of Mothering

A. Desires baby for itself.

Positive:

1. The pregnancy is a planned or desired extension of a stable home life.

Negative:

1. Wants baby to meet own needs, such as someone to love her, someone to get her out of unhappy home, a way to repair faltering relationship.
2. The pregnancy is unwanted.
 - Was the pregnancy planned or a surprise?
 - How do you feel about being a mother?
 - Have you considered terminating the pregnancy or placing the baby for adoption?

B. Expresses consideration of the impact of mothering role on other roles (relationship, career, school).

Positive:

1. Realistic expectations of how baby will affect job, career, school, and personal goals.
2. Interested in learning about child care.

Negative:

1. Lacks insight regarding the physical, emotional, and social demands of parenting.
2. Uninterested in learning about the needs of a baby.

C. Makes lifestyle changes for the baby’s benefit.

Positive:

1. Gives up routines not good for baby (quits smoking, adjusts eating habits).
 - What do you think it will be like to take care of a baby?
 - How do you think your life will be different after you have your baby?
 - How do you feel this baby will affect your job, career, school, and personal goals?

- How will the baby affect your relationship with your significant other?
 - What can you do to help yourself and the baby be as healthy as possible?
 - What can you do to prepare for being a mother?
2. Initiates positive, proactive routines (childbirth classes, prenatal exercise classes, stress reduction).

Negative:

- Rationalizes or denies behavior that places the baby at risk.
- Expresses inability for or lack of interest in proactive behavior.

Attachment

A. Strong feelings regarding gender of baby.

Positive:

1. Verbalizes love and acceptance of either gender.

Negative:

1. Believes baby will be like negative aspects of self and partner.
2. Verbalizes belief that she will be unable to parent a child of a particular gender.
3. Considers a particular gender as conferring more or less status on the family.
 - Why do you prefer a certain gender?
 - How will you feel and what will you do differently if your baby is a boy/girl?

B. Interested in data regarding fetus (e.g., growth and development, heart tones).

Positive:

1. Verbalizes positive thoughts about the baby.
2. Asks questions about the baby’s development and status.

Negative:

1. Shows no interest in fetal growth and development, quickening, and fetal heart tones.
2. Expresses negative feelings about fetus.

Box 33–2 (continued)

3. Rejects counseling regarding nutrition, rest, hygiene.
 - Encourage interest in the fetus. Point out normal development.
 - Explore the mother's reasons for negative feelings and/or rejection of counseling.

C. Fantasizes about baby.

Positive:

1. Prepares for the addition of a baby to her household.
2. Speaks of the baby as her child and her other children's brother and sister.
3. Talks to the baby in utero.
4. Makes positive speculations about the baby's appearance and disposition.

Negative:

1. Bonding conditional depending on gender, age of baby, and/or labor and birth experience.
2. Woman considers only own needs when making plans for baby.
3. Exhibits no attachment behaviors.
4. Failure to prepare.
 - What did you think or feel when you first felt the baby move?
 - Have you started preparing for the baby?
 - What do you think your baby will look like?
 - How would you like your new baby to look?
 - Does this baby have a name?

Acceptance of Child by Significant Others

A. Acknowledges acceptance by significant others of the new responsibility.

Positive:

1. Acknowledges unconditional acceptance of pregnancy and baby by significant others.
2. Partner accepts new responsibility for child.
3. Shares experience of pregnancy with significant others.

Negative:

1. Significant others not supportively involved with pregnancy.
2. Conditional acceptance of pregnancy by significant others depending on gender, ethnicity, age of baby.
3. Decision making does not take in needs of fetus (e.g., food money spent on new car).
4. Partner and family with no/little responsibility for needs of pregnancy, woman/fetus.
 - How does your partner feel about this pregnancy?
 - How do your parents feel?
 - What do your friends think?

- Does your partner have a preference regarding the baby's gender? If so, why?
- How does your partner feel about being a parent?
- What do you think your partner will be like as a parent?
- What do you think your partner will do to help you with child care?
- Have you and your partner talked about how the baby might change your lives?
- Who have you told about your pregnancy?
- Do you have family or friends who can help you take care of a new baby?

B. Concrete demonstration of acceptance of pregnancy/baby by significant others (e.g., baby shower, significant other involved in prenatal education).

Positive:

1. Baby shower.
2. Significant other attends prenatal class with woman.
3. Commitment from the mother's community to help take care of the new baby (watch older children when she is in labor and immediately postpartum, meal planning, housework).
 - If partner attends clinic with woman, note partner's degree of interest (e.g., listens to heart tones).
 - Significant other plans to be with woman during labor and birth.
 - Partner is contributing financially.

Ensures Physical Well-Being

A. Concerns about having normal pregnancy, labor and birth, and baby.

Positive:

1. Preparing for labor and birth, attends prenatal classes, interested in labor and birth.
2. Aware of danger signs during pregnancy.
3. Seeks and uses appropriate healthcare (e.g., time of initial visit, keeps appointments, follows through on recommendations).

Negative:

1. Denies signs and symptoms that might suggest complications of pregnancy.
2. Verbalizes extreme fear of labor and birth—refuses to talk about labor and birth.
3. Misses appointments, fails to follow instructions, refuses to attend prenatal classes.
 - Encourage expression of fears so they can be addressed.
 - Ask about reasons for missed appointments in order to assist with obtaining services (medical transportation, social working, home health nurse).

Note: When "Negative" is not listed in a section, the reader may assume that negative is the absence of positive responses.

Source: Modified and used with permission of the Minneapolis Health Department, Minneapolis, MN.

The accompanying Subsequent Prenatal Assessment feature provides a systematic approach to the regular physical examinations the pregnant woman should undergo for optimal antepartum care and also provides a model for evaluating both the pregnant woman and the expectant partner, if the partner is involved in the pregnancy.

SAFETY ALERT When assessing blood pressure, have the pregnant woman sit up with her arm resting on a table so that her arm is at the level of her heart. Expect a decrease in her blood pressure from baseline during the second trimester because of normal physiologic changes. If this decrease does not occur, evaluate further for signs of preeclampsia.

Subsequent Prenatal Assessment

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
Vital Signs		
Temperature: 36.2°–37.6°C (97°–99.6°F)	Elevated temperature (infection)	Evaluate for signs of infection. Refer to healthcare provider.
Pulse: 60–100 beats/min Rate may increase 10 beats/min during pregnancy	Increased pulse rate (anxiety, cardiac disorders)	Note irregularities. Assess for anxiety and stress.
Respiration: 12–20 breaths/min	Marked tachypnea or abnormal patterns (respiratory disease)	Refer to healthcare provider.
Blood pressure: less than 140/90 mmHg (falls in second trimester)	Greater than 140/90 mmHg	Assess for headache, edema, proteinuria, and hyperreflexia. Refer to healthcare provider. Schedule appointments more frequently.
Weight Gain		
First trimester: 1.6–2.3 kg (3.5–5 lb)	Inadequate weight gain (poor nutrition, nausea, small for gestational age)	Discuss appropriate weight gain.
Second trimester: 5.5–6.8 kg (12–15 lb)	Excessive weight gain (excessive caloric intake, edema, preeclampsia)	Provide nutritional counseling. Assess for presence of edema or anemia.
Third trimester: 5.5–6.8 kg (12–15 lb)		
Edema		
Small amount of dependent edema, especially in last weeks of pregnancy	Edema in hands, face, legs, and feet (preeclampsia)	Identify any correlation between edema and activities, blood pressure, or proteinuria. Refer to healthcare provider if indicated.
Uterine Size		
See the Initial Prenatal Assessment feature in the Concept section for normal changes during pregnancy	Unusually rapid growth (multiple gestation, hydatidiform mole, hydramnios, miscalculation of estimated date of birth)	Evaluate fetal status. Determine height of fundus. Use diagnostic ultrasound.
Fetal Heartbeat		
110–160 beats/min Funic souffle	Absence of fetal heartbeat after 20 weeks of gestation (maternal obesity, fetal demise)	Evaluate fetal status.
Laboratory Evaluation		
Hemoglobin: 12–16 g/dL Pseudoanemia of pregnancy	Less than 11 g/dL (anemia)	Provide nutritional counseling. Hemoglobin check is repeated at 28–36 weeks of gestation. Consider a hemoglobin screen for women of Mediterranean, African, or South Asian descent.
Quad marker screen: blood test performed at 15–22 weeks of gestation. Evaluates four factors—maternal serum alpha-fetoprotein (MSAFP), unconjugated estriol (UE), human chorionic gonadotropin (hCG), and inhibin-A: normal levels	Elevated MSAFP (neural tube defect, underestimated gestational age, multiple gestation); lower-than-normal MSAFP (Down syndrome, trisomy 18); higher-than-normal hCG and inhibin-A (Down syndrome); lower-than-normal UE (Down syndrome)	Recommended for all pregnant women; especially indicated for women with any of the following risk factors: age 35 or over, family history of birth defects, previous child with a birth defect, insulin-dependent diabetes before pregnancy (Medline Plus, 2012). If quad screen abnormal, further testing such as ultrasound or amniocentesis may be indicated.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

Subsequent Prenatal Assessment *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
First trimester integrated screen	Provides the same information as the quad screen in a more accurate and timely fashion as information on trisomy 13, 18 and 21 is available between 11 and 13 weeks' gestation and laboratory tests are combined with ultrasound of the fetal nasal bone and nuchal fold	
NIPT/cell free fetal DNA (cffDNA)	Allows analysis of fetal alleles in maternal serum. Provides information on chromosomal anomalies	
Repeat indirect Coombs test done on Rh-negative women: negative (done at 28 weeks of gestation)	Rh antibodies present (maternal sensitization has occurred)	If Rh negative and unsensitized, Rh immune globulin is given. If Rh antibodies are present, Rh immune globulin is not given; fetus is monitored closely for isoimmune hemolytic disease.
50-g, 1-hour glucose screen (done between 24 and 28 weeks of gestation)	Plasma glucose level greater than 140 mg/dL (GDM) <i>Note:</i> Some facilities use a level of greater than 130 mg/dL, which identifies 90% of women with GDM	Discuss implications of gestational diabetes mellitus (GDM). Refer for a diagnostic 100-g oral glucose tolerance test.
Urinalysis: See the Initial Prenatal Assessment feature in the Concept section for normal findings	See the Initial Prenatal Assessment feature in the Concept section for deviations	Repeat urinalysis at 7 months of gestation. Repeat dipstick test at each visit.
Protein: negative	Proteinuria, albuminuria (contamination by vaginal discharge, urinary tract infection, preeclampsia)	Obtain dipstick urine sample. Refer to healthcare provider if deviations are present.
Glucose: negative	Persistent glycosuria (diabetes mellitus)	Refer to healthcare provider.
<i>Note:</i> Glycosuria may be present because of physiologic alterations in glomerular filtration rate and renal threshold.		
Screening for Group B streptococcus: rectal and vaginal swabs obtained at 35–37 weeks of gestation for all pregnant women	Positive culture (maternal colonization)	Explain fetal/neonatal risks and the need for antibiotic prophylaxis in labor. Refer to healthcare provider for therapy.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.
CULTURAL ASSESSMENT§	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA†
Determine the mother's (and family's) attitudes about the gender of the unborn child	Some women have no preference about the gender of the child; others do. In many cultures, boys are especially valued as firstborn children	Provide opportunities to discuss preferences and expectations; avoid a judgmental attitude to the response.
Ask about the woman's expectations of childbirth. Will she want someone with her for the birth? Whom does she choose? What is the role of her partner?	Some women want their partner present for labor and birth; others prefer a female relative or friend Some women expect to be separated from their partner once cervical dilation has occurred	Provide information on birth options, but accept the woman's decision about who will attend.
§These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.		†This column provides guidelines for further assessment and initial nursing intervention.

(continued on next page)

Subsequent Prenatal Assessment *(continued)*

CULTURAL ASSESSMENT [§]	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA [†]
Ask about preparations for the baby; determine what is customary for the woman	Some women may have a fully prepared nursery; others may not have a separate room for the baby	Explore reasons for not preparing for the baby. Support the mother's preferences, and provide information about possible sources of assistance if the decision is related to a lack of resources.
Expectant Mother		
Psychologic status	Increased stress and anxiety	Encourage woman to take an active part in her care.
First trimester: Incorporates idea of pregnancy; may feel ambivalent, especially if she must give up desired role; usually looks for signs of verification of pregnancy, such as increase in abdominal size or fetal movement	Inability to establish communication; inability to accept pregnancy; inappropriate response or actions; denial of pregnancy; inability to cope	Establish lines of communication. Establish a trusting relationship. Counsel as necessary. Refer to appropriate professional as needed.
Second trimester: Baby becomes more real to woman as abdominal size increases and she feels movement; she begins to turn inward, becoming more introspective		
Third trimester: Begins to think of the baby as a separate being; may feel restless, and may feel that the time of labor will never come; remains self-centered and concentrates on preparing place for baby		
Educational needs: Self-care measures and knowledge about the following: Health promotion Breast care Hygiene Rest Exercise Nutrition Relief measures for common discomforts of pregnancy Danger signs in pregnancy (see Table 33–9)	Inadequate information	Provide information and counseling.
Sexual activity: Woman knows how pregnancy affects sexual activity	Lack of information about effects of pregnancy and/or alternative positions during sexual intercourse	Provide counseling.
Preparation for parenting: appropriate preparation	Lack of preparation (denial, failure to adjust to baby, unwanted child)	Counsel. If lack of preparation is caused by inadequacy of information, provide information.
Preparation for childbirth: Patient is aware of the following: 1. Prepared childbirth techniques 2. Normal processes and changes during childbirth 3. Problems that may occur as a result of drug and alcohol use and of smoking	Continued abuse of drugs and alcohol; denial of possible effect on self and baby	If couple chooses a particular technique, refer to childbirth classes. Encourage prenatal class attendance. Educate woman during visits based on current physical status. Provide reading list for more specific information. Refer for thorough evaluation of substance abuse.
Woman has met other physician or nurse-midwife who may be attending her birth in the absence of primary caregiver	Introduction of new individual at birth may increase stress and anxiety for woman and partner.	Introduce woman to all members of group practice.
[§] These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.		[†] This column provides guidelines for further assessment and initial nursing intervention.

Subsequent Prenatal Assessment *(continued)*

CULTURAL ASSESSMENT [§]	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA [†]
Impending labor: Patient knows signs of impending labor: 1. Uterine contractions that increase in frequency, duration, and intensity 2. Bloody show 3. Expulsion of mucous plug 4. Rupture of membranes	Lack of information	Provide appropriate teaching, stressing importance of seeking appropriate medical assistance.

Expectant Partner

Psychologic status		
First trimester: May express excitement over confirmation of pregnancy; male partner may be pleased with evidence of his virility; concerns move toward providing for financial needs; energetic, may identify with some discomforts of pregnancy, and may even exhibit symptoms	Increasing stress and anxiety; inability to establish communication; inability to accept pregnancy diagnosis; withdrawal of support; abandonment of the mother	Encourage expectant partner to come to prenatal visits. Establish line of communication. Establish trusting relationship.
Second trimester: May feel more confident and be less concerned with financial matters; may have concerns about expectant mother's changing size and shape, her increasing introspection		Counsel. Let expectant partner know that it is normal to experience these feelings.
Third trimester: May have feelings of rivalry with fetus, especially during sexual activity; may make changes in physical appearance and exhibit more interest in self; may become more energetic; fantasizes about child, but usually imagines older child; fears mutilation and death of woman and child		Include expectant partner in pregnancy activities as the partner desires. Provide education, information, and support. Increasing numbers of expectant partners are demonstrating desire to be involved in many or all aspects of prenatal care, education, and preparation.
[§] These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.		[†] This column provides guidelines for further assessment and initial nursing intervention.

The woman's individual needs and the assessment of her risks should determine the frequency of subsequent visits. Generally, the recommended frequency of antepartum visits is as follows:

- Every 4 weeks for the first 28 weeks of gestation
- Every 2 weeks until 36 weeks of gestation
- After week 36, every week until childbirth.

During the subsequent antepartum assessments, most women demonstrate ongoing psychologic adjustment to pregnancy. However, some women may exhibit signs of possible psychologic problems, such as the following:

- Increasing anxiety
- Inability to establish communication
- Inappropriate responses or actions
- Denial of pregnancy
- Inability to cope with stress
- Intense preoccupation with the gender of the baby
- Failure to acknowledge quickening
- Failure to plan and prepare for the baby (e.g., living arrangements, clothing, and feeding methods)
- Indications of substance abuse.

If the woman's behavior indicates possible psychologic problems, the nurse can provide ongoing support and counseling and also refer the woman to appropriate professionals.

Diagnoses

Nursing diagnoses, of course, vary from pregnancy to pregnancy but may include the following:

- *Deficient Knowledge* related to self-care
- *Deficient Fluid Volume* secondary to vomiting/hyperemesis gravidarum
- *Decisional Conflict* related to unexpected pregnancy

- *Anxiety* related to change in role, deficient knowledge, reaction of family members, and so forth
- *Imbalanced Nutrition: Less Than Body Requirements*, related to nausea and vomiting
- *Risk for Overweight* related to excessive caloric intake
- *Readiness for Enhanced Parenting*
- *Readiness for Enhanced Family Processes*.

(NANDA-I © 2014)

Planning

Together, the nurse and patient will establish the plan of care. Sometimes, priorities of care are based on the most immediate needs or concerns expressed by the woman. For example, during the first trimester, when she is experiencing nausea or is concerned about sexual intimacy with her partner, the woman likely will not want to hear about labor and birth. At other times, priorities may develop from findings during a prenatal examination. For example, a woman who is showing signs of preeclampsia may feel physically well and find it hard to accept the nurse's emphasis on the need for frequent rest periods.

Potential goals of nursing care during pregnancy may include the following:

- The woman will increase her daily intake of calcium to the DRI level.
- The woman will articulate the danger signs during pregnancy and when to call the physician's office or seek emergency care.
- The woman will have the opportunity to express concerns and ask questions.
- The woman will articulate methods of self-care.
- The woman with a chronic condition will consult with her obstetrician and her treating physician during the pregnancy.

Implementation

When providing patient care, the nurse should be sensitive to religious or spiritual, cultural, and socioeconomic factors that may influence a family's response to pregnancy as well as to the woman's expectations of the healthcare system. The nurse can avoid stereotyping patients simply by asking each woman about her expectations for the antepartum period. Although many women's responses may reflect what are thought to be traditional norms, other women may have decidedly different views or expectations that represent a blending of beliefs or cultures.

Promote Knowledge Related to Self-care

The nurse may see a pregnant woman only once every 4–6 weeks during the first several months of her pregnancy, during which time it is important to establish an environment of comfort and open communication with each antepartum visit. The nurse conveys interest in the woman as an individual and discusses her concerns and desires. The nurse can be extremely effective in working with the expectant family by answering questions; providing comprehensive information about pregnancy, prenatal healthcare activities,

and community resources; and supporting the healthcare activities of the woman and her family.

Communities often have a wealth of services and educational opportunities available for pregnant women and their families, and the knowledgeable nurse can help expectant families to assess and access these services. A community-based approach supports the family's assumption of equal responsibility with healthcare providers in working toward their common goal of a positive birth experience.

Home care can be of benefit to any pregnant woman, but it is especially effective in removing barriers for women who have difficulty accessing healthcare. These barriers may include lack of locally available healthcare facilities, problems with transportation to the facility, or schedule conflicts with available appointment times because of employment hours or family responsibilities. A prenatal home care visit or phone contact can also be useful for women who anticipate a short inpatient stay after childbirth. At the prenatal contact, the nurse explains the perinatal program and answers any questions the woman or her family have. Currently, home care is most often used for women with prenatal complications that can be managed without hospitalization if effective nursing assessment and care are provided in the home.

Throughout the prenatal period, the nurse shares information with the family, both verbally and through written materials. This information is designed to help the family carry out self-care and wellness measures as needed and report changes that may indicate a health problem. The nurse also provides anticipatory guidance to help the family plan for changes that will occur after childbirth. The expectant woman and her partner and/or other family members are encouraged to identify and discuss issues that could be sources of postpartum stress. Issues to be addressed before the birth may include sharing of baby and household chores, help during the first few days after childbirth, options for babysitting to allow the mother (and couple) some free time, the mother's return to work after the baby's birth, and sibling rivalry. Families resolve these issues in different ways, but the postpartum adjustment period tends to be easier for those who agree on the issues beforehand than for those who do not confront and resolve these issues.

Childbirth education classes are important in promoting adaptation to the event of childbirth for expectant couples. Classes for pregnant adolescents and expectant parents over age 35 are now available in many communities.

Important topics for patient teaching include the following:

- Self-care to promote positive outcomes (e.g., nutrition, activity, avoiding OTC medications, and delegating care of the litter box to other family members)
- Strategies to minimize the discomforts of pregnancy
- Childbirth preparation classes
- Danger signs to report to the provider
- Signs and symptoms of labor.

Exercises to Prepare for Childbirth

Certain exercises help strengthen muscle tone in preparation for birth and promote more rapid restoration of muscle tone

after birth. Some physical changes of pregnancy can be minimized by faithfully practicing prescribed body-conditioning exercises. Many body-conditioning exercises for pregnancy are taught; a few of the more common ones are discussed here.

Handouts are a valuable tool for providing information, as are pictures. When combined, they are especially useful. The nurse can develop a handout that describes the correct way to perform prenatal exercises, and include drawings or photos. For exercises that may be new to a woman, such as the pelvic tilt, the nurse can provide a handout for later reference, but also demonstrate the exercise and have the woman do a return demonstration.

PELVIC TILT The **pelvic tilt**, or pelvic rocking, is an exercise that helps prevent or reduce back strain as it strengthens abdominal muscles. To do the pelvic tilt in early pregnancy, the woman lies on her back and puts her feet flat on the floor. This flexes the knees and helps prevent strain or discomfort. The woman decreases the curvature in her back by pressing her spine toward the floor. With her back pressed to the floor, the woman then tightens her abdominal muscles as she tightens and tucks in her buttocks. In the second and third trimesters of pregnancy, the woman can also perform the pelvic tilt while on her hands and knees (**Figure 33-39** >>), sitting in a chair, or standing with her back against a wall. The body

A

B

C

D

Figure 33-39 >> **A**, Starting position when the pelvic tilt is done on hands and knees. The back is flat and parallel to the floor, the hands are below the head, and the knees are directly below the buttocks. **B**, A prenatal yoga instructor offers pointers for proper positioning for the first part of the tilt: head up, neck long and separated from the shoulders, buttocks up, and pelvis thrust back, allowing the back to drop and release on an inhaled breath. **C**, The instructor helps the woman assume the correct position for the next part of the tilt. It is done on a long exhalation, allowing the pregnant woman to arch her back, drop her head loosely, push away from her hands, and draw in the muscles of her abdomen to strengthen them. Note that in this position, the pelvis and buttocks are tucked under, and the buttock muscles are tightened. **D**, Proper posture. The knees are slightly bent but not locked, and the pelvis and buttocks are tucked under, thereby lengthening the spine and helping support the weighty abdomen. With her chin tucked in, this woman's neck, shoulders, hips, knees, and feet are all in a straight line perpendicular to the floor. Her feet are parallel. This is also the starting position for doing the pelvic tilt while standing.

alignment that results when the pelvic tilt is done correctly should be maintained as much as possible throughout the day.

SAFETY ALERT Doing the pelvic tilt on hands and knees may aggravate back strain. Teach women with a history of minor back problems to do the pelvic tilt only in the standing position.

ABDOMINAL EXERCISES A basic exercise to increase abdominal muscle tone is tightening abdominal muscles with each breath. This exercise can be done in any position, but it is best learned during early pregnancy. The woman lies supine with knees flexed and feet flat on the floor. The woman expands her abdomen and slowly takes a deep breath. Exhaling slowly, she gradually pulls in her abdominal muscles until they are fully contracted. She relaxes for a few seconds and then repeats the exercise. The pregnant woman should avoid the supine position after the first trimester.

Partial sit-ups strengthen abdominal muscle tone and can be done if there is no preexisting diastasis recti. In early pregnancy, partial sit-ups must be done with the knees flexed and the feet flat on the floor to avoid strain on the lower back. The woman stretches her arms toward her knees as she slowly pulls her head and shoulders off the floor to a comfortable level (if she has poor abdominal muscle tone, she may not be able to pull up very far). She then slowly returns to the starting position, takes a deep breath, and repeats the exercise while exhaling. To strengthen the oblique abdominal muscles, the woman repeats the process but stretches the left arm to the side of her right knee, returns to the floor, takes a deep breath, and then, while exhaling, reaches with the right arm to the left knee. During the second and third trimesters, these exercises can be done on a large exercise ball. They can be done approximately five times in a sequence, and the sequence can be repeated at other times during the day as desired. It is important to do the exercises slowly to prevent muscle strain and overtraining. If the pregnant woman does have diastasis recti, isometric abdominal exercises should be done instead.

PERINEAL EXERCISES Perineal muscle tightening, also called **Kegel exercises**, strengthens the pubococcygeus muscle and increases its elasticity (**Figure 33–40** >>). The woman can feel the specific muscle group to be exercised by stopping urination midstream. Doing Kegel exercises while urinating is discouraged because this practice has been associated with urinary stasis and urinary tract infection.

Childbirth educators sometimes use the following technique to teach Kegel exercises: Tell the woman to think of her perineal muscles as an elevator. When she relaxes, the elevator is on the first floor. To do the exercises, she contracts, bringing the elevator to the second, third, and fourth floors. She keeps the elevator on the fourth floor for a few seconds and then gradually relaxes the area. If the exercise is properly done, the woman does not contract the muscles of the buttocks and thighs.

Kegel exercises can be done at almost any time. Some women use ordinary events—for instance, stopping at a red light—as a cue to remember to do the exercise. Others do Kegel exercises while waiting in a checkout line, talking on the telephone, or watching television.

INNER THIGH STRETCH The nurse can advise the pregnant woman to assume a seated position with the knees bent and the bottoms of the feet together. This “tailor sit” stretches the muscles of the inner thighs in preparation for labor and birth.

Evaluate Readiness for Enhanced Family Processes

The problems and concerns of the pregnant woman, the relief of her discomforts, and the maintenance of her physical, psychologic, and spiritual health receive much attention during the antepartum period. However, her well-being is intertwined with the well-being of those to whom she is closest. Thus, the nurse also addresses the needs of the woman’s family to help maintain the integrity of the family unit.

Pubococcygeus muscle with good tone

Pubococcygeus muscle with poor tone

Figure 33–40 >> Kegel exercises. The woman tightens the pubococcygeus muscle to improve support to the pelvic organs.

Periodic prenatal examinations offer the nurse an opportunity to assess the woman's psychologic needs and emotional status. If the woman's partner attends the antepartum visits, the nurse can also identify the partner's needs and concerns. The interchange between the nurse and the woman or her partner will be facilitated if it takes place in a friendly, trusting environment. The woman should have sufficient time to ask questions and air concerns. If the nurse provides the time and demonstrates genuine interest, the woman will be more at ease bringing up questions that she may believe are silly or has been afraid to verbalize. The nurse who has an accurate understanding of all the changes of pregnancy is most able to answer questions and provide information.

CARE OF THE PARTNER While the pregnant woman's partner is present in most cases, the partner's presence cannot be assumed. It is important to assess the woman's support system to determine which significant individuals in her life will play a major role during her childbearing experience.

Anticipatory guidance of the expectant woman's partner, if the partner is involved in the pregnancy, is a necessary part of any plan of care. The partner may need information about the anatomic, physiologic, and emotional changes that occur during and after pregnancy, the couple's sexuality and sexual response, and the reactions that the partner is experiencing. The partner may wish to express feelings about breastfeeding versus formula feeding, the gender of the child, the partner's own ability to parent, and other topics.

If it is culturally acceptable to the couple and personally acceptable to the partner, the nurse may refer the couple to expectant parents' classes. These classes provide valuable information about pregnancy and childbirth using a variety of teaching strategies, such as discussion, films, demonstrations with educational models, and written handouts. Some classes even give the partner the opportunity to get a "feel" for pregnancy by wearing a pregnancy simulator. Such classes also offer the couple an opportunity to gain support from other couples.

The nurse assesses the partner's intended degree of participation during labor and birth and knowledge of what to expect. If the couple prefers that the partner's participation be minimal or restricted, the nurse must support the decision. With this type of consideration and collaboration, the partner is less apt to develop feelings of alienation, helplessness, and guilt during the pregnancy. As the couple's relationship is strengthened and the partner's self-esteem increases, the partner is better able to provide physical and emotional support to the woman during labor and birth.

CARE OF SIBLINGS AND OTHER FAMILY MEMBERS The responses of siblings and other family members to the pregnancy are discussed in detail in the Concept section of this module. Briefly, these responses may include feelings of insecurity and even hostility. Thus, in the plan for prenatal care, the nurse incorporates a discussion about the negative feelings some children develop when anticipating the arrival

of a sibling. Parents may be distressed to see an older child regress to "babyish" behavior or become aggressive toward the newborn. Parents who are unprepared for the older child's feelings of insecurity, anger, jealousy, and rejection may respond inappropriately in their confusion and surprise. The nurse emphasizes that open communication between parents and children (or acting out feelings with a doll if the child is too young to verbalize) helps children master their feelings. Children may feel less neglected and more secure if they know that their parents are willing to help with their anger and aggressiveness.

It is important not to make assumptions about a woman's beliefs, because cultural norms vary greatly both within a culture and from generation to generation. The nurse should observe the woman carefully and take the time to ask questions. Patients will benefit greatly from the nurse's increased awareness of their cultural beliefs and practices.

Identify Concerns and Promote Strengths

The nurse needs to discuss risks, identify concerns, and promote strengths. It is helpful in promoting a sense of well-being for the nurse to treat the pregnancy as normal unless specific health risks are identified. As the pregnancy continues, the nurse identifies and discusses concerns the woman may have related to her age or to specific health problems.

The common discomforts of pregnancy, such as nausea and vomiting, urinary frequency, fatigue, breast tenderness, heartburn, ankle edema, and other problems, can contribute to an unpleasant pregnancy for the woman. At each prenatal visit, the nurse can focus teaching on ways to cope with the potential discomforts the woman may experience.

The nurse can support couples who decide to have amniocentesis by providing information and answering questions about the procedure and by providing comfort and emotional support during the amniocentesis. If the results indicate that the fetus has Down syndrome or another genetic abnormality, the nurse can ensure that the couple has complete information about the condition, its range of possible manifestations, and its developmental implications.

Evaluation

Anticipated outcomes of nursing care include the following:

- The woman and her partner are knowledgeable about the pregnancy and express confidence in their ability to make appropriate healthcare choices.
- The expectant woman and her partner and their children, if any, are able to cope with the pregnancy and its implications for the future.
- The woman receives effective healthcare throughout her pregnancy as well as during birth and the postpartum period.
- The woman and her partner develop skills in child care and parenting.

Nursing Care Plan

The Pregnant Patient

Martina de Herrera and her husband arrived in the United States from Puerto Rico 6 months ago. This is her first prenatal visit since her pregnancy was confirmed 2 days earlier. Mrs. de Herrera's first child is 3 years old and was born in Puerto Rico. Their families live in Puerto Rico, but Mrs. de Herrera's mother has come to visit and help her get settled in their new home. Mrs. de Herrera's husband

speaks some English but is unable to attend the prenatal visit, so she has brought her mother to the prenatal clinic. Mrs. de Herrera's native language is Spanish. Both women speak very little English and seem uncomfortable as they wait for the provider. The nurse needs to complete a health history, collect some laboratory specimens, and get Mrs. de Herrera scheduled for her next appointment.

ASSESSMENT

Subjective: Shaking head side to side, no eye contact, anxious

Objective: BP 128/82 mmHg, pulse 84 beats/min, respirations 16/min, height 5'4", weight 140 lb, urine negative for protein and glucose

DIAGNOSIS

- *Deficient Knowledge* about prenatal care related to barriers in communication and sociocultural factors.

(NANDA-I © 2014)

PLANNING

- The woman will demonstrate understanding of health information received during prenatal visits.

IMPLEMENTATION

- Schedule an interpreter during prenatal visits.
- Refer to posters with pictures to explain routine care and procedures during the prenatal exam.
- Use teaching models to demonstrate procedures.
- Provide brochures about prenatal care in the patient's native language.
- Refer the woman to prenatal classes taught in her native language.
- Involve other members of the healthcare team to assist with prenatal care.

EVALUATION

- The woman responds appropriately to the nurse by using an interpreter.
- The woman demonstrates understanding by pointing to pictures and phrases on posters.
- The woman uses hand gestures to demonstrate understanding.

CRITICAL THINKING

1. Because of the loss of easily understandable tone and correlation with body language in this situation as the patient speaks, how can the nurse assess the woman's anxiety after providing patient teaching?
2. Using an interpreter, how can the nurse determine the woman's understanding of patient teaching?
3. What questions would you ask to assess the patient's cultural beliefs and needs related to her culture?

REVIEW Antepartum Care

RELATE Link the Concepts and Exemplars

Linking the exemplar of antepartum care with the concept of fluids and electrolytes:

1. What recommendations would you make to reduce the risk of dehydration for the pregnant woman who reports vomiting one or two times per day?
2. What electrolyte levels would you want to monitor in the pregnant woman with frequent morning sickness and vomiting?

Linking the exemplar of antepartum care with the concept of stress and coping:

3. You are caring for a woman with four children who had a tubal ligation after delivery of her last baby. During this visit, the woman finds she is pregnant. How can you help her to cope with the discovery and reduce anxiety enough to allow decision making?

4. You are caring for a woman who has been receiving infertility treatments for the past 2 years without success and has just learned she is pregnant. The woman is very anxious about fetal well-being and the possibility of miscarriage. Design a plan of care to promote anxiety reduction.

REFLECT Apply Your Knowledge

Jessica Riley is a single, 18-year-old mother with a 1-year-old son, Ryan. Jessica has had no contact with Ryan's father since before

Ryan was born. Jessica and Ryan live in a small, one-bedroom apartment with Jessica's boyfriend, Casey. Jessica is now 6 months pregnant with Casey's child. Although Jessica works full time at a restaurant, she has struggled financially. She is glad Casey contributes to paying the bills and is not sure how she could financially make it without him. Her mother, Evelyn, helps by watching Ryan in the evenings. In addition, Jessica

has government assistance in the form of WIC coupons and Medicaid. Ryan attends a government-assisted day care program.

Jessica goes to her 24-week prenatal visit. She continues to see the same midwife and likes her a lot because she makes Jessica feel comfortable. Jessica's history indicates she does not exercise and

eats mostly fast foods. Jessica smoked about half a pack of cigarettes a day and drank alcohol socially when she partied.

Jessica tells the nurse who admits her that she tried to stop smoking but hasn't been able to. When asked about alcohol intake, Jessica tells the nurse she is no longer drinking. She shares with the nurse that Casey was giving her a hard time about not drinking, so she has been pretending to drink to keep him happy. While taking Jessica's blood pressure, the nurse notes bruises in the form of fingerprints on her upper arms. While helping Jessica prepare for the examination, the nurse also notes a bruise on her abdomen. When she asks Jessica how it happened, Jessica blushes, stutters, then looks down and mumbles, "I must have bumped into something."

1. Would you assess Jessica further to determine if she has been abused? If so, what specific questions would you ask?
2. What risk factors have you identified related to Jessica's fetus? What nursing strategies can you implement to reduce these risks?
3. What patient teaching would you provide at this prenatal visit?

Exemplar 33.B **Intrapartum Care**

Exemplar Learning Outcomes

33.B Summarize intrapartum care of the pregnant woman.

- Summarize factors important to labor and birth.
- Describe the physiology of labor.
- Outline the stages of labor and birth.
- Summarize the maternal and fetal response to labor.
- Describe maternal and fetal alterations during the intrapartum period.
- Differentiate considerations related to the assessment and care pregnant adolescents and women over 35.
- Illustrate the nursing process in providing culturally competent care to the pregnant woman and her family.

Overview

In the final weeks of pregnancy, both mother and baby begin to prepare for birth. The fetus develops and grows in readiness for life outside of the womb. At the same time, the expectant woman undergoes various physiologic and psychologic changes that prepare her for childbirth. During her prenatal visits, the mother is instructed to call her healthcare provider if any of the following occur:

- Rupture of membranes
- Regular, frequent uterine contractions (nulliparas, 5 minutes apart for 1 hour; multiparas, 6–8 minutes apart for 1 hour)
- Any vaginal bleeding
- Decreased fetal movement.

Increasingly, pregnant women and their families are seeking out family-centered care. **Family-centered care** is a model of care based on the philosophy that the physical, sociocultural, spiritual, and economic needs are combined and considered collectively when planning care for the childbearing family (Katz, 2012). To reflect the consumer demand for family-centered care, most birthing centers now have *birthing rooms*, single rooms where the woman and her partner or other family members will stay for the labor, birth, recovery, and possibly the postpartum period. These rooms may also be called labor, delivery, recovery, and postpartum (LDRP) rooms or single-room maternity care.

The atmosphere of a birthing room is more relaxed than that of a traditional hospital room, and families seem to feel more comfortable in birthing rooms. Another benefit is that the woman does not have to be transferred from one area to another for the actual birth. A birthing room setting not only helps the laboring woman create her own space to labor in, it also enhances the family's comfort and involvement. Birthing rooms usually have beds that can be adapted for birth by removing a small section near the foot. The decor is designed to produce a homelike atmosphere in which families can feel both safe and at ease.

This exemplar discusses in detail the normal progression of labor and culturally appropriate, family-centered care for the laboring mother, fetus, and close family members. A brief discussion of alterations that may occur in the intrapartum period is also provided.

Factors Important to Labor and Birth

The progress of labor is critically dependent on the complementary relationship among the following five factors:

1. Birth passage
2. Fetus
3. Relationship between birth passage and fetus
4. Physiologic forces of labor
5. Psychologic considerations.

Abnormalities affecting any one of these factors can alter the outcome of labor and jeopardize both the expectant woman and her baby.

Birth Passage

The true pelvis, which forms the bony canal through which the fetus must pass, is divided into three sections: the inlet, the pelvic cavity (midpelvis), and the outlet. Factors specific to the birth passage are the following:

- Size of the maternal pelvis, including diameters of the pelvic inlet, midpelvis, and outlet
- Type of maternal pelvis (gynecoid, android, anthropoid, platypelloid, or a combination)
- Ability of the cervix to dilate and efface
- Ability of the vaginal canal and external opening of the vagina (the introitus) to distend.

Fetus

Several aspects of the fetal body and position are critical to the outcome of labor. These include the fetal head, fetal attitude, fetal lie, and fetal presentation. Primary among these are the size and orientation of the fetal head.

Fetal Head

The head is the least compressible and largest part of the fetus. The size of the fetal head is a significant factor in the passage of the fetus during delivery. Once the fetal head has been born, the birth of the rest of the body is rarely delayed. The fetal skull (cranium) has three major parts:

1. Face
2. Base of the skull
3. Vault of the cranium (roof).

The bones of the face and cranial base are well fused and essentially fixed. The base of the cranium is composed of the two temporal bones, each with a sphenoid and ethmoid bone. The bones composing the vault are the two frontal bones, the two parietal bones, and the occipital bone (**Figure 33–41** >>>). These bones are not fused, allowing this

Figure 33–41 >>> Superior view of the fetal skull.

portion of the head to adjust in shape as the presenting part passes through the narrow portions of the pelvis. The cranial bones overlap under pressure of the powers of labor and the resistance of the pelvis. This overlapping is called **molding**.

The **sutures** of the fetal skull are membranous spaces between the cranial bones. The intersections of these sutures are called **fontanels**. Cranial sutures allow molding of the fetal head during birth and help the clinician to identify the position of the fetal head during vaginal examination. The important sutures of the cranial vault are as follows (see Figure 33–41):

- **Frontal (mitotic) suture.** Located between the two frontal bones, this becomes the anterior continuation of the sagittal suture.
- **Sagittal suture.** Located between the parietal bones, this divides the skull into left and right halves; it runs antero-posteriorly, connecting the two fontanels.
- **Coronal suture.** Located between the frontal and parietal bones, this extends transversely left and right from the anterior fontanel.
- **Lambdoidal suture.** Located between the two parietal bones and the occipital bone, this extends transversely left and right from the posterior fontanel.

The anterior and posterior fontanels (along with the sutures) are clinically useful in identifying the position of the fetal head in the pelvis and in assessing the neurologic and hydration status of the newborn after birth. The anterior fontanel is diamond shaped and measures approximately 2 by 3 cm. It permits growth of the brain by remaining unossified for as long as 18 months. The posterior fontanel is much smaller and closes within 8–12 weeks after birth. It is shaped like a small triangle and marks the meeting point of the sagittal suture and the lambdoidal suture.

Following are several important landmarks of the fetal skull (**Figure 33–42** »):

- **Mentum.** This is the fetal chin.
- **Sinciput.** This anterior area is known as the brow.

Figure 33–42 » Lateral view of the fetal skull identifying the landmarks that have significance during birth.

- **Bregma.** This is a large diamond-shaped anterior fontanel.
- **Vertex.** This is the area between the anterior and posterior fontanels.
- **Posterior fontanel.** This is the intersection between posterior cranial sutures.
- **Occiput.** This is the area of the fetal skull occupied by the occipital bone, beneath the posterior fontanel.

The diameters of the fetal skull vary considerably within its normal limits. Some diameters shorten and others lengthen as the head is molded during labor. Fetal head diameters are measured between the various landmarks on the skull. For example, the suboccipitobregmatic diameter is the distance from the undersurface of the occiput to the center of the bregma, or anterior fontanel.

Fetal Attitude

Fetal attitude refers to the relation of the fetal parts to one another, including flexion or extension of the fetal body and extremities. The normal attitude of the fetus is one of moderate flexion of the head, flexion of the arms onto the chest, and flexion of the legs onto the abdomen.

Fetal Lie

Fetal lie refers to the relationship of the cephalocaudal (spinal column) axis of the fetus to the cephalocaudal axis of the woman. The fetus may assume either a longitudinal (vertical) lie or a transverse horizontal lie. A longitudinal lie occurs when the cephalocaudal axis of the fetus is parallel to the woman's spine. A transverse lie occurs when the cephalocaudal axis of the fetus is at a right angle to the woman's spine.

Fetal Presentation

Fetal presentation is determined by fetal lie and by the body part of the fetus that enters the pelvic passage first. This portion of the fetus is referred to as the **presenting part**. Fetal presentation may be cephalic, breech, or shoulder. The most common presentation is cephalic. When this presentation occurs, labor and birth are likely to proceed normally. Breech and shoulder presentations are called **malpresentations** because they are associated with difficulties during labor. With a malpresentation, labor does not proceed as expected.

The fetal head presents itself to the passage in approximately 97% of term births. The cephalic presentation can be further classified according to the degree of flexion or extension of the fetal head (attitude) as follows:

- **Vertex presentation.** The fetal head is completely flexed onto the chest, and the smallest diameter of the fetal head (suboccipitobregmatic) presents to the maternal pelvis (**Figure 33–43A** »). The occiput is the presenting part. Vertex is the most common type of presentation.
- **Military presentation.** The fetal head is neither flexed nor extended. The occipitofrontal diameter presents to the maternal pelvis (**Figure 33–43B**). The top of the head is the presenting part.
- **Brow presentation.** The fetal head is partially extended. The occipitomenal diameter, the largest anteroposterior

Figure 33-43 >> Cephalic presentation. **A**, Vertex presentation. Complete flexion of the head allows the suboccipitobregmatic diameter to present to the pelvis. **B**, Military (median vertex) presentation with no flexion or extension. The occipitofrontal diameter presents to the pelvis. **C**, Brow presentation. The fetal head is in partial (halfway) extension. The occipitotental diameter, which is the largest diameter of the fetal head, presents to the pelvis. **D**, Face presentation. The fetal head is in complete extension, and the submentobregmatic diameter presents to the pelvis.

diameter, is presented to the maternal pelvis (Figure 33-43C). The sinciput is the presenting part (refer to Figure 33-42).

- **Face presentation.** The fetal head is hyperextended (complete extension). The submentobregmatic diameter presents to the maternal pelvis (Figure 33-43D). The face is the presenting part.

Breech presentations occur in 3% of all births (Cunningham et al., 2014). In all variations of the breech presentation, the sacrum is the landmark to be noted. These presentations are classified according to the attitude of the fetus's hips and knees:

- **Complete breech.** The fetal knees and hips are both flexed, the thighs are on the abdomen, and the calves are on the posterior aspect of the thighs. The buttocks and feet of the fetus present to the maternal pelvis.
- **Frank breech.** The fetal hips are flexed, and the knees are extended. The buttocks of the fetus present to the maternal pelvis.
- **Footling breech.** The fetal hips and legs are extended, and the feet of the fetus present to the maternal pelvis. In a single footling breech, one foot presents; in a double footling breech, both feet present.

A shoulder presentation is also called a transverse lie. Most frequently, the shoulder is the presenting part, and the acromion process of the scapula is the landmark to be noted. However, the fetal arm, back, abdomen, or side may present in a transverse lie. The incidence of shoulder presentation is 0.1% of all births (Gabbe et al., 2012).

Relationship Between the Birth Passage and the Fetus

When assessing the relationship of the maternal pelvis and the presenting part of the fetal body, the nurse considers the

engagement of the fetal presenting part, the station or location of the fetal presenting part in the maternal pelvis in relation to the ischial spine, and the fetal position or relationship of the presenting part to one of the four quadrants of the maternal pelvis.

Engagement

Engagement of the presenting part occurs when the largest diameter of the presenting part reaches or passes through the pelvic inlet. Whereas engagement confirms the adequacy of the pelvic inlet, it does not indicate whether the midpelvis and outlet are also adequate.

Engagement can be determined by vaginal examinations and Leopold maneuvers. In primigravidas, engagement occurs approximately 2 weeks before term. Multiparas, however, may experience engagement several weeks before the onset of labor or during the process of labor.

Another variable of engagement is the relationship of the fetal sagittal suture to the mother's symphysis pubis and sacrum. The terms *synclitism* and *asynclitism* describe this relationship. **Synclitism** occurs when the sagittal suture is midway between the symphysis pubis and the sacral promontory. Upon vaginal examination, the suture is felt to be midline between these two maternal landmarks and as though it is in alignment. **Asynclitism** occurs when the sagittal suture is directed toward either the symphysis pubis or the sacral promontory and is felt to be misaligned. Upon vaginal examination, the suture feels somewhat turned to one side within the pelvis, making it asymmetrical. Asynclitism can be either anterior or posterior. It is important to identify asynclitism, because it can lengthen the time of descent or interfere with the descent process. Sometimes, this can lead to inability of the fetal head to fit through the birth canal and can result in the need for a cesarean birth.

Station

Station refers to the relationship of the presenting part to an imaginary line drawn between the ischial spines of the maternal pelvis. In a normal pelvis, the ischial spines mark the narrowest diameter through which the fetus must pass. As a landmark, the ischial spines have been designated as zero (0) station (**Figure 33–44** »). If the presenting part is higher than the ischial spines, a negative number is assigned, noting the number of centimeters above zero station. Engagement is represented when the fetal head reaches zero station. Positive numbers indicate that the presenting part has passed the ischial spines. Station –5 is at the pelvic inlet, and station +5 is at the outlet.

During labor, the presenting part should move progressively from the negative stations to the midpelvis at zero station and into the positive stations. If the presenting part can be seen at the woman's perineum, birth is imminent. Failure of the presenting part to descend in the presence of strong contractions may be caused by disproportion between the maternal pelvis and the fetal presenting part, malpresentation, asynclitism, or multiple fetuses. Station is assessed by vaginal examination.

Fetal Position

Fetal position refers to the relationship between a designated landmark on the presenting fetal part and the front, sides, or back of the maternal pelvis. The chosen landmarks differ according to presentation as follows:

- The landmark for vertex presentations is the occiput.
- The landmark for face presentations is the mentum.

Figure 33–44 » Measuring the station of the fetal head while it is descending. In this view, the station is –2/–3.

- The landmark for breech presentations is the sacrum.
- The landmark for shoulder presentations is the acromion process on the scapula.

To determine position, the nurse notes which quadrant of the maternal pelvis the appropriate landmark is directed toward: left anterior, right anterior, left posterior, or right posterior. If the landmark is directed toward the side of the pelvis, fetal position is designated as transverse rather than anterior or posterior. In documentation, the following abbreviations are used:

- Right (R) or left (L) side of the maternal pelvis
- The landmark of the fetal presenting part: occiput (O), mentum (M), sacrum (S), or acromion process (A)
- Anterior (A), posterior (P), or transverse (T), depending on whether the landmark is in the front, back, or side of the pelvis.

These abbreviations help the healthcare team communicate the fetal position. For example, when the fetal occiput is directed toward the back and to the left of the birth passage, the abbreviation used is LOP (left-occiput-posterior). In the setting of a transverse lie, the fetal spine may be either superior or inferior. This is simply described as *back up* or *back down*, respectively (Strauss, 2015).

Assessment techniques to determine fetal position include inspection and palpation of the maternal abdomen and vaginal examination. The most common fetal presentation is occiput anterior. When this presentation occurs, labor and birth are likely to proceed normally. Presentations other than occiput anterior are more frequently associated with problems during labor; therefore, they are called malpresentations. Presentations and malpresentations are illustrated in **Figure 33–45** ».

Physiologic Forces of Labor

Primary and secondary forces work together to achieve birth of the fetus, fetal membranes, and placenta. The primary force is uterine muscular contractions, which cause the changes of the first stage of labor: complete effacement and dilation of the cervix. The secondary force is the use of abdominal muscles to push during the second stage of labor, which also is known as bearing down.

Contractions

In labor, uterine contractions are rhythmic but intermittent. Between contractions, there is a period of relaxation. This allows the uterine muscles to rest and provides respite for the laboring woman. It also restores uteroplacental circulation, which is important to fetal oxygenation and adequate circulation in the uterine blood vessels.

Each contraction has three phases:

1. **Increment:** the building up of the contraction (the longest phase)
2. **Acme:** the peak of the contraction
3. **Decrement:** the letting up of the contraction.

When describing uterine contractions during labor, healthcare providers use the terms *frequency*, *duration*, and *intensity* (**Figure 33–46** »). **Frequency** refers to the time between the beginning of one contraction and the beginning

Figure 33-45 » Presentations and malpresentations. **Key:** FIRST LETTER: R = right, L = left. SECOND LETTER: O = occiput, M = mentum, S = sacrum, A = acromion process. THIRD LETTER: A = anterior, P = posterior, T = transverse.

Figure 33-46 » Characteristics of uterine contractions.

of the next contraction. **Duration** is measured from the beginning of a contraction to the completion of that same contraction. **Intensity** refers to the strength of the contraction during acme. In most instances, intensity can be estimated by an experienced examiner palpating the uterine fundus during a contraction, but it may be measured directly with an intrauterine catheter. When intensity is measured with an intrauterine catheter, the normal resting pressure in the uterus (between contractions) averages 10–12 mmHg. During acme, the intensity ranges from 25 to 40 mmHg in early labor, 50 to 70 mmHg in active labor, 80 to 100 mmHg during transition, and more than 100 mmHg while the woman is pushing in the second stage (Blackburn, 2013).

At the beginning of labor, the contractions are usually mild. As labor progresses, the duration, intensity, and frequency of the contractions increase. Because the contractions are involuntary, the laboring woman cannot control their duration, frequency, or intensity.

Bearing Down

After the cervix is completely dilated and the fetus has descended enough to stimulate a maternal urge to push, the maternal abdominal muscles contract as the woman pushes (Goer & Romano, 2012). This pushing action (also called *bearing down*) aids in expulsion of the fetus and placenta. If the cervix is not completely dilated, however, bearing down can cause cervical edema, which retards dilation, and may cause tearing and bruising of the cervix and maternal exhaustion.

Psychosocial Considerations

The final critical factor is the parents' psychosocial readiness, including their fears, anxieties, birth fantasies, excitement level, feelings of joy and anticipation, and level of social support. These psychosocial factors affect both parents. Both are making a transition into a new role, and both have expectations of themselves during the labor and birth experience and as caregivers for their child and their new family. Psychosocial factors that affect labor and birth include the couple's accomplishment of the tasks of pregnancy, usual coping mechanisms in response to stressful life events, support system, preparation for childbirth, and cultural influences. Even pregnant women and partners who attend childbirth preparation classes and have a solid support system can be concerned about what labor will be like. Many couples, even in the intense happiness and excitement of the event, may be

concerned about whether they will be able to perform the way they expect, whether the pain will be more than the mother expects or can cope with, and whether the partner can provide helpful support. Although birth is usually a happy and joyful event, it is also a time of physical and emotional stress. Whether that stress is positive or negative, it can affect a couple's responses to the labor itself.

A woman approaching her first labor faces a totally new experience, and the woman who has given birth before knows that this labor might be very different from her previous experience. Most women wonder whether they will live up to their expectations for themselves, whether they will experience a physical injury (e.g., lacerations, episiotomy, or cesarean incision), and whether significant others will be supportive. Many women are excited and happy that labor has begun; however, they may have concerns about the labor process itself.

Expectant women mentally prepare for labor through meaningful action and imaginary rehearsal. The actions frequently consist of "nesting behavior" (housecleaning, decorating the nursery) and a "psyching up" for the labor, which varies depending on the woman's self-confidence, self-esteem, and previous experiences with stress. Specific actions to prepare for labor may focus on becoming better informed and prepared. In addition, just as a woman tries on the maternal role during pregnancy, fantasizing about labor seems to help her understand and become better prepared for it. Fantasies about the excitement of the baby's birth and the sharing of the experience involve the woman in constructive preparation. Many pregnant women have dreams about their baby, labor, birth, and parenting. Some women may fear the pain of contractions, whereas others may welcome the opportunity to feel the birth process. Some women view the pain as threatening and associate it with a loss of control over their bodies and emotions. Others see the pain as a rite of passage into motherhood and a necessary means to an end. It is helpful for the woman to realize that she is safe and that labor pain is not the same sign of danger as pain in other circumstances. Assurances from the nurse that labor is progressing normally can go a long way toward reducing anxiety (and thereby reducing pain) and providing positive reinforcement that the mother is doing a good job.

Empowerment and having control over one's body play a key role in determining whether the woman views her labor and birth positively. Women who viewed their birth experiences as being positive were also more likely to have a sense

of well-being about themselves after the experience (Haines et al., 2013). Some women view the birth experience as a challenge in which they will have the opportunity to succeed and provide their baby with a joyful reception into the world.

The laboring woman's support system also influences the course of labor and birth. Some women prefer not to have a support person or family member with them during the birth process. For some, this process is a private moment that the woman may wish to reserve for herself. However, most women choose to have significant individuals (family members, partner, or friend) with them during labor and birth. This social support tends to have a positive effect. For some families, the birth event is a celebration in which they may want as many significant others present as possible. Some women may want to create a joyful, festive atmosphere that includes the grandparents, friends, and other children. A labor partner's presence at the bedside provides a means to enhance communication and to demonstrate feelings of love. Communication needs may include talking and the use of affectionate and reassuring words from the partner. Affection may also take the form of holding hands, hugging, touching, or gentle reassurance for the laboring woman.

How the woman views the birth experience in hindsight may affect her mothering behaviors. It appears that any activities by the expectant woman or by healthcare providers that enhance the birth experience benefit the mother-baby connection. Studies have shown that when some women are disappointed with their birth experience, they may have some initial difficulties and be at higher risk for postpartum mood disorders (Gurber et al., 2012). The partner's experience of the birth and opportunities for bonding may have important implications for parenting as well. Psychosocial factors associated with a positive birth experience are summarized in **Box 33-3** ».

Physiology of Labor

In addition to considering the five critical factors affecting the progress of labor and birth, it is essential to explore the physiology of the normal birth experience.

Box 33-3

Factors Associated with a Positive Birth Experience

- Motivation for the pregnancy
- Attendance at childbirth education classes
- A sense of competence or mastery
- Self-confidence and self-esteem
- Feelings of empowerment
- Positive relationship with mate
- Maintaining control during labor
- Support from partner or other individual during labor
- Not being left alone in labor
- Trust in the medical/nursing staff
- Having personal control of breathing patterns, comfort measures
- Choosing a healthcare provider who has a compatible philosophy of care
- Receiving clear information regarding procedures

Possible Causes of Labor Onset

The process of labor usually begins between 37 and 42 weeks of gestation, when the fetus is mature and ready for birth. Despite research, the exact cause of labor onset is not clearly understood. However, some important aspects have been identified: Progesterone relaxes smooth muscle tissue; estrogen stimulates uterine muscle contractions; and connective tissue loosens to permit the softening, thinning, and eventual opening of the cervix (Blackburn, 2013). Currently, researchers are focusing on the role of fetal membranes (chorion and amnion), the decidua, prostaglandin, corticotropin-releasing hormone, and progesterone withdrawal in relation to labor onset (Blackburn, 2013).

Myometrial Activity

In true labor, with each contraction the muscles of the upper uterine segment shorten and exert a longitudinal traction on the cervix, causing effacement. **Effacement** is thinning of the cervix as it is drawn upward into the uterine side walls. The cervix changes progressively from a long, thick structure to a structure that is tissue-paper thin (**Figure 33-47** »). In primigravidas, effacement usually precedes dilation.

Contractions are stimulated by the hormone oxytocin. Oxytocin is a potent uterine stimulant and is frequently used as an agent to induce or augment labor in term fetuses or when delivery is necessitated. Uterine sensitivity to oxytocin is increased during pregnancy (Blackburn, 2013). Oxytocin is produced in the hypothalamus and secreted into the bloodstream, but it is also produced in uterine tissues during late gestation, with concentrations increasing at the onset of labor. Oxytocin receptors are most likely formed in the gestational tissues, which when stimulated produce myometrial activity (Cunningham et al., 2014).

The uterus shortens with each contraction, which in turn pulls the lower uterine segment upward. This shortening causes flexion of the fetal body, thrusting the presenting part down toward the lower uterine segment and the cervix. The pressure exerted by the fetus is called the fetal axis pressure. As the uterus shortens, the longitudinal muscle fibers elongate, and the lower uterine segment becomes more distensible and removes resistance on the presenting part as the uterus is pulled upward. This action and the hydrostatic pressure of the fetal membranes cause cervical dilation. The cervical os and cervical canal widen from less than 1 cm to approximately 10 cm, allowing birth of the fetus. When the cervix is completely dilated and retracted into the lower uterine segment, it can no longer be palpated. At the same time, the round ligament pulls the fundus forward, aligning the fetus with the bony pelvis.

Note that the metric system is used for measurement in labor and delivery. Dilation of the cervix is measured in centimeters, for example.

Changes in the Pelvic Floor

Direct pressure from the fetal head pushes the rectum and vagina downward and forward with each contraction along the curve of the pelvic floor. As the fetal head descends to the pelvic floor, the pressure of the presenting part causes the perineal structure, which was once approximately 5 cm

Figure 33-47 » Effacement of the cervix in the primigravida. **A**, Beginning of labor. There is no cervical effacement or dilation. The fetal head is cushioned by amniotic fluid. **B**, Beginning cervical effacement. As the cervix begins to efface, more amniotic fluid collects below the fetal head. **C**, Cervix is about one-half (50%) effaced and slightly dilated. The increasing amount of amniotic fluid below the fetal head exerts hydrostatic pressure on the cervix. **D**, Complete effacement and dilation.

in thickness, to change to a structure less than 1 cm thick. A normal physiologic anesthesia is produced as a result of the decreased blood supply to the area. The anus everts, exposing the interior rectal wall as the fetal head descends forward (Blackburn, 2013).

Premonitory Signs of Labor

Most primigravidas and many multiparas experience the following signs and symptoms of impending labor: lightening, Braxton Hicks contractions, cervical changes, bloody show, rupture of membranes, and a sudden burst of energy.

Lightening

Lightening describes the effects that occur when the fetus begins to settle into the pelvic inlet (engagement). With fetal

descent, the uterus moves downward, and the fundus no longer presses on the diaphragm, so breathing is eased. However, with increased downward pressure of the presenting part, the woman may notice the following:

- Leg cramps or pains caused by pressure on the nerves that course through the obturator foramen in the pelvis
- Increased pelvic pressure
- Increased urinary frequency
- Increased venous stasis, leading to edema in the lower extremities
- Increased vaginal secretions resulting from congestion of the vaginal mucous membranes.

Braxton Hicks Contractions

Before the onset of labor, **Braxton Hicks contractions** (the irregular, intermittent contractions that have been occurring throughout the pregnancy) may become uncomfortable. The pain seems to be focused in the abdomen and groin but may feel like the “drawing” sensations experienced by some women with dysmenorrhea. Braxton Hicks contractions that are strong enough to disturb the mother without affecting cervical change or fetal descent are sometimes referred to as “false” labor. Prelabor contractions may be exhausting. If the contractions are fairly regular, the woman has no way of knowing whether they are the beginning of active labor and she may come to the hospital or birthing center for a vaginal examination to determine whether cervical dilation is occurring. These prelabor contractions may be exacerbated by inadequate fluid intake, a full bladder, sexual activity, or a urinary tract infection. An episode of regular contractions may resolve or continue, becoming active labor. It is important to remember that women with contractions that occur on a regular basis before 37 completed weeks of gestation should be assessed to determine whether they are experiencing preterm labor.

Cervical Changes

Considerable change occurs in the cervix during the prenatal and intrapartum period. At the beginning of pregnancy, the cervix is rigid and firm, and it must soften so that it can stretch and dilate to allow passage of the fetus. This softening of the cervix is called ripening.

As term approaches, the action of enzymes, such as collagenase and elastase, breaks down the collagen fibers of the cervix. As the collagen fibers change, their ability to bind together decreases because of increasing amounts of hyaluronic acid, which loosely binds collagen fibrils, and decreasing amounts of dermatan sulfate, which tightly binds collagen fibrils. The water content of the cervix also increases. All these changes result in a weakening and softening of the cervix.

Bloody Show

During pregnancy, cervical secretions accumulate in the cervical canal to form a barrier called a mucous plug. With softening and effacement of the cervix, the mucous plug is often expelled, resulting in a small amount of blood loss from the exposed cervical capillaries. The resulting pink-tinged secretions are called **bloody show**. Bloody show is considered to be a sign that labor will begin within 24–48 hours. Vaginal examination that includes manipulation of the cervix may also result in a blood-tinged discharge, which is sometimes confused with bloody show.

Rupture of Membranes (ROM)

In approximately 12% of women, the amniotic membranes rupture before the onset of labor. After membranes rupture, 90% of women will experience spontaneous labor within 24 hours (Jazayeri, 2014). Membrane rupture prior to the onset of labor is referred to as **premature rupture of membranes (PPROM)**. Many clinicians recommend induction of labor in the setting of term PROM to avoid intra-amniotic infection. There is, however, no quality evidence to support this practice, and patients should be given the option of awaiting spontaneous labor (Goer & Romano, 2012).

At the beginning of labor, the amniotic membranes may bulge through the cervix in the shape of a cone. When the membranes rupture, the amniotic fluid may be expelled in large amounts. **Spontaneous rupture of membranes (SROM)** generally occurs at the height of an intense contraction with a gush of the fluid out of the vagina. If engagement has not occurred, the danger exists that a portion of the umbilical cord may be expelled with the fluid (prolapsed cord). In addition, because of these potential problems, the woman is advised to notify her healthcare provider and proceed to the hospital or birthing center. In some instances the fluid is expelled in small amounts and may be confused with episodes of urinary incontinence associated with urinary urgency, coughing, or sneezing. The discharge should be checked to ascertain its source and to determine further action. In some instances, the membranes are ruptured by the healthcare provider, using an instrument called an amniohook. This procedure is called *amniotomy* or **artificial rupture of membranes (AROM)**.

When the membranes rupture and leakage of amniotic fluid from the vagina occurs before 37 weeks of gestation, the term **preterm premature rupture of membranes (PPROM)** is used. PPRM occurs in up to 25% of all cases of preterm labors, complicates more than 3% of pregnancies each year (Jazayeri, 2014), and is associated with more than one third of preterm births. Infection often precedes PPRM. When PPRM is suspected, strict sterile technique should be used in any vaginal examination.

Sudden Burst of Energy

Some women report a sudden burst of energy approximately 24–48 hours before labor. This often finds expression in nesting behaviors. The cause of this energy spurt is unknown. In prenatal teaching, warn prospective mothers not to overexert themselves during this energy burst in order to avoid being overtired when labor begins.

Other Signs

Additional premonitory signs include the following:

- Weight loss of 1–3 lb resulting from fluid loss and electrolyte shifts produced by changes in estrogen and progesterone levels.
- Diarrhea, indigestion, or nausea and vomiting just before onset of labor. The cause of these signs is unknown.

Differences Between True and False Labor

The contractions of true labor produce progressive dilation and effacement of the cervix. They occur regularly and increase in frequency, duration, and intensity. The discomfort of true labor contractions usually starts in the back and radiates around to the abdomen. The pain is not relieved by ambulation; in fact, walking may intensify the pain.

The contractions of false labor do not produce progressive cervical effacement and dilation. Classically, they are irregular and do not increase in frequency, duration, and intensity. The contractions may be perceived as a hardening or “balling up” without discomfort, or discomfort may occur mainly in the lower abdomen and groin. The discomfort may be

TABLE 33–10 Comparison of True and False Labor

True Labor	False Labor
Contractions are at regular intervals.	Contractions are irregular.
Intervals between contractions gradually shorten.	Usually no change.
Contractions increase in duration and intensity.	Usually no change.
Discomfort begins in back and radiates around to abdomen.	Discomfort is usually in abdomen.
Intensity usually increases with change in activity.	Change of activity has no effect on contractions.
Cervical dilation and effacement are progressive.	No change.
Contractions do not decrease with rest or warm tub bath.	Rest and warm tub lessen contractions.

relieved by ambulation, changing positions, drinking a large amount of water, or taking a warm shower or tub bath.

The pregnant woman will find it helpful to know the characteristics of true labor contractions as well as the premonitory signs of ensuing labor. At times, however, the only way to differentiate accurately between true and false labor is to assess dilation. The woman must feel free to come in for accurate assessment of labor and should be counseled not to feel foolish if the labor is false. The nurse must reassure the woman that false labor is common and that it often cannot be distinguished from true labor except by vaginal examination. **Table 33–10** » provides a comparison of true and false labor.

Stages of Labor and Birth

To assist healthcare providers, common terms have been developed as benchmarks to subdivide the labor process into phases and stages of labor. It is important to note, however, that these represent theoretical separations in the process. A laboring woman will not usually experience distinct differences from one stage to another.

The first stage begins with the onset of true labor and ends when the cervix is completely dilated at 10 cm and the mother has the urge to push. The second stage begins with urge to

push in the setting of complete dilation and ends with the birth of the newborn. The third stage begins with the birth of the newborn and ends with the delivery of the placenta.

Some clinicians identify a fourth stage. During this stage, which lasts 1–4 hours after delivery of the placenta, the uterus effectively contracts to control bleeding at the placental site (Cunningham et al., 2014).

First Stage

The first stage of labor is divided into the latent, active, and transition phases. Each phase of labor is characterized by physical and psychologic changes and is summarized in **Table 33–11** ».

Latent Phase

The latent (or prodromal) phase starts with the beginning of regular contractions, which are usually mild. The woman feels able to cope with the discomfort. She may be relieved that labor has finally started and that the end of pregnancy has come. Although she may be anxious, she is able to recognize and express those feelings of anxiety. The woman is often smiling and eager to talk about herself and answer questions. Excitement is high, and her partner or other support person is often equally elated.

TABLE 33–11 Characteristics of Labor

	First Stage			
	Latent Phase	Active Phase	Transition Phase	Second Stage
Labor				
Nullipara	<20 hr in most cases	1.1–3.8 hr	1–3.2 hr	≤3 hr, may be longer than 3 hours with epidural anesthesia
Multipara	<14 hr in most cases	0.9–3.2 hr	0.6–2 hr	<1 hr, may be as much as 2 hours with epidural
Cervical dilation	0–6 cm	6–8 cm	8–10 cm	
Contractions				
<i>Note:</i> Contractions patterns may vary considerably. Patterns that do not fit the parameters outlined here are only classified as pathologic in the setting of protraction or arrest of labor.				
Frequency	Every 10–30 min	Every 2–5 min	Every 1.5–2.0 min	Every 1.5–2.0 min
Duration	30–40 sec	40–60 sec	60–90 sec	60–90 sec
Intensity	Begin as mild and progress to moderate; 25–40 mmHg by intra-uterine pressure catheter (IUPC)	Begin as moderate and progress to strong; 50–70 mmHg by IUPC	Strong by palpation; 70–90 mmHg by IUPC	Strong by palpation; 70–100 mmHg by IUPC

Uterine contractions become established during the latent phase and increase in frequency, duration, and intensity. They may start as mild contractions lasting 30 seconds with a frequency of 10–30 minutes and progress to moderate ones lasting 30–40 seconds with a frequency of 5–7 minutes. As the cervix begins to dilate, it also effaces, although little or no fetal descent is evident. For a woman in her first labor (nullipara), the latent phase of the first stage of labor averages 8.6 hours but does not typically exceed 20 hours. The latent phase in multiparas averages 5.3 hours and does not typically exceed 14 hours. Such specific descriptions of the latent/prodromal phase are guidelines and the actual experiences of women prior to the active phase vary widely. Timing and duration of contractions and time elapsed before the onset of the active phase do not, in themselves, require intervention or influence management. Maternal exhaustion may call for therapeutic rest or in-hospital hydration (King et al., 2013).

Active Phase

When the woman enters the early active phase, her anxiety and her sense of the need for energy and focus tend to increase as she senses the intensification of contractions and pain. She may begin to fear a loss of control or may feel the need to “really work and focus” on the contractions. Women will use a variety of coping mechanisms. Some women exhibit a sense of purpose and the need for regrouping, whereas others may feel a decreased ability to cope or a sense of helplessness. Women who have support persons and family available often experience greater satisfaction and have less anxiety compared to women without support.

During this phase, the cervix dilates from approximately 6 to 8 cm (1.6 to 2.8 in.). Fetal descent is progressive and the rate of cervical dilation most often increases. During the active phase, contractions become more frequent and longer in duration, and they increase in intensity. By the end of the active phase, contractions may have a frequency of 2–5 minutes, a duration of 40–60 seconds, and strong intensity.

Transition Phase

The transition phase is the last part of the first stage of labor. When the woman enters the transition phase, she may demonstrate an acute awareness of the need for her energy and attention to be completely focused on the task at hand. She may experience significant anxiety or feel out of control. She becomes acutely aware of the increasing force and intensity of the contractions. Irritability and feelings of self-doubt may occur. She may become restless, frequently changing position in an attempt to get comfortable. The nurse should recognize these behaviors as normal and communicate such to the laboring woman and her support person.

By the time the woman enters the transition phase, she is inner directed and often tired. She may not want to be left alone; at the same time, the support person may be feeling the need for a break. The nurse should reassure the woman that she will not be left alone. It is crucial that the nurse be available as relief support at this time and keep the patient informed about where her labor support people are if they leave the room. Some women have the intuition that the end of labor is occurring and know that birth is near; an instinct to have support people remain often occurs.

During the transition phase, contractions have a frequency of approximately every 1.5–2 minutes, a duration of 60–90 seconds, and strong intensity. The transition phase does not usually last longer than 3 hours for nulliparas or longer than 1 hour for multiparas (King et al., 2013). The total duration of the first stage may be increased by approximately 1 hour if epidural anesthesia is used.

As dilation approaches 10 cm, there may be increased rectal pressure and an uncontrollable desire to bear down, an increased amount of bloody show, and rupture of membranes (if it has not already occurred). With the peak of a contraction, the woman may experience a sensation of intense pressure. If laboring without anesthesia, she may fear that she will be “torn open” or “split apart.” She may also fear that the sensations indicate that something is wrong. The nurse should inform the patient that what she is feeling is normal in this stage of labor. Even with assurance, however, the woman may increasingly doubt her ability to cope with labor and may become apprehensive, irritable, and withdrawn. She may be terrified of being left alone, though she might not want anyone to talk to or touch her. However, with the next contraction, she may ask for verbal and physical support.

Other characteristics of this phase may include the following:

- Increasing bloody show
- Hyperventilation
- Generalized discomfort, including low backache, shaking and cramping in legs, and increased sensitivity to touch
- Increased need for partner’s and/or nurse’s presence and support
- Restlessness
- Increased apprehension and irritability
- An inner focusing on her contractions
- A sense of bewilderment, frustration, and anger at the contractions
- Requests for medication
- Hiccoughing, belching, nausea, or vomiting
- Beads of perspiration on the upper lip or brow
- Increasing rectal pressure and feeling the urge to bear down.

The woman in this phase is anxious to “get it over with.” She may be amnesic and sleep between her now-frequent contractions. Her support persons may start to feel fatigue and may feel helpless, and they may want more participation from the nurse as their efforts to alleviate the woman’s discomfort seem less effective.

Second Stage

The second stage of labor begins with complete cervical dilation and ends with birth of the baby. For primigravidas, the second stage should be completed within 3–4 hours after the cervix becomes fully dilated; for multiparas, the second stage is often less than 15 minutes long. Contractions continue with a frequency of about every 1.5–2 minutes, a duration of 60–90 seconds, and strong intensity (Cheng, 2014). Descent of the fetal presenting part continues until it reaches the perineal floor.

As the fetal head descends, the woman usually has the urge to push because of pressure from the fetal head on the sacral and obturator nerves. As she pushes, intra-abdominal pressure is exerted from contraction of the maternal abdominal muscles. As the fetal head continues its descent, the perineum begins to bulge, flatten, and move anteriorly. Most women feel acute, increasingly severe pain and a burning sensation as the perineum distends. The amount of bloody show may increase. The labia begin to part with each contraction, and between contractions, the fetal head appears to recede. With succeeding contractions and maternal pushing effort, the fetal head descends farther. **Crowning** occurs when the head no longer recedes and remains visible at the vaginal introitus between contractions; this means that birth is imminent.

The woman may feel some relief that the transition phase of the first stage is over, the birth is near, and she can push. Some women feel a sense of purpose now that they can be actively involved. The woman may be focused and should be encouraged to center all her energy into pushing. The nurse should encourage resting between contractions as well. The support person can offer ice chips, fan the woman, who is often overheated and fatigued, offer verbal encouragement, and provide support to the legs.

For women without childbirth preparation, this stage can become frightening. The nurse should encourage the woman to work with her contractions and not fight them. A support person who has never seen a labor may also become disconcerted during this time. The nurse can assist the support person in performing activities and offering encouragement that assists the woman during the birth process. The woman may feel she has lost her ability to cope and may become embarrassed, or she may demonstrate extreme irritability toward the staff or her supporters as she attempts to regain control over her body. Some women feel a great sense of purpose and are unrelenting in their efforts to work with each and every contraction, and some women will be very forceful with and directive of staff and support persons. Although not as common, some women may not experience an overwhelming urge to push and will require guidance and encouragement by the nurse to effectively push during contractions. All of these reactions and emotions are normal and should be supported as the woman works toward the birth.

Positional Changes of the Fetus

For the fetus to pass through the birth canal, the fetal head and body must adjust to the passage by certain positional changes. These changes, called **cardinal movements** or mechanisms of labor, are described here in the order in which they occur (**Figure 33–48** »):

- **Descent.** This occurs because of four forces: (1) pressure of the amniotic fluid, (2) direct pressure of the uterine fundus on the breech, (3) contraction of the abdominal muscles, and (4) extension and straightening of the fetal body. The head enters the inlet in the occiput transverse or oblique position because the pelvic inlet is widest from side to side. The sagittal suture is equidistant from the maternal symphysis pubis and the sacral promontory.
- **Flexion.** This occurs as the fetal head descends and meets resistance from the soft tissues of the pelvis, the muscles

of the pelvic floor, and the cervix. As a result of the resistance, the fetal chin flexes downward onto the chest.

- **Internal rotation.** The fetal head must rotate to fit the diameter of the pelvic cavity, which is widest in the anteroposterior diameter. As the occiput of the fetal head meets resistance from the levator ani muscles and their fascia, the occiput rotates—usually from left to right—and the sagittal suture aligns in the anteroposterior pelvic diameter.
- **Extension.** The resistance of the pelvic floor and the mechanical movement of the vulva opening anteriorly and forward assist with extension of the fetal head as it passes under the symphysis pubis. With this positional change, the occiput, and then the brow and face, emerge from the vagina.
- **Restitution.** The shoulders of the fetus enter the pelvis inlet obliquely and remain oblique when the head rotates to the anteroposterior diameter through internal rotation. Because of this rotation, the neck becomes twisted. Once the head is born and is free of pelvic resistance, the neck untwists, turning the head to one side (restitution), and aligns with the position of the back in the birth canal.
- **External rotation.** As the shoulders rotate to the anteroposterior position in the pelvis, the head turns farther to one side (external rotation).
- **Expulsion.** After the external rotation, and through the pushing efforts of the laboring woman, the anterior shoulder meets the undersurface of the symphysis pubis and slips under it. As lateral flexion of the shoulder and head occurs, the anterior shoulder is born before the posterior shoulder. The body follows quickly.

Spontaneous Birth (Vertex Presentation)

As the fetal head distends the vulva with each contraction, the perineum becomes extremely thin, and the anus stretches and protrudes. With time, the head extends under the symphysis pubis and is born. When the anterior shoulder meets the underside of the symphysis pubis, a gentle push by the mother aids in the birth of the shoulders. The body then follows. See a birth sequence in **Figure 33–49** ».

Third Stage

The third stage of labor is defined as the period of time from the birth of the baby until the completed delivery of the placenta, and should be completed within 30 minutes of the birth of the baby. Intervention is required if separation of the placenta from the uterine wall has not occurred after 30 minutes (see *Retained placenta* in the Alterations and Therapies feature).

Placental Separation

After the baby is born, the uterus contracts firmly, diminishing its capacity and the surface area of placental attachment. The placenta begins to separate because of this decrease in surface area. As this separation occurs, bleeding results in formation of a hematoma between the placental tissue and the remaining decidua. This hematoma accelerates the separation process. The membranes are the last to separate. They are peeled off the uterine wall as the placenta descends into the vagina.

Figure 33-49 » Mechanisms of labor. **A**, Descent. **B**, Flexion. **C**, Internal rotation. **D**, Extension. **E**, External rotation.

Signs of placental separation are as follows:

- A globular uterus
- A rise of the fundus in the abdomen
- A sudden gush or trickle of blood
- Further protrusion of the umbilical cord out of the vagina.

Placental Delivery

When the signs of placental separation appear, the woman may bear down to aid in placental expulsion. If this fails and the healthcare provider has ascertained that the fundus is firm, gentle traction may be applied to the cord while counter-pressure is exerted on the lower uterine segment with the provider's opposite hand to guard against uterine inversion (a prolapse of the uterine fundus to or through the cervix). The direction of traction should follow the sacral and symphyseal curves, and care should be taken to avoid allowing the placenta to fall into the collection pan in an uncontrolled fashion. This may snap off adherent membranes, leaving them in the uterus to cause infection and/or abnormal bleeding.

If the placenta separates from the outer margins inward, it will roll up and present sideways, with the maternal surface delivering first. This is known as the Duncan mechanism of placental delivery and, because the placental surface is rough, is commonly called "dirty Duncan" (see Figure 33-12). If the placenta separates from the inside to the outer margins, it is delivered with the fetal (shiny) side presenting (see Figure 33-13). This is known as the Schultz mechanism of placental delivery or, more commonly, "shiny Schultz."

Fourth Stage

The fourth stage of labor is the time, from 1 to 4 hours after birth, during which physiologic readjustment of the mother's

body begins. With the birth, hemodynamic changes occur. Normal blood loss may be as much as 500 mL. With this blood loss and removal of the weight of the pregnant uterus from the surrounding vessels, blood is redistributed into venous beds. This results in a moderate drop in both systolic and diastolic blood pressure, increased pulse pressure, and moderate tachycardia (Cunningham et al., 2014).

The uterus remains contracted in the midline of the abdomen. The fundus is usually midway between the symphysis pubis and umbilicus. Its contracted state constricts the vessels at the site of placental implantation. Immediately after birth of the placenta, the cervix remains open.

Nausea and vomiting usually cease. The woman may be thirsty and hungry. She may experience a shaking chill, which is thought to be associated with the ending of the physical exertion of labor. The bladder may be hypotonic because of trauma during the second stage and/or administration of anesthetics that decrease sensations. Hypotonic bladder can lead to urinary retention.

Maternal and Fetal Response to Labor

Maternal Systemic Response to Labor

The labor and birth process affects nearly all maternal physiologic systems.

Cardiovascular System

The mother's cardiovascular system is stressed both by the uterine contractions and by the pain, anxiety, and apprehension she experiences. During pregnancy, circulating blood volume increases by 50%. The increase in cardiac output

peaks between the second and third trimester, although during labor there is a significant increase in cardiac output. With each contraction, 300–500 mL of blood volume is forced back into the maternal circulation, which results in an increase in cardiac output of as much as 10–15% over the typical third-trimester levels (Blackburn, 2013). Further increases in cardiac output occur as the laboring woman experiences pain with uterine contractions and her anxiety and apprehension increase.

Maternal position also affects cardiac output. In the supine position, cardiac output decreases, heart rate increases, and stroke volume decreases. When the mother turns to a lateral (side-lying) position, cardiac output increases. Women with preexisting heart disease have higher rates of arrhythmias in labor (Blackburn, 2013).

Blood Pressure

As a result of increased cardiac output, blood pressure (both systolic and diastolic) rises during uterine contractions. In the first stage of labor, systolic pressure may increase by 35 mmHg and diastolic pressure may increase by approximately 25 mmHg during a contraction. There may be further increases in the second stage during pushing (Blackburn, 2013). The nurse should ensure that blood pressure measurements are not obtained during uterine contractions because they can result in inaccurate readings.

Respiratory System

Oxygen demand and consumption increase at the onset of labor because of the presence of uterine contractions. As anxiety and pain from contractions increase, hyperventilation frequently occurs. With hyperventilation, the arterial partial pressure of carbon dioxide (PaCO_2) falls, and respiratory alkalosis results (Powrie, Greene, & Camann, 2012).

By the end of the first stage of labor, most women develop a mild metabolic acidosis that is compensated for by respiratory alkalosis (see the module on Acid–Base Balance). As the woman pushes in the second stage of labor, her PaCO_2 levels may rise along with her blood lactate levels (because of muscular activity), leading to mild respiratory acidosis. By the time the baby is born (end of the second stage), the metabolic acidosis is uncompensated for by respiratory alkalosis (Blackburn, 2013).

The changes in acid–base status that occur in labor quickly reverse in the fourth stage because of changes in the woman's respiratory rate. Acid–base levels return to pregnancy levels by 24 hours after birth and to nonpregnant levels by a few weeks after birth (Blackburn, 2013; Powrie et al., 2012).

Renal System

During labor, increases are seen in the maternal renin level, plasma renin activity, and angiotensinogen level. These elevations are thought to be important in the control of uteroplacental blood flow during birth and the early postpartum period (Blackburn, 2013).

Structurally, the base of the bladder is pushed forward and upward when engagement occurs. The pressure from the presenting part may impair blood and lymph drainage from the base of the bladder, leading to edema (Cunningham et al., 2014).

Gastrointestinal System

During labor, gastric motility and absorption of solid food are reduced. Gastric emptying time is prolonged, and gastric volume (amount of contents that remain in the stomach) remains increased, regardless of the time the last meal was taken (Blackburn, 2013). Some narcotics also delay gastric emptying time and add to the risk of aspiration if general anesthesia is used.

Immune System and Other Blood Values

The white blood cell (WBC) count increases to 25,000–30,000 cells/mm³ during labor and the early postpartum period. The change in WBCs is mostly because of increased neutrophils resulting from a physiologic response to stress. The increased WBC count makes it difficult to identify the presence of an infection.

Maternal blood glucose levels decrease during labor because glucose is used as an energy source during uterine contractions. The decreased blood glucose levels lead to a decrease in insulin requirements (Blackburn, 2013).

Pain

Pain during labor comes from a complexity of physical causes. Each mother experiences and copes with pain differently. Past experiences coping with pain will likely influence how the woman copes with pain during the labor process. Multiple factors affect a patient's reaction to labor pain.

Causes of Pain During Labor

The pain associated with the first stage of labor is unique in that it accompanies a normal physiologic process. Even though perception of the pain of childbirth varies among women, a physiologic basis exists for discomfort during labor. Pain during the first stage of labor arises from dilation of the cervix, which is the primary source of pain; stretching of the lower uterine segment; pressure on adjacent structures; and hypoxia of the uterine muscle cells during contraction (Blackburn, 2013). The areas of pain include the lower abdominal wall and the areas over the lower lumbar region and the upper sacrum.

During the second stage of labor, pain is caused by hypoxia of the contracting uterine muscle cells, distention of the vagina and perineum, and pressure on adjacent structures. Pain during the third stage of labor results from uterine contractions and cervical dilation as the placenta is expelled. This stage of labor is short, and afterward, anesthesia is needed primarily for episiotomy repair.

Factors Affecting Response to Pain

Many factors affect the individual's perception of and response to pain. For example, childbirth preparation classes may reduce the need for analgesia during labor. Preparing for labor and birth through reading, talking with others, or attending a childbirth preparation class frequently has positive effects for the laboring woman and her partner. The woman who knows what to expect and what techniques she may use to increase comfort tends to be less anxious during the labor. A tour of the birthing center and an opportunity to see and feel the environment also help reduce anxiety (especially with the first child), because during admission many new things are happening and they seem to occur all at once.

In addition, individuals tend to respond to painful stimuli in the way that is acceptable in their culture. In some cultures, it is natural for members to communicate pain, no matter how mild, whereas in other cultures, members stoically accept pain, either out of fear or because it is expected. Nurses need to be aware of cultural norms and demonstrate culturally competent care to women and their families in the intrapartum setting to facilitate satisfying birth experiences.

Response to pain may also be influenced by fatigue and sleep deprivation. The fatigued patient has less energy and ability to use such strategies as distraction or imagination to deal with pain. As a result, she may lose her ability to cope with labor and choose analgesics or other medications to relieve the discomfort.

A woman's previous experience with pain and anxiety also affects her ability to manage current and future pain. Women who have had experience with pain seem to be more sensitive to painful stimuli compared to those who have not. Unfamiliar surroundings and events may increase anxiety, as may separation from family and loved ones. Anticipation of discomfort and questions about whether the mother can cope with the contractions may increase anxiety as well.

Both attention and distraction influence the perception of pain. When the sensation of pain is the focus of attention, the perceived intensity is greater. A sensory stimulus, such as a back rub, can provide distraction and help refocus the woman's attention on the stimulus rather than the pain. Randomized controlled trials have shown that the continuous presence of a support person improves the woman's coping ability and perception of her experience. Furthermore, consistent provision of social support and comfort measures shortens the duration of labor, decreases use of analgesia and anesthesia, and reduces the rate of operative delivery (King et al., 2013).

Fetal Response to Labor

When the fetus is healthy, the mechanical and hemodynamic changes of normal labor have no adverse effects. However, certain physiologic responses, including heart rate, acid-base, hemodynamic changes, and fetal sensation experiences do occur.

Heart Rate

Fetal heart rate decelerations (periodic decreases in FHR from the normal baseline) can occur with intracranial pressures of 40–55 mmHg as the head pushes against the cervix. The currently accepted explanation of this **early deceleration** is hypoxic depression of the central nervous system, which is under vagal control. The absence of these head-compression decelerations in some fetuses during labor is explained by the existence of a threshold that is reached more gradually in the presence of intact membranes and lack of maternal resistance. These early decelerations are harmless in a normal fetus.

Acid–Base Status

Blood flow is decreased to the fetus at the peak of each contraction, leading to a slow decrease in pH status. During the second stage of labor, as uterine contractions become longer and stronger and the woman often holds her breath to push, the fetal pH decreases more rapidly. Although women are

encouraged to maintain slow, evenly paced breathing, holding of the breath often occurs. As the base deficit increases, fetal oxygen saturation drops by approximately 10% (Blackburn, 2013).

Hemodynamic Changes

The adequate exchange of nutrients and gases in the fetal capillaries and intervillous spaces depends, in part, on the fetal blood pressure. Fetal blood pressure is a protective mechanism for the normal fetus in the anoxic periods caused by the contracting uterus during labor. The fetal and placental reserves are usually enough to ensure that the fetus comes through these anoxic periods unharmed (Blackburn, 2013).

Fetal Sensation

Beginning at approximately 37 or 38 weeks of gestation (full term), the fetus is able to experience sensations of light, sound, and touch. The full-term fetus is able to hear music and the maternal voice. Even in utero, the fetus is sensitive to light and will move away from a bright light source. In addition, the full-term fetus is aware of pressure sensations during labor, such as the touch of the healthcare provider during a vaginal exam or the pressure on the head as a contraction occurs. Although the fetus may not be able to process this input, it is important to note that as the woman labors, the fetus also experiences the labor.

Alterations During Intrapartum Care

Most births occur without the need for operative obstetric intervention. In some instances, however, procedures are necessary to maintain the safety of the woman and the fetus. The most common of these procedures are labor induction, episiotomy, cesarean birth, and vaginal birth after cesarean (VBAC).

Generally, women are aware of the possible need for an obstetric procedure during their labor and birth. However, some women expect to have a normal, physiologic experience and feel disappointed, angry, or even guilty when an unanticipated procedure becomes necessary. This conflict between expectation and the need for intervention presents a challenge to maternity nurses. To support patient-centered care, the nurse provides information regarding any procedure to help the woman and her partner or other support person understand what is proposed, the anticipated benefits and possible risks, and any alternatives.

Cervical Ripening

Induction of labor may be necessary or beneficial in certain clinical situations. When the cervix is unfavorable (usually defined as a Bishop score less than 6; see **Table 33-12 >>>**), the use of cervical ripening agents increases the likelihood of a successful induction of labor. Misoprostol (Cytotec) and formulations of prostaglandin E₂ (PGE₂) gel for **cervical ripening** (softening and effacing of the cervix) are drugs that may be used for the pregnant woman at or near term when there is a medical or obstetric indication for induction of labor. Mechanical methods designed to ripen the cervix include the use of balloon catheters to encourage mechanical dilation.

TABLE 33–12 Bishop Scoring System

Score	Factor				
	Dilation (cm)	Position of Cervix	Effacement (%)	Station (from –3 to +3)	Cervical Consistency
0	Closed	Posterior	0–30	–3	Firm
1	1–2	Midposition	40–50	–2	Medium
2	3–4	Anterior	60–70	–1, 0	Soft
3	5–6	—	80	+1, +2	—

Source: Data from Bishop, E. H. (1964). Pelvic scoring for elective inductions. *Obstetrics & Gynecology*, 24, 266.

Use of Misoprostol

Misoprostol (Cytotec) is a synthetic PGE₁ analogue that can be used to soften and ripen the cervix and to induce labor. It is available as a tablet that is inserted into the vagina, or it can be taken orally or sublingually. The use of Cytotec for cervical ripening has fluctuated. Cytotec was widely used in the 1990s for cervical ripening and induction of labor until several reports showed an increase in the rates of uterine rupture. However, there is now a large body of research that supports its safety and efficacy when used appropriately (Phend, 2013). Cytotec is approved by the FDA for prevention of peptic ulcer disease and has had special labeling for indication of cervical ripening and induction of labor since 2002 (Phend, 2013).

Research has shown that the use of Cytotec for ripening the cervix and inducing labor is more effective than the use of oxytocin or prostaglandin agents and is less costly. Women who receive Cytotec to induce labor typically deliver within 24 hours of administration. The use of Cytotec is also associated with lower cesarean birthrates. When compared with women who have been induced using prostaglandin agents or oxytocin, the adverse outcomes do not differ among the three methods (ACOG, 2013f). Most adverse maternal and fetal outcomes associated with misoprostol have been associated with the use of doses larger than the recommended 25 mcg. Intravaginal misoprostol has been found to be as efficacious as or superior to dinoprostone gel (Cunningham et al., 2014). Guidelines for misoprostol induction include the following (ACOG, 2013f):

- The initial dosage should be 25 mcg.
- Recurrent administration should not exceed dosing intervals of more than 3–6 hours.
- Oxytocin should not be administered less than 4 hours after the last Cytotec dose.
- Cytotec should be administered only where the uterine activity and FHR can be monitored continuously for an initial observation period.

Contraindications for Cytotec include the following:

- Nonreassuring FHR tracing
- Frequent uterine contractions of moderate intensity.

Use of Prostaglandin Agents

The two most commonly used types of prostaglandin gel are Prepidil and Cervidil. Prepidil gel contains 0.5 mg

dinoprostone (a form of prostaglandin E₂ for intracervical application) and is placed intracervically. Cervidil is packaged in an intravaginal insert that resembles a 2-cm-square piece of cardboard. It is placed in the posterior vagina and is left in place to provide a slow release of 10 mg dinoprostone at a rate of 0.3 mg/hr over 12 hours.

The advantage of Cervidil is that it can be removed easily if an adverse reaction occurs. Both preparations have been demonstrated to cause cervical ripening, shorter labor, and lower requirements for oxytocin during labor induction (ACOG, 2013f). Vaginal birth is achieved within 24 hours for most women. The incidence of cesarean birth is reduced when prostaglandin agents are used before labor induction.

Risks of prostaglandin administration include uterine tachysystole (more than five contractions in 10 minutes), nonreassuring fetal status, higher incidence of postpartum hemorrhage, and uterine rupture that can occur even in the absence of a previous uterine incision (Creasy et al., 2014). Women with a previous uterine incision should not receive prostaglandin agents, because the risk of uterine rupture is greatly increased (ACOG, 2013f). Prostaglandin should be used with caution in women with compromised cardiovascular, hepatic, or renal function and in women with asthma or glaucoma (Creasy et al., 2014).

Use of Mechanical Methods

Balloon catheters are the safest and most common mechanical method of cervical ripening, though laminaria may still be used in some institutions. Advantages of mechanical agents for cervical ripening are similar efficacy when compared to hormonal agents, less cost, lower incidence of systemic side effects, and lower incidence of uterine tachysystole (Davidson, 2013).

Balloon catheters have been used for cervical ripening for many years to promote mechanical dilation. A Foley catheter with a 25- to 80-mL balloon is passed through the undilated cervix and then inflated. The weighted balloon applies pressure on the internal os of the cervix and acts to ripen the cervix. This technique can be used alone or in conjunction with pharmacologic or additional mechanical methods. Advantages of the balloon catheter include higher vaginal birth rates and lower rates of hypersystolic labor when combined with PGE₂ gel (Goldberg, 2015). One study examined cervical ripening after Foley catheter insertion and found that the mean change in the Bishop score was 3.56 after placement of a Foley bulb catheter. The average time from

Foley bulb expulsion until birth was 8 hours and 27 minutes, which indicates that Foley bulb induction is a safe and effective means to induce cervical ripening (Posner, Black, & Jones, 2013). A systematic review of the evidence of mechanical methods of cervical ripening and induction found that in women with an unfavorable cervix, Foley catheter placement prior to induction with oxytocin significantly reduced the duration of labor and reduced the risk of a cesarean section (Posner et al., 2013).

Nursing Care During Cervical Ripening

Physicians, CNMs, and labor and delivery nurses who have had special education and training may administer agents for cervical ripening. Maternal vital signs are assessed for a baseline, and an electronic fetal monitor is applied for at least 20 minutes to obtain an external tracing of uterine activity, FHR pattern, and a reactive nonstress test (NST). If a nonreactive test is obtained, consultation with the healthcare provider is required. After the gel, intravaginal insert, or tablet has been inserted, the woman is instructed to remain lying down with a rolled blanket or hip wedge under her right hip to tip the uterus slightly to the left for the first 30–60 minutes to maintain the cervical ripening agent in place. Gel may leak from the endocervix. The nurse monitors the woman for uterine tachysystole and FHR abnormalities (changes in baseline rate, variability [fluctuations in the FHR], and presence of decelerations) for 30 minutes to 2 hours if a prostaglandin gel agent is used (ACOG, 2013f). If tachysystole occurs, the woman is positioned on her left side and oxygen is administered if fetal stress is noted. The administration of a tocolytic agent (such as a subcutaneous injection of 0.25 mg terbutaline) should be considered if the uterine tachysystole pattern continues. The gel may be removed if severe nausea, vomiting, or tachysystole develops (Wilson, Shannon, & Shields, 2017). Treatment with antiemetics, antipyretics, and antidiarrheal agents usually is not indicated. Women who receive Cervidil or Cytotec tend to remain in the acute care setting so the contraction pattern and fetal status can be monitored continuously for an initial observation period (ACOG, 2013f).

Women undergoing induction via balloon catheters do not need continuous fetal monitoring. The nurse can perform intermittent monitoring along with the maternal vital signs. The nurse should also assess the location of the catheter to ensure that the catheter has not become displaced. This can be achieved by marking the catheter tubing at the introitus and noting whether movement has occurred. Vaginal examinations should not be performed.

Labor Induction

The ACOG defines **labor induction** as the stimulation of uterine contractions before the spontaneous onset of labor, with or without ruptured fetal membranes, for the purpose of accomplishing birth. Induction may be indicated in the presence of the following (Cunningham et al., 2014):

- Diabetes mellitus
- Renal disease
- Preeclampsia–eclampsia
- Chronic pulmonary disease

- Premature rupture of membranes
- Chorioamnionitis
- Postterm gestation greater than 42 weeks
- Mild abruptio placentae without evidence of nonreassuring fetal status
- Intrauterine fetal demise
- Intrauterine fetal growth restriction
- Isoimmunization
- Oligohydramnios
- Nonreassuring fetal status
- Nonreassuring antepartum testing.

Relative indications include chronic hypertension, systemic lupus erythematosus, gestational diabetes, coagulation disorders, cholestasis of pregnancy, polyhydramnios, fetal anomalies requiring specialized neonatal care, logistical factors (risk of rapid birth, distance from hospital), psychologic factors, advanced cervical dilation, previous stillbirth, and postterm gestation greater than 41 weeks (Cunningham et al., 2014).

All contraindications to spontaneous labor and vaginal birth are contraindications to the induction of labor. Maternal contraindications include, but are not limited to, the following (Cunningham et al., 2014):

- Patient refusal
- Placenta previa or vasa previa
- Transverse fetal lie
- Previous classic uterine incision (or any vertical incision in the upper portion of the uterus)
- Active genital herpes infection
- Umbilical cord prolapse
- Absolute cephalopelvic disproportion.

Before induction is attempted, appropriate assessment must indicate that both the woman and the fetus are ready for the onset of labor. This includes evaluation of fetal maturity and cervical readiness. The gestational age of the fetus is best evaluated by accurate maternal menstrual dating and early ultrasound exams. Amniotic fluid studies provide valuable information regarding fetal lung maturity.

Forceps-assisted Birth

Forceps are designed to assist the birth of a fetus by providing traction or by providing the means to rotate the fetal head to an occipitoanterior position. In medical literature and practice, **forceps-assisted birth** is also known as *instrumental delivery*, *operative delivery*, or *operative vaginal delivery*. There are many different types of forceps, each with special functions. The type of forceps used is determined by the physician assisting with the birth and the clinical situation.

Indications for Use of Forceps

Indications for the use of forceps include the presence of any condition that threatens the mother or fetus and that can be relieved by birth. Conditions that put the woman at risk include heart disease, acute pulmonary edema or pulmonary

compromise, certain neurologic conditions, intrapartum infection, prolonged second stage, or exhaustion. Fetal conditions include premature placental separation, prolapsed umbilical cord, and nonreassuring fetal status. Forceps may be used when the fetal station is very low to shorten the second stage of labor and spare the woman's pushing effort (when exhaustion or heart disease is present) or when regional anesthesia or paralysis has affected the woman's motor innervation, and she cannot push effectively (Cunningham et al., 2014).

Risk factors for a forceps- or vacuum-assisted birth (discussion to follow) are as follows (Cunningham et al., 2014):

- Nulliparity
- Maternal age (35 and over)
- Maternal height of less than 150 cm (4 ft 11 in.)
- Pregnancy weight gain of more than 15 kg (33 lb)
- Postdate gestation (41 weeks or more)
- Epidural anesthesia
- Fetal presentation other than occipitoanterior
- Presence of dystocia (labor dysfunction)
- Presence of a midline episiotomy
- Abnormal FHR tracing.

Neonatal and Maternal Risks

Some newborns may develop a small area of ecchymosis or edema, or both, along the sides of the face as a result of forceps application. Cephalohematoma (and subsequent hyperbilirubinemia) may occur as well as transient facial paralysis. Other reported complications include low Apgar scores, retinal hemorrhage, corneal abrasions, ocular trauma, other trauma (Erb palsy, fractured clavicle), elevated neonatal bilirubin levels, and prolonged hospital stay (Cunningham et al., 2014).

Maternal risks may include trauma such as lacerations of the birth canal, periurethral lacerations, and extensions of a median episiotomy into the anus, resulting in increased bleeding, bruising, hematomas, and pelvic floor injuries. Women who give birth with the assistance of forceps are more likely to have a third- or fourth-degree laceration and report more perineal pain and sexual problems in the postpartum period (Cunningham et al., 2014). In addition, an increase in postpartum infections, cervical lacerations, and prolonged hospital stays has been reported (Cunningham et al., 2014). Women who give birth with the assistance of forceps may also experience urinary and rectal incontinence, anal sphincter injury, and postpartum metritis (Cunningham et al., 2014).

Vacuum Extraction

Vacuum extraction is an obstetric procedure used by physicians and CNMs to assist the birth of a fetus by applying suction to the fetal head. The vacuum extractor accounts for 68% of all operative vaginal births. Its use has increased by 41% since 1990 and continues to rise (Cunningham et al., 2014). The vacuum extractor is composed of a soft suction cup attached to a suction bottle (pump) by tubing. The suction cup, which comes in various sizes, is placed against the occiput of the fetal head, avoiding the fontanelles. Care must

be taken to ensure that no cervical or vaginal tissue is trapped under the cup. The pump is used to create negative pressure (suction) of approximately 50–60 mmHg in a stepwise sequence or rapid application. An artificial caput (“chignon”) is formed as the fetal scalp is pulled into the cup.

The longer the duration of suction, the more likely the newborn is to have a scalp injury. Although there are no data on the duration of use, ACOG advises a 30-minute time limit (Simpson & Creehan, 2013). Although there are no specifications on the number of attempts, failure to descend with multiple attempts is an indicator that a cesarean birth may be needed. In addition, if more than three “pop-offs” occur (the suction cup pops off the fetal head), the procedure should be discontinued. The most common indication for the use of the vacuum extractor is a prolonged second stage of labor or nonreassuring FHR pattern. Vacuum extraction is also used to relieve the woman of pushing effort, or when analgesia or fatigue interferes with her ability to push effectively, or in cases of nonreassuring fetal status when prompt birth is indicated. The vacuum extractor is preferred to forceps in cases of suspected cephalopelvic disproportion (CPD), when successful passage of the fetal head requires all potential space inside the vaginal canal. True CPD is an absolute contraindication to vacuum extraction. Other contraindications include nonvertex presentations, maternal or suspected fetal coagulation defects, known or suspected hydrocephalus, and fetal scalp trauma (Cunningham et al., 2014). Relative contraindications include suspected fetal macrosomia, high fetal station, face or breech presentation, gestation less than 34 weeks, incompletely dilated cervix, and previous fetal scalp blood sampling (Cunningham et al., 2014).

Neonatal complications include scalp lacerations, bruising, subgaleal hematomas, cephalohematomas, intracranial hemorrhages, subconjunctival hemorrhages, neonatal jaundice, fractured clavicle, Erb palsy, damage to the sixth and seventh cranial nerves, retinal hemorrhage, and fetal death. In addition, shoulder dystocia occurs more often (Cunningham et al., 2014). There appear to be more neonatal complications and injuries with use of a metal suction cup device than with soft cup devices. In the presence of a preterm gestation, risk of periventricular-intraventricular hemorrhage (PV-IVH) has been a concern, and some studies provide conflicting recommendations. Maternal complications include perineal trauma, edema, third- and fourth-degree lacerations, postpartum pain, and infection (Simpson & Creehan, 2013). Women who give birth with the aid of a vacuum extractor report more sexual difficulties in the postpartum period. Maternal genital tract and anal sphincter injuries occur less frequently with the vacuum extractor than with forceps.

Episiotomy

An **episiotomy** is a surgical incision of the perineal body to enlarge the outlet. The episiotomy has long been thought to minimize the risk of lacerations of the perineum and overstretching of perineal tissues. However, episiotomy may actually increase the risk of fourth-degree perineal lacerations (Blackburn, 2013). Research suggests, first, that rather than protecting the perineum from lacerations, the presence of an episiotomy makes it more likely that the woman will have anal sphincter tears and, second, that perineal lacerations

heal more quickly than deep perineal tears (Blackburn, 2013). In clinical practice, research has shown that the incidence of major perineal trauma (extension to or through the anal sphincter) is more likely to happen if a midline episiotomy is done (Gurol-Urganci et al., 2013). Women with previous episiotomies that resulted in a third- or fourth-degree extension were more likely to have a repeat occurrence when episiotomy was used initially compared to women who had a spontaneous laceration without the use of episiotomy (Yogev et al., 2014). Additional complications associated with episiotomy are blood loss, infection, pain, and perineal discomfort that may continue for days or weeks past birth, including painful intercourse (Lyndon et al., 2012). Episiotomy is indicated for protection against injury to the anterior external genitalia, expediting delivery in the setting of non-reassuring fetal status, or enlarging the space in which to apply forceps or disimpact the fetal anterior shoulder. The ACOG discourages the use of episiotomy when it is not indicated. Rates have fallen from over 60% in 1979 to 12% in 2012 (Robinson, 2015).

Overall factors that place a woman at increased risk for episiotomy are primigravid status, large or macrosomic fetus, occipitoposterior position, use of forceps or vacuum extractor, and shoulder dystocia. Other factors that may be mitigated by nurses, physicians, and CNMs include the following:

- Use of lithotomy and other recumbent positions (causes excessive and uneven stretching of the perineum)
- Encouraging or requiring sustained breath holding during second-stage pushing (causes excessive and rapid perineal stretching, can adversely affect blood flow in mother and fetus, and requires woman to be responsive to caregiver directions rather than to her own urges to push spontaneously)
- Arbitrary time limit placed by the physician or CNM on the length of the second stage.

Preventive Measures

General tips to help reduce the incidence of lacerations and episiotomies include the following:

- Perineal massage during pregnancy for nulliparous women
- Natural pushing during labor and avoiding the lithotomy position or pulling back on legs, which tightens the perineum
- Side-lying position for pushing, which helps slow birth and diminish tears
- Warm or hot compresses on the perineum and firm counterpressure
- Encouraging a gradual expulsion of the baby at the time of birth by encouraging the mother to “push, take a breath, push, take a breath,” thereby easing the baby out slowly
- Avoiding immediate pushing after epidural placement.

Episiotomy Procedure

The two types of episiotomy are midline and mediolateral, with midline being the most common in current use. Just

before birth, when approximately 3–4 cm (1.2–1.6 in.) of the fetal head is visible during a contraction, the episiotomy is performed by using sharp scissors with rounded points (Cunningham et al., 2014). The midline incision begins at the bottom center of the perineal body and extends straight down the midline to the fibers of the rectal sphincter. The mediolateral incision begins in the midline of the posterior fourchette and extends at a 45° angle downward to the right or left.

The episiotomy is usually performed with regional or local anesthesia but may be done without anesthesia in emergency situations. It is generally proposed that as crowning occurs, the distention of the tissues causes numbing. Repair of the episiotomy and any lacerations is completed either during the period between birth of the baby and expulsion of the placenta or after expulsion of the placenta. Adequate anesthesia must be given for the repair.

Cesarean Birth

Cesarean birth (the birth of the baby through an abdominal and uterine incision) is one of the oldest known surgical procedures. Until the 20th century, cesarean procedures were used primarily to save the fetus of a dying woman. As the maternal and perinatal morbidity and mortality rates associated with cesarean birth steadily decreased throughout the 20th century, the proportion of cesarean births increased. Beginning in the early 1970s the cesarean birth rate rose steadily for almost two decades. In 1989, however, in an effort to control healthcare costs, the number of cesarean births began to decline, but from 2010–2012, the rate of cesarean births performed in the United States reached an all-time high of 32.8% (Martin et al., 2015). Since then, the rate has dropped to 32.2% in 2014 (CDC, 2015b).

Cesarean birth rates differ dramatically in other parts of the world. Worldwide, women living in urban areas are four times more likely to have a cesarean compared to women living in rural areas. Countries with low cesarean birth rates (less than 17%) include the Netherlands, Finland, and Norway. The highest rates were found in Italy, Portugal, and the United States, with rates greater than 30%. Overall, the incidence of cesarean birth has continued to increase worldwide (World Health Organization [WHO], 2015).

The increasing rate of cesarean births in the United States is linked to a rise in repeat cesarean births fueled by concerns about the risk of uterine rupture with a vaginal birth after a previous cesarean birth. There is also an increase in requests from women for cesarean births so that they can avoid the pain of labor and vaginal birth. Statements in some medical literature that vaginal births could result in pelvic floor damage during the birth process have led some women to consider cesarean births (King et al., 2013). There is an emerging trend as well to “schedule” birth by cesarean section to meet specific needs of the parents, such as coordinating work projects, arranging for babysitting of older children, or allowing relatives who must travel from other geographic locations to be present for the birth itself.

Cesarean birth on request is associated with a reduction in maternal hemorrhage risk; however, it is also associated with increases in neonatal respiratory problems, longer hospitalizations, and increased complications in subsequent pregnancies, including placenta implantation problems and

uterine rupture (ACOG, 2013g). Cesarean birth without medical indications should not be recommended for women desiring several children, for women less than 39 weeks of gestation, or when pregnancy dating is unknown or may be inaccurate. It should also not be motivated by the potential lack of anesthesia availability in an institution (ACOG, 2013g).

Many other factors have contributed to the rise in the cesarean birth rate and need to be considered in any discussion about decreasing the rate. These factors include an increased use of epidural anesthesia, maternal age over 35, failed labor inductions, decline in vaginal breech deliveries, decreases in operative vaginal deliveries, increased repeat cesarean rates, reduced vaginal birth after cesarean birth rates, increased physician scheduling of cesarean births for personal convenience, political pressure from malpractice insurance carriers who attempt to dictate practice standards, and fear of litigation (ACOG, 2013g).

Indications

Commonly accepted indications for cesarean birth include complete placenta previa, breech presentation, transverse lie, placental abruption accompanied by nonreassuring fetal status, active genital herpes, umbilical cord prolapse, arrest of descent and/or arrest of dilation, nonreassuring fetal status, previous classic incision on the uterus (either previous cesarean birth or myomectomy), more than one previous cesarean birth, benign and malignant tumors that obstruct the birth canal, and cervical cerclage.

Certain maternal medical conditions are contraindications to a vaginal birth and warrant a cesarean birth (Society for Maternal-Fetal Medicine, 2012). These medical conditions include the following:

- Cardiac disorders
- Severe maternal respiratory disease
- Central nervous system disorders that increase intracranial pressure
- Mechanical vaginal obstruction, such as an ovarian mass or lower uterine segment fibroids
- HIV infection in the mother
- Severe mental illness that results in an altered state of consciousness.

Other indications that are now commonly associated with cesarean birth, although in some circumstances may allow the child to be delivered vaginally, include breech presentation, previous cesarean birth, major congenital anomalies, and severe Rh isoimmunization.

Maternal Mortality and Morbidity

Cesarean births have a higher maternal mortality rate than vaginal births. In the United States, women undergoing a cesarean birth have a twofold risk of most complications associated with delivery compared with women who give birth vaginally (Cunningham et al., 2014; Stranges, Wier, & Elixhauser, 2012). In England, emergency cesarean birth is associated with a ninefold risk of death when compared with vaginal delivery, and elective cesarean births have a threefold risk (Cunningham et al., 2014). Perinatal morbidity is also considerably higher in women who have had a cesarean.

Common postoperative complications include infection, reactions to anesthesia agents, blood clots, and bleeding. Women who have had a cesarean birth are twice as likely to be rehospitalized within 60 days of birth when compared with women who have had a vaginal birth. Other sources of maternal morbidity that are directly associated with cesarean birth include ureteral injury, bladder laceration, and wound infection (Cunningham et al., 2014).

Skin Incisions

The skin incision for a cesarean birth is either transverse (Pfannenstiel) or vertical, and it is not indicative of the type of incision made into the uterus. Time factors, patient preference, previous vertical skin incision, or physician preference determines the type of skin incision.

The transverse incision is made across the lowest and narrowest part of the abdomen. Because the incision is made just below the pubic hairline, it is almost invisible after healing. The limitation of this type of skin incision is that it does not allow extension of the incision if needed. Because it usually requires more time to make and repair, this incision is used when time is not of the essence (e.g., with arrest of descent and/or arrest of dilation and stable fetal and maternal status).

The vertical incision is made between the navel and the symphysis pubis. This type of incision is quicker and, therefore, is preferred in cases of nonreassuring fetal status when rapid birth is indicated, with preterm or macrosomic babies, or when the woman is significantly obese (Cunningham et al., 2014; Posner et al., 2013).

Uterine Incisions

The two major locations of uterine incisions are in the lower uterine segment and in the upper segment of the uterine corpus. The type of uterine incision depends on the need for the cesarean. The choice of incision affects the woman's opportunity for a subsequent vaginal birth and her risks of a ruptured uterine scar with a subsequent pregnancy.

The lower uterine segment incision most commonly used is a transverse incision. The lower uterine segment transverse incision is preferred for the following reasons (Cunningham et al., 2014):

- The lower segment is the thinnest portion of the uterus and involves less blood loss.
- It requires only moderate dissection of the bladder from the underlying myometrium.
- It is easier to repair, although repair takes longer.
- The site is less likely to rupture during subsequent pregnancies.
- There is a decreased chance for adherence of bowel or omentum to the incision line.

Disadvantages of this type of segment incision include the following:

- It takes longer to make a transverse incision.
- It is limited in size because of the presence of major vessels on either side of the uterus.
- It has a greater tendency to extend laterally into the uterine vessels.

- The incision may stretch and become a thin window, but it usually does not create problems clinically until subsequent labor ensues.

The lower uterine segment vertical incision is preferred for multiple gestation, abnormal presentation, placenta previa, nonreassuring fetal status, and preterm and macrosomic fetuses. Disadvantages of this type of incision include the following:

- The incision may extend downward into the cervix.
- More extensive dissection of the bladder is needed to keep the incision in the lower uterine segment; hemostasis and closure are more difficult.
- The vertical incision carries a higher risk of rupture with subsequent labor. Consequently, once a vertical incision is performed, future births need to be via cesarean.

One other incision, the classic incision, was the method of choice for many years but is used infrequently today. This vertical incision was made into the upper uterine segment. It resulted in greater blood loss and was more difficult to repair. Most important, it carried an increased risk of uterine rupture with subsequent pregnancy, labor, and birth, because the upper uterine segment is the most contractile portion of the uterus.

Analgesia and Anesthesia

There is no perfect anesthesia for cesarean birth. Each has its advantages, disadvantages, possible risks, and side effects. Goals for the administration of analgesia and anesthesia include safety, comfort, and emotional satisfaction for the patient.

Preparation for Cesarean Birth

Because one of every four births is a cesarean, preparation for this possibility should be an integral part of all prenatal education. The nurse should encourage pregnant women and their partners to discuss the possibility of a cesarean birth, and their specific needs and desires under those circumstances, with their healthcare provider. Their preferences may include the following:

- Participating in the choice of anesthetic
- Partner or significant other being present during the procedures and/or birth
- Partner or significant other being present in the recovery or postpartum room
- Video recording and/or taking pictures of the birth
- Delayed instillation of eye drops to promote eye contact between parent and newborn in the first hours after birth
- Physical contact or holding the newborn while in the operating and/or recovery room (by the partner if the mother cannot hold the baby)
- Breastfeeding in the recovery area within the first hour of birth.

Information that couples need about cesarean birth includes the following:

- What preparatory procedures to expect
- Description or viewing of the birthing room

- Types of anesthesia for birth and analgesia available postpartum
- Sensations that may be experienced
- Roles of significant others
- Interaction with newborn
- Immediate recovery phase
- Postpartum phase.

Preparing the woman and her family for cesarean birth involves more than the procedures of establishing an intravenous line, instilling a urinary indwelling catheter, and performing an abdominal prep. Good communication skills are essential in preparing the woman and her support person. The use of therapeutic touch and direct eye contact (if culturally acceptable and possible) assists the woman in maintaining a sense of control and lessens her anxiety.

If the cesarean birth is scheduled and not an emergency procedure, the nurse has ample time for preoperative teaching and to provide an opportunity for the woman and her support person to express their concerns, ask questions, and develop a relationship with the nurse.

In preparation for surgery, the woman is given nothing by mouth. To reduce the likelihood of serious pulmonary damage if gastric contents are aspirated, antacids may be administered within 30 minutes of surgery. If epidural anesthesia is used, the nurse may assist with the procedure, monitor the woman's blood pressure and response, and continue electronic fetal monitoring. An abdominal and perineal prep is done, and an indwelling catheter is inserted to prevent bladder distention. An intravenous line is started with a large-bore needle to permit rapid administration of blood if that becomes necessary. Preoperative medication may be ordered. The pediatrician should be notified and preparation made to receive the new baby. The nurse ensures that the neonatal radiant warmer is working and that resuscitation equipment is available.

The nurse assists in positioning the woman on the operating table. Fetal heart rate is assessed before surgery and during preparation because fetal hypoxia can result from the mother lying in the supine position. The operating room table is adjusted so that it slants slightly to one side, or a hip wedge (folded blanket or towels) is placed under the right hip to tip the uterus slightly and reduce compression of blood vessels. The uterus should be displaced 15 degrees from the midline. This helps relieve the pressure of the heavy uterus on the vena cava and lessens the incidence of vena cava compression and maternal supine hypotension. The suction should be in working order, and the urine collection bag should be positioned under the operating table to obtain proper drainage. Auscultation or electronic fetal monitoring of the fetal heart rate is continued until immediately before the procedure. If the fetus was monitored internally, a last-minute check is done to ensure that the fetal scalp electrode has been removed.

The nurse continues to provide reassurance and to describe the various procedures being performed (along with their rationales) to ease anxiety and give the woman a sense of control.

Women undergoing elective cesarean birth can be given information about the postoperative experience before their

birth experience. Important components of patient education that can be emphasized before birth include dealing with postoperative discomfort, splinting the incision to decrease pain, frequent deep breathing and coughing, and the importance of early ambulation. Patients who receive this information before the birth are more apt to remember it when the information is reviewed in the early postpartum period.

Preparation for Repeat Cesarean Birth

When the parents are anticipating a repeat cesarean birth, they have a general understanding of what will occur, which can help them make informed choices about their birth experience. Those who have had previous negative experiences need an opportunity to describe what they felt. Encourage the parents to identify what they would like to be different and to list options that would make the experience more positive. Those who have already had positive experiences need reassurance that their needs and desires will be met in a similar manner. Provide all families the opportunity to discuss any fears or anxieties. For women who previously labored and then had an unexpected cesarean birth, the experience may be perceived as negative. Emphasize the positive aspects of a repeat cesarean birth. These include participation in selecting the birth date, lack of fatigue related to labor, ability to prepare and make arrangements for other children, and the ability for other family members or friends to be present at the hospital during or immediately after birth if desired by the couple.

Preparation for Emergency Cesarean Birth

When the need for a cesarean birth emerges suddenly, the period preceding surgery must be used to its greatest advantage. It is imperative that the nurse use the most effective communication skills in supporting the parents. The nurse describes what they may anticipate during the next few hours and gives the woman information about (and the rationale for) any procedure before it begins. It is essential for the nurse to explain what is going to happen, why it is being done, and what sensations the woman may experience. This allows the woman to be informed and to consent to the procedure, which gives her a sense of control and reduces her feelings of helplessness.

Supporting the Partner

Every effort should be made to include the partner in the birth experience. When attending a cesarean birth, the partner wears protective coverings similar to those worn by others in the operating suite. A stool can be placed beside the woman's head so that the partner can sit nearby to provide physical touch, visual contact, and verbal reassurance.

To promote the participation of the partner who chooses not to be in the operating suite, the nurse can do the following:

- Allow the partner to be nearby, where the partner can hear the newborn's first cry.
- Encourage the partner to carry or accompany the newborn to the nursery for the initial assessment.
- Involve the partner in postpartum care in the recovery room.

In some emergency circumstances, a support person may not be permitted in the operating room. Some facilities have policies that prohibit a support person from being in the operating room if the woman requires general anesthesia or if an emergency birth is being performed. In these situations, the support person should receive a thorough explanation of what is happening and why, be advised when the staff will return to provide information, know the expected length of time for the procedure, and be reassured that the mother is receiving the care she and the baby need. Because this exclusion is stressful for family members, the staff needs to provide information as soon as possible after providing emergency care to the mother.

Immediate Postnatal Recovery Period

After birth, the nurse assesses the Apgar score (Apgar scoring is described fully in Exemplar 33.D, Newborn Care) and completes the same initial assessment and identification procedures used for vaginal births.

Identification bands must be placed on the newborn and the mother (as well as on the support person, if present) before removing the baby from the operating room. The nurse should make every effort to assist the parents in bonding with their baby. If the mother is awake, one of her arms can be freed to enable her to touch and stroke the baby. The newborn may be placed on the mother's chest or held in an *en face* (face-to-face) position. If physical contact is not possible, the nurse should provide a running narrative so that the mother knows what is happening with her baby. The nurse assists the anesthesiologist or nurse anesthetist with raising the mother's head so that she can see her baby immediately after birth. The parents can be encouraged to talk to the baby, and the partner can hold the baby until the family is taken to the recovery room.

The nurse caring for the postpartum woman assesses the mother's vital signs every 5 minutes until they are stable, then every 15 minutes for an hour, and then every 30 minutes until the woman is discharged to the postpartum unit. The nurse remains with the woman until she is stable.

The nurse evaluates the dressing and perineal pad every 15 minutes for at least an hour. Gently palpate the fundus to determine whether it is remaining firm; palpation may be performed by placing a hand to support the incision. Intravenous oxytocin is usually administered to promote the contractility of the uterine musculature. If the mother has been under general anesthesia, she should be positioned on her side to facilitate drainage of secretions, turned, and assisted with coughing and deep breathing every 2 hours for at least 24 hours. If she has received a spinal or epidural anesthetic, the level of anesthesia is checked every 15 minutes for the first 2 hours and then hourly until full sensation has returned. It is important for the nurse to monitor intake and output and to observe the urine for a bloody tinge, which could mean surgical trauma to the bladder. The healthcare provider prescribes medication to relieve the mother's pain and nausea, and that medication is administered as needed.

Bonding can be promoted by encouraging mother and baby skin-to-skin contact for the first hour uninterrupted and performing all assessments and procedures on the newborn at the mother's bedside if both are stable.

Vaginal Birth After Cesarean

In the late 1980s there was an increasing trend to have a *trial of labor after cesarean* (TOLAC) and **vaginal birth after cesarean (VBAC)** in cases of nonrecurring indications for a cesarean (for example, twins, umbilical cord prolapse, placenta previa, nonreassuring fetal status). This trend was influenced by consumer demand and studies that support VBAC as a viable and safe alternative. VBAC rates peaked in the late 1990s and then the practice came under renewed scrutiny, causing rates to decline into the 2000s. This prompted the National Institutes of Health to review the matter and issue a statement on the safety of TOLAC. Consensus among providers is that all women who meet eligibility criteria should be offered TOLAC (King et al., 2013). The average VBAC success rate is 60–80% (ACOG, 2015c). The ACOG guidelines (2015c) state that the following aspects should be met when identifying candidates for a trial of labor:

- No contraindications for vaginal birth
- A woman with one or two previous cesarean births and a low transverse uterine incision
- A clinically adequate pelvis based on clinical pelvimetry or prior vaginal birth
- A woman with one previous cesarean birth with an undocumented uterine scar unless there is a high suspicion there was a classic incision performed previously
- Absence of other uterine scars or history of previous uterine rupture
- A physician who is able to do a cesarean needs to be available throughout active labor
- In-house anesthesia personnel are available for an emergency cesarean birth if warranted.

The absolute risks of VBAC are small. The incidence of uterine rupture is 0.9% of all TOLACs (ACOG, 2015c). Risks associated with VBAC are listed in **Box 33–4** >>.

The nursing care of a woman undergoing VBAC varies according to institutional protocols. Generally, if the woman is at low risk (has had one previous cesarean with a lower uterine segment incision), her blood count, type, and screen are obtained on admission; a heparin lock is inserted for intravenous access if needed; continuous electronic fetal monitoring (EFM) is used; and clear fluids may be taken. If the woman is at higher risk, NPO status should be maintained, and, in

addition to the care listed, an intrauterine catheter may be inserted to monitor intrauterine pressures during labor.

Supportive and comfort measures are very important. The woman may be excited about this opportunity to experience labor and vaginal birth but apprehensive if she does not know what to expect from labor. The nurse provides information and encouragement for the laboring woman and her partner.

Intrapartum Risk Factors

A number of other alterations may occur during the intrapartum period. These include precipitous birth, abruptio placentae, placenta previa, premature rupture of membranes, preterm and postterm labor, hypertonic labor, hypotonic labor patterns, fetal malpresentation, fetal macrosomia, nonreassuring fetal status, prolapsed umbilical cord, anaphylactoid syndrome of pregnancy (amniotic fluid embolism), cephalopelvic disproportion, retained placenta, lacerations, placenta accreta, shoulder dystocia, and perinatal loss. These alterations are described in the Alterations and Therapies feature. Perinatal loss is discussed in the module on Grief and Loss.

>> Go to **Pearson MyLab Nursing and eText** for Chart 6, *Intrapartum High-Risk Factors*.

Lifespan Considerations

Lifespan considerations during labor and delivery primarily relate to a woman's age. Young women of adolescent years and women over the age of 35 pose some unique considerations for the nurse.

The Adolescent During Labor and Delivery

As with all women, each adolescent in labor is different. The nurse must assess what each teen brings to the experience as follows:

- Has the young woman received prenatal care?
- What are her attitudes and feelings about the pregnancy?
- Who will attend the birth, and what is each individual's relationship to the woman?
- What preparation has she had for the experience?
- What are her expectations and fears regarding labor and birth?
- How has her culture influenced her?
- What are her usual coping mechanisms?
- What are her plans for the newborn?

Any adolescent who has not had prenatal care requires close observation during labor. Fetal well-being is established by fetal monitoring. Adolescent women are at risk for pregnancy and labor complications and must be assessed carefully. The nurse must be especially alert for any physiologic complications of labor. The young woman's prenatal record is carefully reviewed for risks, and the adolescent is screened for preeclampsia, cephalopelvic disproportion, anemia, cigarette smoking, alcohol and drugs ingested during pregnancy, sexually transmitted infections (see the exemplar on Sexually Transmitted Infections in the module on Sexuality), and size–date discrepancies.

Box 33–4

Risks Associated with Vaginal Birth After Cesarean

- Uterine rupture
- Scar dehiscence
- Hysterectomy
- Uterine infection
- Neonatal death
- Intrauterine fetal demise
- Stillbirth
- Transfusion
- Hypoxic ischemic encephalopathy

Alterations and Therapies

Intrapartum

ALTERATION	DESCRIPTION	THERAPIES
Precipitous birth	Rapid progression of labor, with birth occurring within 3 hours or less.	<ul style="list-style-type: none"> The nurse's primary responsibility is to provide a physically and psychologically safe experience for the woman and her baby. If birth is imminent, do not leave the mother alone, even for a minute. Provide reassurance, and send auxiliary personnel to retrieve the emergency birth pack.
Abruptio placentae	Premature separation of a normally implanted placenta from the uterine wall; may be a catastrophic event depending on the severity of the resulting hemorrhage, which may be vaginal or may be unseen because it collects in the uterus or abdomen.	<ul style="list-style-type: none"> Monitor uterine resting tone, which is frequently increased with abruptio placentae. Monitor abdominal girth measurements to determine internal blood collection. Monitor vital signs, hemoglobin and hematocrit, and urine output.
Placenta previa	Implantation of the placenta in the lower uterine segment rather than the upper portion, resulting in placental separation with dilation of the cervix.	<ul style="list-style-type: none"> Teach all pregnant women the importance of reporting any bright-red vaginal bleeding, often scant at first. Avoid vaginal examination if placenta previa is suspected. Assess blood loss, pain, vital signs, fetal well-being, and uterine contractility. Provide emotional support for the mother and family.
Premature rupture of membranes	Spontaneous rupture of the membranes before the onset of labor. Preterm PROM (PPROM) is the rupture of membranes occurring before 37 weeks of gestation associated with infection, previous history of PPRM, hydramnios, multiple pregnancy, urinary tract infection, amniocentesis, placenta previa, abruptio placentae, trauma, cervical insufficiency, bleeding during pregnancy, and maternal genital tract anomalies.	<ul style="list-style-type: none"> Assess for duration of rupture, appearance of amniotic fluid, and fetal well-being. Monitor woman for signs of infection, including WBC count and vital signs. Assess for potential cord compression if witnessed rupture. Educate the woman and her partner regarding implications of PROM and all treatments.
Preterm labor	Labor that occurs between 20 and 36 completed weeks of pregnancy. Patients are admitted if at high risk for delivery in the setting of advanced cervical dilation, history of preterm delivery, or positive fetal fibronectin (fFN), a protein in the membranes found in vaginal secretions before 20 weeks and after 37 weeks. Detection of fFN on a vaginal swab between 24 and 34 weeks gestation increases suspicion of preterm labor (King et al., 2013); if at low risk for imminent delivery, patients are sent home on pelvic rest and normal activity.	<ul style="list-style-type: none"> Administer IV magnesium sulfate for 12 hours maximum for fetal neuroprotection, and IM betamethasone. Monitor blood pressure every 10–15 minutes, serum magnesium levels, reflexes, respiratory rate, urinary output, and level of sedation, and be prepared to administer calcium if toxicity is suspected. Provide emotional support to the woman, who may be fearful for fetal well-being. Teach woman to recognize onset of labor, to perform home uterine activity monitoring, to evaluate contraction activity, and symptoms to report.
Postterm labor	A pregnancy that exceeds 42 weeks, occurring most frequently in primigravidas, women with history of postterm pregnancies, or fetal anencephaly.	<ul style="list-style-type: none"> Conduct ongoing assessment of fetal well-being. Assess fluid for meconium following rupture of membranes. Provide patient education. Provide emotional support, encouragement, and recognition of the woman's anxiety.
Hypertonic labor	Ineffective uterine contractions of poor quality occurring in the latent phase of labor with increased resting tone of the myometrium and frequent contractions.	<ul style="list-style-type: none"> Provide comfort and support to the laboring woman and her partner. Provide supportive measures such as change of position, quiet environment, back rubs, or guided imagery. Consider therapeutic rest.

(continued on next page)

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPIES
Hypotonic labor patterns	Usually developing in the active phase of labor, characterized by fewer than two to three contractions in a 10-minute period of low intensity causing minimal discomfort; often the result of overstretching of the uterus, bowel or bladder distention, arrest of descent, or fetal malposition.	<ul style="list-style-type: none"> Assess contractions, maternal vital signs, and FHR, watching for signs of infection or dehydration. Promote maternal–fetal well-being. Monitor for maternal exhaustion. Assess for meconium if rupture of membranes. Consider augmentation of labor.
Fetal malpresentation	Any presentation that is not right-occiput-anterior (ROA), occiput-anterior (OA), or left-occiput-anterior (LOA), which may prolong labor or require a cesarean section.	<ul style="list-style-type: none"> Assist with position change to promote fetal repositioning. Promote rest if labor is prolonged. Provide patient education. Prepare for surgery if cesarean section is required.
Fetal macrosomia	A newborn weight of > 4000 g at birth, often associated with excessive maternal weight gain, maternal obesity, uncontrolled maternal diabetes, grand multiparity, prolonged gestation, or those with a previous baby with macrosomia >4000 g (Cunningham et al., 2014).	<ul style="list-style-type: none"> Identify women at risk, and assess FHR for nonreassuring fetal status. Assess for labor dysfunction or lack of fetal descent. Provide support, encouragement, and education. Monitor for hemorrhage postpartum. Assess newborn after delivery for cephalohematoma.
Nonreassuring fetal status	When the oxygen supply is insufficient to meet the physiologic needs of the fetus, a nonreassuring fetal status may result, which may be transient or chronic. Demonstrated by change in FHR, decreased fetal movement, meconium-stained amniotic fluid, or ominous FHR patterns.	<ul style="list-style-type: none"> Review prenatal history, and note any risk factors. Assess fetal heart rate, and note characteristics of amniotic fluid with rupture. Promote maternal positioning to maximize uteroplacental fetal blood flow.
Prolapsed umbilical cord	The umbilical cord precedes the fetal presenting part, placing pressure on the cord and reducing or stopping blood flow to and from the fetus. Of greatest risk when rupture of membranes occurs before engagement of fetal presenting part.	<ul style="list-style-type: none"> Assess FHR, and observe for prolapse for a full minute when membranes rupture. If loop of cord is discovered, a gloved hand elevates the fetal presenting part to relieve pressure until the cesarean delivery can be accomplished. Administer oxygen by face mask to increase fetal oxygenation. If the presenting part is well applied to the cervix, then ambulation should be encouraged. If the presenting part is not well applied to the cervix, the woman is at an increased risk of cord prolapse and ambulation should be discouraged; however, the woman can sit with the head of the bed elevated or in a rocking chair to facilitate gravity.
Anaphylactoid syndrome of pregnancy (amniotic fluid embolism)	In the presence of a small tear in the amnion or chorion high in the uterus, an area of separation in the placenta, or cervical tear, a small amount of amniotic fluid may leak into the chorionic plate and enter the maternal circulatory system as an amniotic fluid embolism. The more debris in the amniotic fluid (e.g., meconium), the greater the maternal danger.	<ul style="list-style-type: none"> Administer oxygen under positive pressure, and summon emergency assistance. Establish intravenous access quickly. Perform cardiopulmonary resuscitation if respiratory and cardiac arrest occur. Call anesthesiologist immediately. Provide support to the woman's partner and family members.
Cephalopelvic disproportion (CPD)	Occurs when the fetal head is too large to pass through any part of the birth passage, which can result in prolonged labor, uterine rupture, necrosis of maternal soft tissues, cord prolapse, excessive molding of the fetal head, or damage to the fetal skull and central nervous system.	<ul style="list-style-type: none"> Assess adequacy of maternal pelvis for a vaginal birth, size of the fetus, and its presentation and position. Suspect CPD when labor is prolonged, cervical dilation and effacement are slow, and engagement of the presenting part is delayed. Provide support to the couple, and keep them informed of what is happening and about the procedures being performed. Assess cervical dilation and fetal descent more frequently. Monitor contractions and fetal well-being continuously. Position to optimize pelvic diameters.

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPIES
Retained placenta	Retention of the placenta beyond 30 minutes after birth, resulting in bleeding that may lead to shock.	<ul style="list-style-type: none"> Assess for excessive bleeding and uterine contraction after delivery. Monitor maternal vital signs.
Lacerations	Tearing of the cervix or vagina, indicated by bright-red vaginal bleeding in the presence of a well-contracted uterus. The highest risk is in young or nulliparous women and during operative vaginal delivery (forceps or vacuum assisted).	<ul style="list-style-type: none"> Monitor for bright-red blood during labor. Promote perineal massage prenatally. If lacerations occur, manage pain and apply ice to the area after delivery to reduce edema. Teach the mother to rinse the perineum after every elimination and use sitz baths to reduce discomfort.
Placenta accreta	The chorionic villi attach directly to the myometrium of the uterus in placenta accreta. Two other types of placental adherence are <i>placenta increta</i> , in which the myometrium is invaded, and <i>placenta percreta</i> , in which the myometrium is penetrated. The adherence itself may be total, partial, or focal, depending on the amount of placental involvement.	<ul style="list-style-type: none"> Assess for bleeding. Monitor vital signs. Prepare woman for surgical intervention and possible hysterectomy.
Shoulder dystocia	Impaction of the fetal anterior shoulder behind the maternal pubic bone after the birth of the head. Risk factors include macrosomia, history of shoulder dystocia, and rapid labor. However, most shoulder dystocias are not predictable. Pressure from the maternal bone on the fetal brachial plexus can result in paralysis of the arm. Failure to resolve the problem may lead to fetal hypoxia, encephalopathy, and death.	<ul style="list-style-type: none"> The healthcare provider will perform maneuvers to free the shoulder. Call for assistance from the unit and nursery staff. Maintain an orderly atmosphere and clear communication. Emphasize the importance of and helping the mother to cooperate with maneuvers and avoid pushing. Monitor fetal status. Monitor time from birth of the head to fetal expulsion. Reposition the mother to maximize pelvic diameters. Apply suprapubic pressure on provider request to assist in dislodging the shoulder.
Perinatal loss	Death of a fetus or newborn from the time of conception through the end of the newborn period 28 days after delivery.	<ul style="list-style-type: none"> Discussed in detail in the module on Grief and Loss.

The support role of the nurse depends on the young woman's support system during labor. The adolescent may not be accompanied by someone who will stay with her during childbirth, or she may have her mother, the father of the baby, or a close friend as her labor partner. Regardless of whether the teen has a support person, the nurse needs to establish a trusting relationship with her. In this way, the nurse can help the teen understand what is happening to her. Establishing a nurturing rapport is essential. Some nurses may view adolescent pregnancy as a negative event; however, it is important to treat the young woman with respect. The adolescent who is given positive reinforcement will leave the experience with increased self-esteem despite the emotional problems that may accompany her situation.

If a support person accompanies the adolescent, that individual also needs the nurse's encouragement and support. The nurse must explain changes in the young woman's behavior, substantiate her wishes, and describe ways the support person can be of help. The nursing staff needs to reinforce the adolescent's feelings that she is wanted and important.

The adolescent who has taken childbirth education classes is generally better prepared for labor compared to the adolescent who has not. However, the nurse must keep in mind that the younger the adolescent, the less she may be able to participate actively in the process, even if she has taken prenatal classes.

The very young adolescent (ages 14 and younger) has fewer coping mechanisms and less experience to draw on than her older counterparts. Because her cognitive development is incomplete, the younger adolescent may have fewer problem-solving capabilities. Her ego integrity may be more threatened by the experience of labor, and she may be more vulnerable to stress and discomfort. She may be more child-like and dependent than older teens. As a result, the very young adolescent needs someone to rely on at all times during labor. The nurse must be sure that instructions and explanations are simple and concrete. During the transition phase, the adolescent may become withdrawn and unable to express her need to be nurtured. Touch, soothing encouragement, and measures to provide comfort help her maintain

control and meet her needs for dependence. During the second stage of labor, the young adolescent may feel as if she is losing control and may reach out to those around her. By remaining calm and giving directions, the nurse helps her cope with feelings of helplessness.

The middle adolescent (ages 15–17 years) often attempts to remain calm and unflinching during labor. The experienced nurse realizes that a caring attitude will still help the young woman. Many older adolescents believe that they “know it all,” but they may be no more prepared for childbirth than their younger counterparts. The nurse’s reinforcement and nonjudgmental manner will help them save face. If the adolescent has not taken childbirth preparation classes, she may require preparation and explanations.

The older teenager (ages 18–19 years) responds to the stresses of labor in a manner similar to that of the adult woman.

Adolescents, regardless of their age, need ongoing education throughout labor and in the early postpartum period. Provide clear explanations. Encourage these patients in particular to ask questions and seek information.

Even if the adolescent is planning to relinquish her newborn, she should be given the option of seeing and holding the baby. She may be reluctant to do this at first, but the grieving process is facilitated if the mother sees the baby. However, seeing or holding the newborn should be the young woman’s choice.

Adolescents need individualized care for the issues that they face in the postpartum period. They may experience additional psychosocial issues unique to their age group and their developmental level. Adolescents are also at an increased risk for unintended subsequent pregnancies and abortions. Proper discharge teaching includes contraceptive options (Gavin et al., 2013).

Labor and Delivery Over Age 35

Generally, women over age 35 respond to the stresses of labor similarly to their younger counterparts.

In the United States and Canada, the risk of death during labor and delivery has declined dramatically during the past 30 years for women of all ages. However, the risk of maternal death is higher for women over age 35 and even higher for women age 40 and older. These women are more likely to have a chronic medical condition that can complicate pregnancy. Preexisting medical conditions such as hyperten-

sion or diabetes probably play a more significant role than age in maternal well-being and the outcome of pregnancy. In addition, the rates of miscarriage, stillbirth, preterm birth, low birth weight, and perinatal morbidity and mortality are higher in pregnant women over age 35 (Carolan, 2013). Nevertheless, while the risk of pregnancy complications is higher in women over age 35 who have a chronic condition such as hypertension or diabetes or who are in poor general health, the risks are much lower than previously believed for physically fit women without preexisting medical problems (Cunningham et al., 2014).

NURSING PROCESS

Maternal–newborn nursing has kept pace with the changing philosophy of childbirth. Nurses who choose positions in a birthing area are presented with opportunities to interact with patients in a wide variety of situations, ranging from a family that wants maximum interaction to one that wants to be left alone as much as possible. In addition, despite the increasing focus on family-centered care, the nurse must always be ready to meet the needs and concerns of the woman who is laboring alone. In every case, nurses strive to provide high-quality, individualized care.

The physiologic and psychologic events that occur during labor call for continual and rapid adaptations by the mother and fetus. Frequent and accurate assessments are crucial to the progress of these adaptations. In current nursing practice, the traditional assessment techniques of observation, palpation, and auscultation are augmented by the judicious use of technology, such as ultrasound and electronic monitoring. These tools may provide more detailed information for assessment; however, it is important for the nurse to remember that the technology only provides data. It is the nurse who truly monitors the mother and her baby.

Maternal Assessment

Assessment of the mother begins with a patient history and screening for intrapartum risk factors. The nurse obtains a brief oral history when the woman is admitted to the birthing area. Typically, the nurse assesses the maternal and fetal vital signs immediately (**Table 33–13** >>>). If the vital signs are within normal limits, the interview continues. If a problem is identified, nursing care is then prioritized.

TABLE 33–13 Nursing Assessments in the First Stage

Phase	Mother	Fetus
Latent	Blood pressure and respirations each hour if in normal range. Temperature every 4 hours unless over 37.5°C (99.6°F) or membranes ruptured, then every 2 hours. Uterine contractions every 30 minutes.	FHR every 60 minutes for low-risk women and every 30 minutes for high-risk women if normal characteristics are present (average variability, baseline in the 110–160 beats/min range, without late or variable decelerations) or assess the heart rate every 30 minutes if the provider orders intermittent auscultation in a low-risk setting. Note fetal activity. If electronic fetal monitor is in place, assess for reactive nonstress test.
Active	Blood pressure, pulse, and respirations every hour if in normal range. Uterine contractions palpated every 15–30 minutes.	FHR every 30 minutes for low-risk women and every 15 minutes for high-risk women if normal characteristics are present.
Transition	Blood pressure, pulse, and respirations every hour. Contractions palpated every 15–30 minutes.	FHR every 15–30 minutes if normal characteristics are present.

It is common for the healthcare provider to send the prenatal records to the labor and birthing unit before the woman's due date. Review this information to ensure that changes have not occurred since the information was documented. During the initial interview, the nurse is building a trusting relationship. It is often helpful if the nurse sits down and appears unrushed, makes direct eye contact (if culturally appropriate), and begins the interview with a statement such as "I am going to be asking you some very personal and specific questions so that we can provide the best care for both you and your baby." This conveys a nonjudgmental approach, shows respect, and makes the expectant mother feel more at ease. Each agency has its own admission forms, but they usually include the following information:

- Woman's name and age
- Religious preference and spiritual practices
- Last menstrual period and estimated date of birth
- Attending physician or CNM
- Personal data: blood type; Rh factor; results of serology testing; prepregnant and present weight; allergies to medications, foods, or other substances; prescribed and OTC medications taken during the pregnancy; and history of drug and alcohol use and smoking during the pregnancy
- History of previous illness, such as tuberculosis, heart disease, diabetes, convulsive disorders, and thyroid disorders; asthma; sickle cell, Tay-Sachs, and other inherited disorders; or pregnancy-related complications (e.g., preterm labor, gestational diabetes, preeclampsia, or low platelets)
- Problems in the prenatal period, such as elevated blood pressure, bleeding problems, recurrent urinary tract infections, other infections, abnormal laboratory findings (e.g., abnormal glucose screen indicating gestational diabetes or low hemoglobin or hematocrit indicating anemia), or sexually transmitted infections
- Pregnancy data: gravida, para, abortions, and neonatal deaths
- Method chosen for newborn/infant feeding
- Type of childbirth education or newborn/infant care classes
- Previous newborn/infant care experience
- Woman's preferences regarding labor and birth, such as no episiotomy, no analgesics or anesthetics, or the presence or absence of the partner or others at the birth
- Pediatrician, family practice physician, or nurse practitioner
- Additional data: history of special tests, such as nonstress test, biophysical profile, or ultrasound; history of any preterm labor; onset of labor; amniotic fluid membrane status; and brief description of any previous labor and birth
- Onset of labor, status of amniotic membranes (intact, ruptured, time of rupture, color, and odor).

Because of the prevalence of domestic violence in our society (see the exemplar on Abuse, in the module on Trauma), the nurse needs to consider the possibility that the

pregnant woman may have experienced abuse at some point in her life. Many victims of domestic violence, sexual assault, or childhood abuse may be anxious about the labor process or may experience anxiety during labor. Therefore, it is essential to review the woman's prenatal record and any other available records for information that may indicate abuse or a history of victimization by violence.

Intrapartum High-risk Screening

Screening for intrapartum high-risk factors is an integral part of assessing the woman in labor. As the history is obtained, the nurse notes the presence of any potential risk factors that may be considered high-risk conditions. For example, the woman who reports a physical symptom such as intermittent bleeding needs further assessment to rule out abruptio placentae or placenta previa before the admission process continues. It is important to determine the difference between vaginal bleeding and bloody show. In addition to identifying the presence of a high-risk condition, the nurse must recognize the implications of the condition for the laboring woman and her fetus. For example, if there is an abnormal fetal position, the nurse understands that the labor may be prolonged and that prolapse of the umbilical cord is more likely, thereby increasing the possibility of a cesarean birth.

Although physical conditions are frequently listed as the major factors that increase risk during the intrapartum period, socioeconomic and cultural variables, such as poverty, nutrition, the amount of prenatal care, living conditions, cultural beliefs regarding pregnancy, and communication patterns, may also precipitate a high-risk situation. Mental illness is a risk factor as well, because it can result in episodic prenatal care or the need to take psychotropic medications during the pregnancy (Davidson, 2013). In addition, research indicates that women who experience posttraumatic stress disorder (PTSD) may be at increased risk for some pregnancy complications (Onoye et al., 2013). (See the exemplar on Posttraumatic Stress Disorder, in the module on Trauma.) Other risk factors include smoking, drug use, and consumption of alcohol during pregnancy. The nurse can quickly review the prenatal record for number of prenatal visits; weight gain during pregnancy; progression of fundal height; assistance, such as Medicaid and WIC participation; exposure to environmental agents; and history of traumatic life events, including abuse.

A partial list of intrapartum risk factors appears in **Box 33-5** ». Keep these factors in mind during the assessment.

Box 33-5

Selected Intrapartum Risk Factors

- Intermittent bleeding
- Abnormal fetal presentation
- Poverty
- Poor nutrition
- Lack of prenatal care
- Mental illness
- PTSD
- Smoking
- Drug use
- Alcohol use

Intrapartum Physical and Psychosociocultural Assessment

A physical examination is part of the admission procedure and part of the ongoing care of the patient. Although the intrapartum physical assessment is not as complete and thorough as the initial prenatal physical examination (see the Concepts section of this module), it does involve assessment of some body systems and the actual labor process.

The physical assessment portion includes assessments performed immediately on admission as well as ongoing assessments. Nurses conduct ongoing assessments in all clinical situations. For example, when the woman is changing into her gown, the nurse can assess the skin for bruises, needle marks, burns, or other abnormalities. The nurse can also determine whether the woman appears to be undernourished or overnourished. When labor is progressing rapidly, however, the nurse may not have time for a complete assessment. In that case, the critical physical assessments include maternal vital signs, labor status, fetal status, and laboratory findings.

Assessment of psychosocial history is a critical component of intrapartum nursing assessment. An estimated one third of all pregnant women are exposed to some type of psychotropic medication during their pregnancies. In addition, an estimated 10% of pregnant women meet the criteria for major depressive disorder during pregnancy and another 18% have depressive symptoms while pregnant (Dalfen, 2014). Perinatal depression is a common complication of pregnancy with potentially devastating consequences if it goes unrecognized and untreated (ACOG, 2015d). Any mental illness can play a role in how the woman copes with the labor and birth experience and should be assessed by the admitting nurse. Women with identified disorders will need ongoing assessment during the labor and birth.

The nurse can begin gathering data about sociocultural factors as the woman enters the birthing area. The nurse observes the communication pattern between the woman and her support person and their responses to admission questions and initial teaching. If the woman and her support person do not speak English and translators are not available among the birthing unit staff, the course of labor and the nurse's ability to interact and provide support and education are affected. The couple must receive information in their primary language to make informed decisions (see Nursing Care Plan in Exemplar 33.A). Communication may also be affected by cultural practices, such as beliefs about when to speak, who should ask questions, or whether it is acceptable to let others know about discomfort. People from certain cultures may want to experience birth naturally and may decline pain medications. In some cultures, the partner is not expected to be present in the birthing area. Nurses need to be culturally competent so that this is not interpreted as lack of interest in the birth, the mother, or the baby (Spector, 2017).

Individualized nursing care can best be planned and implemented when nurses know and honor the values and beliefs of the laboring woman (Spector, 2017). To avoid stereotyping patients, the nurse always asks the woman and her family about individual beliefs and preferences. Nurses who feel uncertain about what to ask or to consider need to

explore the varying cultural values and beliefs of the people residing in their community. Although some communities have a prominent culture that may follow certain rituals, the nurse should still ask each patient about her own individual beliefs and preferences.

The final section of the assessment guide addresses ideas, knowledge, fantasies, and fears about childbearing. The nurse should ask the patient whether she has any special needs. However, because some women may not know what needs may arise, ongoing assessment is imperative. It is important for the nurse to pay specific attention to body language, eye contact, and other nonverbal cues that may indicate the woman is experiencing anxiety or other feelings. By assessing the patient's cultural and psychosocial status, the nurse can better meet the woman's needs for information and support. The nurse can then assist the woman and her partner; in the absence of a partner, the nurse may become the support person.

The Intrapartum Assessment feature provides a framework the nurse can use when examining the laboring woman.

Assessment of Contractions

Once contractions begin, the nurse must assess the nature of the contractions and any accompanying pain. When palpating a woman's uterus during a contraction, compare the consistency to your nose, chin, and forehead to determine the intensity. Many experienced nurses note that the feel during mild contractions is similar in consistency to the tip of the nose, moderate contractions feel more like the chin, and with strong contractions, the uterus feels firm, much like the forehead.

It is also important to assess the laboring woman's perception of pain. How does she describe the pain? What is her affect? Is this contraction more uncomfortable than the last one? Is the nurse's palpation of intensity congruent with the woman's perception? (For instance, the nurse might evaluate a contraction as mild in intensity, whereas the laboring woman evaluates it as very strong.) A nurse's assessment is not complete unless the laboring woman's affect and response to the contractions are also noted and charted.

Electronic monitoring of uterine contractions provides continuous data. Electronic monitoring is routinely used in many birth settings for high-risk patients and those having oxytocin-induced labor. Electronic monitoring may be done externally, with a device that is placed against the maternal abdomen, or internally, with an intrauterine pressure catheter.

EXTERNAL ELECTRONIC MONITORING OF

CONTRACTIONS When monitoring contractions by external means, the portion of the monitoring equipment called a tocodynamometer, or "toco," is positioned against the fundus of the uterus and held in place with an elastic belt. The toco contains a flexible disk that responds to pressure. When the uterus contracts, the fundus tightens and the change in pressure against the toco is amplified and transmitted to the electronic fetal monitor. The monitor displays the uterine contraction as a pattern on graph paper.

External monitoring offers several advantages, including a continuous recording of the frequency and duration of uterine contractions, and it is noninvasive. However, it does

Intrapartum Assessment: First Stage of Labor

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
Vital Signs		
Blood pressure (BP): less than 140 systolic and 90 and greater than 90/50 diastolic	High blood pressure (essential hypertension, preeclampsia, renal disease, apprehension, anxiety, or pain) Low blood pressure (supine hypotension) Hemorrhage/hypovolemia Shock Drugs Side effect of epidural anesthesia	Evaluate history of preexisting disorders, and check for presence of other signs of preeclampsia. Do not assess during contractions; implement measures to decrease anxiety and reassess. Provide quiet environment. Have O ₂ available. Notify anesthesiologist.
Pulse: 60–100 beats/min (normal, nonpregnant) Additional 10–20 beats/min during pregnancy	Increased pulse rate (excitement or anxiety, cardiac disorders, early shock, drug use)	Evaluate cause, reassess to see if rate continues; report to healthcare provider.
Respirations: 16–24 breaths/min (or pulse rate divided by 4)	Marked tachypnea (respiratory disease), hyperventilation in transition phase Decreased respirations (narcotics)	Assess between contractions; if marked tachypnea continues, assess for signs of respiratory disease or respiratory distress.
	Hyperventilation (anxiety/pain)	Encourage slow breaths if woman is hyperventilating.
Pulse oximetry 95% or greater	Pulse oximetry less than 90%: hypoxia, hypotension, hemorrhage	Administer O ₂ ; notify healthcare provider.
Temperature: 36.2°–37.6°C (97°–99.6°F)	Elevated temperature (infection, dehydration, prolonged rupture of membranes, epidural regional block)	Assess for other signs of infection or dehydration.
Weight		
25–35 lb greater than prepregnant weight	Weight gain greater than 35 lb (fluid retention, obesity, large baby, diabetes mellitus, preeclampsia) Weight gain less than 15 lb (small for gestational age, substance abuse, psychosocial problems)	Assess for signs of edema. Evaluate dietary patterns from prenatal record.
Lungs		
Normal breath sounds, clear and equal	Rales, rhonchi, friction rub (infection), pulmonary edema, asthma	Reassess; refer to healthcare provider.
Fundus		
At 40 weeks of gestation, located just below the xiphoid process	Uterine size not compatible with estimated date of birth (small for gestational age, large for gestational age, hydramnios, multiple pregnancy, placental/fetal anomalies, malpresentation)	Reevaluate history regarding pregnancy dating. Refer to healthcare provider for additional assessment.
Edema		
Slight amount of dependent edema	Pitting edema of face, hands, legs, abdomen, sacral area (preeclampsia)	Check deep tendon reflexes for hyperactivity; check for clonus; refer to healthcare provider.
Hydration		
Normal skin turgor, elastic	Poor skin turgor (dehydration)	Assess skin turgor; refer to healthcare provider for deviations. Provide fluids per healthcare provider orders.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

(continued on next page)

Intrapartum Assessment: First Stage of Labor *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
Perineum		
Tissues smooth, pink color	Varicose veins of vulva, herpes lesions/genital warts	Note on patient record need for follow-up in postpartum period; reassess after birth, refer to healthcare provider.
Clear mucus; may be blood tinged with earthy or human odor	Profuse, purulent, foul-smelling drainage	Suspected gonorrhea or chorioamnionitis; report to healthcare provider; initiate care to newborn's eyes; notify neonatal nursing staff and pediatrician.
Presence of small amount of bloody show that gradually increases with further cervical dilation	Hemorrhage	Assess BP and pulse, pallor, diaphoresis, report any marked changes. Standard precautions.
Labor Status		
Uterine contractions: regular pattern	Failure to establish a regular pattern, prolonged latent phase Hypertonicity Hypotonicity Dehydration	Evaluate whether woman is in true labor. Ambulate if in early labor. Evaluate patient status and contractile pattern. Obtain a 20-minute electronic fetal monitoring strip. Notify healthcare provider. Provide hydration.
Cervical dilation: progressive cervical dilation from size of fingertip to 10 cm (3.9 in.)	Rigidity of cervix (frequent cervical infections, scar tissue, failure of presenting part to descend)	Evaluate contractions, fetal engagement, position, and cervical dilation. Inform patient of progress.
Cervical effacement: progressive thinning of cervix	Failure to efface (rigidity of cervix, failure of presenting part to engage); cervical edema (pushing effort by woman before cervix is fully dilated and effaced, trapped cervix)	Evaluate contractions, fetal engagement, and position. Notify healthcare provider if cervix is becoming edematous; work with woman to prevent pushing until cervix is completely dilated. Keep vaginal exams to a minimum.
Fetal descent: progressive descent of fetal presenting part from station -5 to + 4	Arrest of descent (abnormal fetal position or presentation, macrosomic fetus, inadequate pelvic measurements)	Evaluate fetal position, presentation, and size.
Membranes: may rupture before or during labor	Rupture of membranes more than 12–24 hours before onset of labor	Assess for ruptured membranes using Nitrazine test tape before doing vaginal exam. Follow standard precautions. Keep vaginal exams to a minimum to prevent infection. When membranes rupture in the birth setting, immediately assess FHR to detect changes associated with prolapse of umbilical cord (FHR slows).
Findings on Nitrazine test tape: Membranes probably intact: Yellow pH 5.0 Olive pH 5.5 Olive green pH 6.0	False-positive results may be obtained if large amount of bloody show is present, previous vaginal examination has been done using lubricant, or tape is touched by nurse's fingers	Assess fluid for consistency, amount, odor; assess FHR frequently. Assess fluid at regular intervals for presence of meconium staining. Follow standard precautions while assessing amniotic fluid.
Membranes probably ruptured: Blue-green pH 6.5 Blue-gray pH 7.0 Deep blue pH 7.5		Teach woman that amniotic fluid is continually produced (to allay fear of "dry birth"). Teach woman that she may feel amniotic fluid trickle or gush with contractions. Change pads often.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.

Intrapartum Assessment: First Stage of Labor *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
Amniotic fluid clear, with earthy or human odor, no foul-smelling odor	Greenish amniotic fluid (fetal stress) Bloody fluid (vasa previa, abruptio placentae) Strong or foul odor (amnionitis)	Assess FHR; do vaginal exam to evaluate for prolapsed cord; apply fetal monitor for continuous data; report to healthcare provider. Take woman's temperature and report to healthcare provider.
Fetal Status		
FHR: 110–160 beats/min	Less than 110 or greater than 160 beats/min (nonreassuring fetal status); abnormal patterns on fetal monitor: decreased variability, late decelerations, variable decelerations, absence of accelerations with fetal movement	Initiate interventions based on particular FHR pattern.
Presentation: cephalic, 97%; breech, 3%	Face, brow, breech, or shoulder presentation	Report to healthcare provider; after presentation is confirmed as face, brow, breech, or shoulder, woman may be prepared for cesarean birth.
Position: left-occiput-anterior (LOA) most common	Persistent occipital-posterior (OP) position; transverse arrest	Carefully monitor maternal and fetal status. Reposition mother in side-lying or on hands and knees position to promote rotation of fetal head.
Activity: fetal movement	Hyperactivity (may precede fetal hypoxia) Complete lack of movement (nonreassuring fetal status or fetal demise)	Carefully evaluate FHR; apply fetal monitor. Carefully evaluate FHR; apply fetal monitor. Report to healthcare provider.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing intervention.
CULTURAL ASSESSMENT§	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA§§
Cultural influences determine customs and practices regarding intrapartum care.	Individual preferences may vary.	
Ask the following questions: ■ Who would you like to remain with you during your labor and birth?	She may prefer only her partner or other support person to remain or may also want family and/or friends.	Provide support for her wishes by encouraging desired people to stay. Provide information to others (with the woman's permission) who are not in the room.
■ What would you like to wear during labor?	She may be more comfortable in her own clothes.	Offer supportive materials, such as disposable pads, if needed to protect her clothing. Avoid subtle signals to the woman that she should not have chosen to remain in her own clothes. Have other clothing available if the woman desires. If her clothing becomes contaminated, it will be simple to place it in a plastic bag.
■ What activity would you like during labor?	She may want to ambulate most of the time, stand in the shower, sit in the Jacuzzi, sit on a chair/stool/birthing ball, remain on the bed, and so forth.	Support the woman's wishes; provide encouragement and complete assessments in a manner so her activity and positional wishes are disturbed as little as possible.
■ What position would you like for the birth?	She may feel more comfortable in lithotomy position with stirrups and her upper body elevated, side-lying or sitting in a birthing bed, standing, or squatting, or on hands and knees.	Collect any supplies and equipment needed to support her in her chosen birthing position. Provide information to the support person regarding any changes that may be needed based on the chosen position.
§These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.		§§This column provides guidelines for further assessment and initial nursing intervention.

(continued on next page)

Intrapartum Assessment: First Stage of Labor *(continued)*

CULTURAL ASSESSMENT [§]	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA ^{§§}
■ Is there anything special you would like?	She may want the room darkened or to have curtains and windows open, music playing, her support person to cut the umbilical cord, to save a portion of the umbilical cord, to save the placenta, to videotape the birth, or other particular preferences.	Support requests, and communicate requests to any other nursing or medical personnel (so requests can continue to be supported and not questioned). If another nurse or physician does not honor the request, act as advocate for the woman by continuing to support her unless her desire is truly unsafe.
Ask the woman if she would like like fluids, and ask what temperature she prefers.	She may prefer clear fluids other than water (tea, clear juice). She may prefer iced, room temperature, or warmed fluids.	Provide fluids as desired.
Observe the woman's response when privacy is difficult to maintain and her body is exposed.	Some women do not seem to mind being exposed during an exam or procedure; others feel acute discomfort.	Maintain privacy and respect the woman's sense of privacy. If the woman is unable to provide specific information, the nurse may draw from general information regarding cultural variation: Southeast Asian women may not want any family member in the room during exam or procedures. The woman's partner may not be involved with coaching activities during labor or birth. Muslim women may need to remain covered during the labor and birth and avoid exposure of any body part. The husband may need to be in the room but remain behind a curtain or screen so he does not view his wife at this time.
If the woman is to breastfeed, ask if she would like to feed her baby immediately after birth.	She may want to feed her baby right away or may want to wait a little while.	
[§] These are only a few suggestions. We do not mean to imply that this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.		^{§§} This column provides guidelines for further assessment and initial nursing intervention.
PSYCHOSOCIAL ASSESSMENT	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA ^{††}
Preparation for Childbirth		
Does the woman have some information regarding process of normal labor and birth?	Some women do not have any information regarding childbirth.	Add to present information base.
Does the woman have breathing and/or relaxation techniques to use during labor?	Some women do not have any method of relaxation or breathing to use, and some do not desire them.	Support breathing and relaxation techniques that the patient is using; provide information if needed.
Have the woman and support person done extensive preparation for childbirth?	Some women have strong opinions regarding labor and birth preparation.	Support the woman's wishes to participate in her birth experience; support the woman's birth plan.
Response to Labor		
Latent phase: relaxed, excited, anxious for labor to be well established	May feel unable to cope with contractions because of fear, anxiety, or lack of information.	Provide support and encouragement, establish trusting relationship.
Active phase: becomes more intense, begins to tire	May remain quiet and without any sign of discomfort or anxiety, may insist that she is unable to continue with the birthing process.	Provide support and coaching if needed.
		^{††} This column provides guidelines for further assessment and initial nursing intervention.

Intrapartum Assessment: First Stage of Labor *(continued)*

PSYCHOSOCIAL ASSESSMENT	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA ^{††}
Transitional phase: feels tired, may feel unable to cope, needs frequent coaching to maintain breathing patterns		
Coping mechanisms: ability to cope with labor through use of support system, breathing, relaxation techniques, and comfort measures, including frequent position changes in labor, immersion in warm water, and massage	May feel marked anxiety and apprehension, may not have coping mechanisms that can be brought into this experience, or may be unable to use them at this time. Survivors of sexual abuse may demonstrate fear of intravenous lines or needles, may recoil when touched, may insist on a female caregiver, may be very sensitive to body fluids and cleanliness, and may be unable to labor lying down.	Support coping mechanisms if they are working for the woman; provide information and support if she exhibits anxiety or needs alternative to present coping methods. Encourage participation of partner or other individual if a supportive relationship seems apparent. Establish rapport and a trusting relationship. Provide information that is true and offer your presence.
Anxiety		
Some anxiety and apprehension is within normal limits.	May show anxiety through rapid breathing, nervous tremors, frowning, grimacing, clenching of teeth, thrashing movements, crying, increased pulse and blood pressure	Provide support, encouragement, and information. Teach relaxation techniques. Support controlled breathing efforts. May need to provide a paper bag to breathe into if woman says her lips are tingling. Note FHR.
Sounds During Labor		
	Some women are very quiet; others moan or make a variety of noises.	Provide a supportive environment. Encourage woman to do what feels right for her.
Support System		
Physical intimacy between mother and partner (or mother and support person/doula); caretaking activities, such as soothing conversation and touching	Some women would prefer no contact; others may show clinging behaviors.	Encourage caretaking activities that appear to comfort the woman; encourage support for the woman; if support is limited, the nurse may take a more active role.
Support person stays in proximity	Limited interaction may come from a desire for quiet.	Encourage support person to stay close (if this seems appropriate).
Relationship between mother and partner or support person: involved interaction	The support person may seem to be detached and maintain little support, attention, or conversation.	Support interactions; if interaction is limited, the nurse may provide more information and support. Ensure that the support person has short breaks, especially before transition.
		^{††} This column provides guidelines for further assessment and initial nursing intervention.

not accurately record the intensity of the uterine contraction, and it is difficult to obtain an accurate fetal heart rate in some women, such as those who are very obese, those who have hydramnios, or those with a very active fetus. In addition, the woman may be bothered by the belt if it requires frequent readjustment when she changes position. Electronic monitoring allows the nurse to continually monitor the fetus if concerns arise based on the fetal heart rate. It also enables the nurse and physician or CNM to observe the pattern of the FHR over a period of time by examining the electronic fetal monitoring strip.

INTERNAL ELECTRONIC MONITORING OF CONTRACTIONS

Internal intrauterine monitoring provides the same data as external monitoring, as well as accurate measurement of uterine contraction intensity (the strength of the contraction and the actual pressure within the uterus). After membranes have ruptured, the physician or CNM (or the nurse in some facilities) inserts the **intrauterine pressure catheter** into the uterine cavity and connects it by a cable to the electronic fetal monitor. It is important to first assess the fetal position and to review a past ultrasound to determine the location of the placenta,

because the internal monitor should be placed away from the placenta. If an ultrasound has not been previously obtained, the healthcare provider may wish to obtain one on the unit or have the sonographer perform such an exam.

The pressure within the uterus in the resting state and during each contraction is measured by a small micropressure device located in the tip of the catheter. Internal electronic monitoring is used when it is imperative to have accurate intrauterine pressure readings to evaluate the stress on the uterus or to determine the adequacy of contractions. The advantage of the intrauterine pressure monitor is that it can directly measure the intensity of the contraction. It can be used when the external monitor may not be accurately assessing the contraction strength, such as in cases of maternal obesity. It can also be used when oxytocin is being administered to ensure that uterine contractions are adequate.

During internal electronic monitoring, the nurse should also evaluate the woman's labor status by palpating the intensity and resting tone of the uterine fundus during contractions. Technology is a useful tool if used as an adjunct to good assessment skills, but it is not a replacement for those skills.

Cervical Assessment

Cervical dilation and effacement are evaluated directly by vaginal examination. The vaginal examination can provide information about the adequacy of the maternal pelvis, membrane status, characteristics of amniotic fluid, and fetal position and station.

Fetal Assessment

A complete intrapartum fetal assessment requires determination of the fetal position and presentation as well as evaluation of the fetal status.

Assessment of Fetal Position

Fetal position is determined in the following ways:

- Inspection of the woman's abdomen
- Palpation of the woman's abdomen
- Vaginal examination to determine the presenting part
- Ultrasound
- Auscultation of fetal heart rate.

INSPECTION Observe the woman's abdomen for size and shape. Assess the lie of the fetus by noting whether the uterus projects up and down (longitudinal lie) or left to right (transverse lie).

PALPATION: LEOPOLD MANEUVERS **Leopold maneuvers** are a systematic way to evaluate the maternal abdomen. Frequent practice increases the examiner's skill in determining fetal position by palpation. (See the Concepts section for information on how to perform Leopold maneuvers.) Leopold maneuvers may be difficult to perform on women who are obese or those who have excessive amniotic fluid (hydramnios). Before performing Leopold maneuvers, the nurse should have the woman empty her bladder and then lie on her back with her feet on the bed and her knees bent.

VAGINAL EXAMINATION AND ULTRASOUND Other assessment techniques to determine fetal position and presentation include vaginal examination and the use of ultrasound to visualize the fetus. During the vaginal examination, the examiner can palpate the presenting part if the cervix is dilated. Information about the position of the fetus and the degree of flexion of its head (in cephalic presentations) can also be obtained. Visualization by ultrasound is used when the fetal position cannot be determined by abdominal palpation.

AUSCULTATION OF FETAL HEART RATE The handheld Doppler ultrasound is used to auscultate the FHR between, during, and immediately after uterine contractions. A fetoscope may also be used. Instead of listening haphazardly over the woman's abdomen for the FHR, the nurse may choose to perform Leopold maneuvers first. Leopold maneuvers not only indicate the probable location of the FHR but also help determine the presence of multiple fetuses, fetal lie, and fetal presentation.

The FHR is heard most clearly at the fetal back (**Figure 33-50** >>). In a cephalic presentation, the FHR is best heard in the lower quadrants of the maternal abdomen. In a breech presentation, it is heard at or above the level of the maternal umbilicus. In a transverse lie, the FHR may be heard best just above or just below the umbilicus. As the presenting part descends and rotates through the pelvic structure during labor, the location of the FHR tends to descend and move toward the midline.

After the FHR is located, it is usually counted for 30 seconds, starting at the acme or immediately after a contraction, and multiplied by 2 in order to obtain the number of beats per minute. It is also appropriate to listen for a full minute, particularly after a change in status such as rupture of membranes (Freeman et al., 2012). If the FHR is irregular or has changed markedly from the last assessment, or if an audible deceleration is heard, the nurse listens for a full minute, through and immediately after a contraction. In these situations, continuous electronic fetal monitoring is warranted (Menihan & Kopel, 2014). It is important to note that intermittent auscultation has been found to be as effective as the electronic method for fetal surveillance.

Electronic Monitoring of Fetal Heart Rate

Electronic fetal monitoring produces a continuous tracing of the FHR, which allows many characteristics of the FHR to be visually assessed. A growing number of physicians and nurses, however, are beginning to question the widespread use of this technology. Although fetuses who are monitored continuously have a reduction in seizures, there is no reduction in cerebral palsy, newborn/infant mortality, or adverse neonatal outcomes. Women who receive continuous fetal monitoring are more likely to undergo a cesarean birth or an instrument-assisted birth (Resnik, 2013).

INDICATIONS FOR ELECTRONIC MONITORING If one or more of the following factors are present, the FHR and contractions are monitored electronically:

- Previous history of a stillbirth at 38 or more weeks of gestation

Figure 33-50 » Location of fetal heart rate in relation to the more commonly seen fetal positions. The FHR is heard more clearly over the fetal back.

- Presence of a complication of pregnancy (e.g., preeclampsia, placenta previa, abruptio placentae, multiple gestation, and prolonged or premature rupture of membranes)
- Induction of labor (labor that is begun as a result of some type of intervention [e.g., an intravenous infusion of oxytocin])
- Preterm labor
- Decreased fetal movement
- Nonreassuring fetal status
- Meconium staining of amniotic fluid (meconium has been released into the amniotic fluid by the fetus, which may indicate a problem)
- Trial of labor following a previous cesarean birth (Menihan & Kopel, 2014)

- Maternal fever
- Placental problems.

METHODS OF ELECTRONIC MONITORING External monitoring of the fetus is usually accomplished by ultrasound. A transducer, which emits continuous sound waves, is placed on the maternal abdomen. When placed correctly, the sound waves bounce off the fetal heart and are picked up by the electronic monitor. The actual moment-by-moment FHR is displayed graphically on a screen (**Figure 33-51** »). In some instances, the monitor may track the maternal heart rate instead of the FHR. However, the nurse can avoid this error by comparing the maternal pulse to the FHR.

Recent advances in technology have led to the development of new ambulatory methods of external monitoring. Using a telemetry system, a small, battery-operated transducer transmits signals to a receiver connected to the monitor. This system, which is held in place with a shoulder strap, allows the patient to ambulate, helping her to feel more comfortable and less confined during labor. Many of the newer models can also be worn in the tub and can be completely submerged in water, making a more natural birthing experience possible even for women who require continuous monitoring for medical indications. In contrast, the system depicted in Figure 33-51 requires the laboring woman to remain close to the electrical power source for the monitor.

Internal monitoring requires an internal spiral electrode. Women who require internal monitoring are typically confined to bed and cannot ambulate. To place the fetal scalp electrode (FSE) on the fetal occiput, the amniotic membranes must be ruptured, the cervix must be dilated at least 2 cm (0.08 in.), the presenting part must be down against the cervix, and the presenting part must be known (i.e., the nurse must be able to detect the actual part of the fetus that is down against the cervix). If all these factors are present, the labor and birth nurse (if specialty training has been completed), physician, or CNM inserts a sterile internal spiral electrode into the vagina and places it against the fetal head. The spiral electrode is rotated clockwise until it is attached to the scalp. It is essential that the electrode not be placed over the eye or a fontanel, so the fetal position must be determined before a scalp electrode is applied. Wires that extend from the spiral electrode are attached to a leg plate (placed on the woman's thigh) and then attached to the electronic fetal monitor. This method of monitoring the FHR provides more accurate continuous data than external monitoring because the signal is clearer and movement of the fetus or the woman does not interrupt it (**Figure 33-52** »).

Internal monitoring has both risks and benefits. It provides a more accurate fetal tracing and is more effective in monitoring the fetal status. In rare cases, the scalp electrode can be placed on the fetal fontanel or, if the fetus is in a face presentation, on an eye, thus causing fetal injury. Women with certain medical conditions, such as HIV infection, should not be monitored with internal monitoring, because it can increase the risk of viral transmission.

The FHR tracing at the top of **Figure 33-53** » was obtained by internal monitoring with a spiral electrode; the uterine contraction tracing at the bottom of the figure was obtained by external monitoring with a toco. Note that the

Figure 33-51 » Electronic fetal monitoring by external technique. The ultrasound device, placed over the fetal back, transmits information on the fetal heart rate. Information from both the tocodynamometer and ultrasound device is transmitted to the electronic fetal monitor. The FHR is indicated in four ways: on the digital display, as a blinking light, by sound, and on special monitor paper. The uterine contractions are displayed on the graph paper.

Figure 33-52 » Technique for internal, direct fetal monitoring. **A**, Spiral electrode. **B**, Attaching the spiral electrode to the scalp. **C**, Attached spiral electrode with the guide tube removed.

Figure 33-53 » Normal fetal heart rate range is from 110 to 160 beats/min. The FHR tracing in the upper portion of the graph indicates an FHR range of 140–155 beats/min. The bottom portion depicts uterine contractions. Each dark vertical line marks 1 minute, and each small rectangle represents 10 seconds. The contraction frequency is about every 2.5 minutes, and the duration of the contractions is 50–60 seconds.

FHR is variable (the tracing moves up and down instead of in a straight line). In Figure 33-53, each dark vertical line represents 1 minute; therefore, contractions are occurring about every 2.5–3 minutes. The FHR is evaluated by assessing an electronic monitor tracing for baseline rate, baseline variability, and periodic changes.

BASELINE FETAL HEART RATE The **baseline fetal heart rate** refers to the average FHR rounded to increments of 5 beats/min observed during a 10-minute period of monitoring. This excludes periodic or episodic changes, periods of marked variability, and segments of the baseline that differ by more than 25 beats/min. The duration should be at least 2 minutes (Menihan & Kopel, 2014). Normal FHR (baseline rate) ranges from 110 to 160 beats/min. There are two abnormal variations of the baseline rate—those above 160 beats/min (tachycardia) and those below 110 beats/min (bradycardia). Another change affecting the baseline is called **baseline FHR variability**, which is fluctuation in the FHR baseline of 2 cycles per minute or greater, with irregular amplitude and inconstant frequency (Cunningham et al., 2014).

A *wandering baseline* fluctuates between 120 and 160 beats/min in an unsteady wandering pattern and can be associated with neurologic impairment of the fetus or a preterminal event (Cunningham et al., 2014). Possible causes for this pattern include congenital defects or metabolic acidosis. Immediate interventions are needed in order to enhance fetal oxygenation. Birth should be anticipated (Hamilton & Warrick, 2013).

Fetal tachycardia is a sustained rate of 161 beats/min or above. Marked tachycardia is 180 beats/min or above.

Causes of tachycardia include the following (Cunningham et al., 2014):

- Early fetal hypoxia, which leads to stimulation of the sympathetic system as the fetus compensates for reduced blood flow
- Maternal fever, which accelerates the metabolism of the fetus
- Maternal dehydration
- Beta-sympathomimetic drugs, such as ritodrine, terbutaline, atropine, and isoxsuprine, which have a cardiac stimulant effect
- Chorioamnionitis (fetal tachycardia may be the first sign of developing intrauterine infection)
- Maternal hyperthyroidism (thyroid-stimulating hormones may cross the placenta and stimulate FHR)
- Fetal anemia (the heart rate is increased as a compensatory mechanism to improve tissue perfusion)
- Tachydysrhythmias (fetal dysrhythmias occur in less than 1% of all pregnancies).

Tachycardia is considered to be an ominous sign if it is accompanied by late decelerations, severe variable decelerations, or decreased variability. If tachycardia is associated with maternal fever, treatment may consist of antipyretics and/or antibiotics.

Fetal bradycardia is a rate of less than 110 beats/min during a 10-minute period or longer. Causes of fetal bradycardia include the following (Cunningham et al., 2014):

- Late (profound) fetal hypoxia (depression of myocardial activity)

- Maternal hypotension, which results in decreased blood flow to the fetus
- Prolonged umbilical cord compression (fetal baroreceptors are activated by cord compression, and this produces vagal stimulation, which results in decreased FHR)
- Fetal arrhythmia, which is associated with complete heart block in the fetus
- Uterine tachysystole
- Abruptio placentae
- Uterine rupture
- Vagal stimulation in the second stage (because this does not involve hypoxia, the fetus can recover)
- Congenital heart block
- Maternal hypothermia.

Bradycardia may be a benign or an ominous (preterminal) sign. If there is variability, the bradycardia is considered to be benign. Bradycardia accompanied by decreased variability and late decelerations is considered to be ominous and a sign of nonreassuring fetal status (Cunningham et al., 2014).

ARRHYTHMIAS AND DYSRHYTHMIAS Arrhythmias, a term often used interchangeably with dysrhythmias, are disturbances in the FHR pattern that are not associated with abnormal electrical impulse formation or conduction in the fetal cardiac tissue but are related to a structural abnormality or congenital heart disease. The majority of fetal arrhythmias are irregular rhythms (Anderson & Stone, 2013). Fetal arrhythmias may be detected when listening to the FHR on a fetal monitor. It is important to rule out artifacts or electrical interference, which may occur. Most true arrhythmias are accompanied by baseline bradycardia, baseline tachycardia, or an abrupt baseline spiking. Whereas 90% of dysrhythmias are benign, 10% can be life threatening and require the consultation of a neonatal or pediatric cardiology expert (Miller, Miller, & Tucker, 2013).

VARIABILITY Baseline variability is a measure of the interplay (the push-pull effect) between the sympathetic and parasympathetic nervous systems. Baseline variability is fluctuations in the FHR of two cycles per minute or greater. **Figure 33-54** depicts the different ranges of variability. The amplitudes of the peaks and troughs in beats per minute are defined as follows (Papadakis, McPhee, & Rabow, 2014):

- *Absent*: amplitude undetectable
- *Minimal*: amplitude detectable but less than 5 beats/min
- *Moderate*: amplitude 6–25 beats/min
- *Marked*: amplitude greater than 25 beats/min.

Reduced variability is the best single predictor for determining fetal compromise (Cunningham et al., 2014). Fetal acidosis and subsequent hypoxia are highest in fetuses that have absent or minimal variability.

Causes of decreased variability include the following (Cunningham et al., 2014):

- Hypoxia and acidosis (decreased blood flow to the fetus)
- Administration of drugs such as meperidine hydrochloride (Demerol), diazepam (Valium), or hydroxyzine (Vistaril) that depress the fetal central nervous system

A

B

C

D

Figure 33-54 Variability. **A**, Marked variability. **B**, Moderate variability. **C**, Minimal variability. **D**, Absent variability.

- Fetal sleep cycle (during fetal sleep, variability is decreased; fetal sleep cycles usually last for 20–40 minutes each hour)
- Fetus of less than 32 weeks of gestation (fetal neurologic control of heart rate is immature)
- Fetal dysrhythmias
- Fetal anomalies affecting the heart, central nervous system, or autonomic nervous system
- Previous neurologic insult
- Tachycardia.

Causes of marked variability include the following (King et al., 2013):

- Early mild hypoxia (variability increases as a result of compensatory mechanism)
- Fetal stimulation or activity (stimulation of autonomic nervous system because of abdominal palpation, maternal vaginal examination, application of spiral electrode on fetal head, or acoustic stimulation)
- Fetal breathing movements
- Advancing gestational age (greater than 30 weeks of gestation).

Absent variability that does not appear to be associated with a fetal sleep cycle or the administration of drugs is a warning sign of nonreassuring fetal status. It is especially ominous if absent or minimal variability is accompanied by late decelerations (explained shortly). If decreased variability

is noted on monitoring, consider application of a spiral electrode to obtain more accurate information.

ACCELERATIONS **Accelerations** are transient increases in the FHR normally caused by fetal movement. When the fetus moves, its heart rate increases, just as the heart rates of adults increase during exercise. Often, accelerations accompany uterine contractions, usually because the fetus moves in response to the pressure of the contractions. Accelerations of this type are thought to be a sign of fetal well-being and adequate oxygen reserve. The accelerations with fetal movement are the basis for nonstress tests.

DECELERATIONS **Decelerations** are periodic decreases in FHR from the normal baseline. They are categorized as early, late, and variable according to the time of their occurrence in the contraction cycle and their waveform (**Figure 33-55**). Nursing interventions for decelerations are outlined in **Table 33-14**.

Figure 33-55 Types and characteristics of early, late, and variable decelerations.

TABLE 33–14 Guidelines for Management of Variable, Late, and Prolonged Deceleration Patterns

Pattern	Nursing Interventions
Variable decelerations (Cause: umbilical cord compression)	Report findings to healthcare provider and document in chart. Provide explanation to woman and partner.
Isolated or occasional, moderate	Change maternal position to one in which FHR pattern is most improved. Perform vaginal examination to assess for prolapsed cord or change in labor progress. Monitor FHR continuously to assess current status and for further changes in FHR pattern.
Variable decelerations, severe and uncorrectable (Cause: umbilical cord compression)	Administer oxygen by face mask at 7–10 L/min. Report findings to healthcare provider and document in chart. Provide explanation to woman and partner. Prepare for probable cesarean birth. Follow interventions previously listed. Prepare for vaginal birth unless baseline variability is decreasing or FHR is progressively rising, in which case cesarean, forceps, or vacuum birth is indicated. Maintain good hydration with intravenous (IV) fluids (normal saline or lactated Ringer solution).
Late decelerations (Cause: uteroplacental insufficiency)	Administer oxygen by face mask at 7–10 L/min. Report findings to healthcare provider and document in chart. Provide explanation to woman and partner. Monitor for further FHR changes. Maintain maternal position on left side. Maintain good hydration with intravenous (IV) fluids (normal saline or lactated Ringer solution). Discontinue oxytocin if it is being administered and late decelerations persist despite other interventions. Monitor maternal blood pressure and pulse for signs of hypotension; possibly increase flow rate of IV fluids to treat hypotension. Follow orders of healthcare provider for treatment for hypotension if present. Increase IV fluids to maintain volume and hydration (normal saline or lactated Ringer solution). Assess labor progress (dilation and station).
Late decelerations with tachycardia or decreasing variability (Cause: uteroplacental insufficiency)	Report findings to healthcare provider and document in chart. Maintain maternal position on left side. Administer oxygen by face mask at 7–10 L/min. Discontinue oxytocin if it is being administered. Assess maternal blood pressure and pulse. Increase IV fluids (normal saline or lactated Ringer solution). Assess labor progress (dilation and station). Prepare for immediate cesarean birth. Explain plan of treatment to woman and partner. Assist healthcare provider with fetal blood sampling (if ordered).
Prolonged decelerations (Cause: multiple issues that result in prolonged impaired perfusion)	Perform vaginal examination to rule out prolapsed cord or to determine progress in labor status. Change maternal position as needed to try to alleviate decelerations. Discontinue oxytocin if it is being administered. Notify healthcare provider of findings/initial interventions and document in chart. Provide explanation to woman and partner. Increase IV fluids (normal saline or lactated Ringer solution). Administer tocolytic if hypertonus noted and if ordered by healthcare provider. Anticipate normal FHR recovery following deceleration if FHR previously normal. Anticipate intervention if FHR previously abnormal or deceleration lasts > 3 minutes.

When the fetal head is compressed, cerebral blood flow is decreased, which leads to central vagal stimulation and results in early deceleration. The onset of early deceleration is associated with the onset of the uterine contraction. This type of deceleration is of uniform shape, is usually considered to be benign, and does not require intervention.

SAFETY ALERT The presence of repetitive early decelerations may be a sign of advanced dilation or the beginning of the second stage of labor (King et al., 2013). If the monitoring strip shows recurring early decelerations, ask the laboring woman whether she is experiencing any pressure. Pressure that occurs only with the contractions typically indicates advanced dilation. Intense pressure that does not change or ease up when the contractions cease may indicate the beginning of the second stage. A vaginal examination may be performed to establish the amount of dilation.

Late deceleration is caused by uteroplacental insufficiency resulting from decreased blood flow and oxygen transfer to the fetus through the intervillous spaces during uterine contractions. The most common causes of late decelerations are maternal hypotension resulting from the administration of epidural anesthesia and uterine tachysystole associated with oxytocin infusion (Groll, 2012). The onset of the deceleration occurs after the onset of a uterine contraction and is of a uniform shape that tends to reflect associated uterine contractions. The late deceleration pattern is considered to be a nonreassuring sign and requires continuous assessment. If late decelerations continue and birth is not imminent, a cesarean birth may be indicated.

Variable decelerations occur if the umbilical cord becomes compressed, reducing blood flow between the placenta and fetus. The resulting increase in peripheral resistance in the fetal circulation causes fetal hypertension. Fetal hypertension stimulates the baroreceptors in the aortic arch and carotid sinuses, slowing the FHR. The onset of variable decelerations differs in timing with the onset of the contraction, and the decelerations are variable in shape. This pattern requires further assessment.

A sinusoidal pattern appears similar to a waveform. The characteristics of this pattern include absence of variability and the presence of a smooth, wavelike shape. The pattern resembles a perfect letter “S” lying on its side. These patterns can be pseudosinusoidal (benign) or true sinusoidal. The true pattern is associated with Rh alloimmunization, fetal anemia, severe fetal hypoxia, umbilical cord occlusion, twin-to-twin transfusion, or a chronic fetal bleed. Pseudosinusoidal patterns are usually temporary and commonly occur with the administration of medications such as meperidine (Demerol) or butorphanol tartrate (Stadol) (Groll, 2012).

Decelerations are also classified based on the rate in which the FHR leaves the baseline FHR:

- **Abrupt decelerations** occur in less than 30 seconds (King et al., 2013)
- **Variable decelerations** descend abruptly.
- **Gradual decelerations** require 30 seconds or more to descend. Both early and late decelerations descend gradually (King et al., 2013).

- **Episodic decelerations** occur independently of the uterine contractions and are frequently the result of external stimulations, such as vaginal exams.
- **Periodic decelerations** refer to decelerations that occur with the contractions and are considered to be repetitive if they occur with 50% of the contractions (King et al., 2013).
- **Prolonged decelerations** are those that leave the baseline for more than 2 minutes but less than 10 minutes.

EVALUATION OF FETAL HEART RATE TRACINGS Evaluation of the electronic monitor tracing begins by looking at the uterine contraction pattern. To evaluate the contraction pattern, the nurse does the following:

1. Determine the uterine resting tone.
2. Assess the contractions: What is the frequency? What is the duration? What is the intensity?

The next step is to evaluate the FHR tracing as follows:

1. Determine the baseline: Is the baseline within the normal range? Is there evidence of tachycardia? Is there evidence of bradycardia?
2. Determine FHR variability: Is variability absent? Minimal? Moderate? Marked?
3. Determine whether a sinusoidal pattern is present.
4. Determine whether there are periodic changes: Are accelerations present? Do they meet the criteria for a reactive nonstress test? Are decelerations present? Are they uniform in shape? If so, determine whether they are early or late decelerations. Are they nonuniform in shape? If so, determine whether they are variable decelerations.

After evaluating the FHR tracing for the factors just listed, the nurse may further classify the tracing as reassuring (normal) or nonreassuring (worrisome). Reassuring patterns contain normal parameters and do not require additional treatment or intervention. Characteristics of reassuring FHR patterns include the following:

- Baseline rate is 110–160 beats/min.
- Variability is moderate.
- Periodic patterns consist of accelerations with fetal movement, and early decelerations may be present.

Nonreassuring patterns may indicate that the fetus is becoming stressed and intervention is needed. Characteristics of nonreassuring patterns include the following:

- Severe variable decelerations (FHR drops below 70 beats/min for longer than 30–45 seconds and is accompanied by rising baseline or decreasing variability or slow return to baseline.)
- Late decelerations of any magnitude
- Absence of variability
- Prolonged deceleration (a deceleration that lasts 60–90 seconds or more)
- Severe (marked) bradycardia (FHR baseline of 70 beats/min or less).

Nonreassuring patterns may require continuous monitoring and more involved treatment and intervention (see Table 33–14).

Box 33–6

The Three-Tier Fetal Heart Rate Interpretation System

Category I

Category I FHR tracings include *all* of the following:

- Baseline rate: 110–160 beats/min
- Baseline FHR variability: moderate
- Late or variable decelerations: absent
- Early decelerations: present or absent
- Accelerations: present or absent.

Category II

Category II FHR tracings include all FHR tracings not categorized as Category I or Category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of Category II FHR tracings include any of the following:

- Baseline rate
 - Bradycardia not accompanied by absent baseline variability
 - Tachycardia
- Baseline FHR variability
 - Minimal baseline variability
 - Absent baseline variability not accompanied by recurrent decelerations
 - Marked baseline variability

■ Accelerations

- Absence of induced accelerations after fetal stimulation

■ Periodic or episodic decelerations

- Recurrent variable decelerations accompanied by minimal or moderate baseline variability
- Prolonged deceleration of 2 minutes or more but less than 10 minutes
- Recurrent late decelerations with moderate baseline variability
- Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” or “shoulders.”

Category III

Category III FHR tracings include:

- Absent baseline FHR variability and any of the following:
 - Recurrent late decelerations
 - Recurrent variable decelerations
 - Bradycardia
- Sinusoidal pattern.

Source: Data from American College of Obstetricians & Gynecologists (ACOG) (2009, reaffirmed 2013). *Intrapartum fetal heart rate monitoring: Nomenclature, interpretation, and general management principles*. (ACOG Practice Bulletin No. 106.) Washington, DC: ACOG.

After evaluating the FHR tracing for the factors listed, the nurse may categorize the tracing according to the Three-Tier Fetal Heart Rate Interpretation System shown in **Box 33–6** ». The three-tier system for the categorization of FHR patterns is recommended by ACOG, Association of Women’s Health, Obstetric, and Neonatal Nurses (AWHONN), and the National Institute of Child Health and Human Development (Callahan & Caughley, 2013). Categorization of the FHR tracing evaluates the fetus at that point in time; tracing patterns can and will change. An FHR tracing may move back and forth between categories depending on the clinical situation and management strategies employed.

- **Category I FHR tracings are normal.** They are strongly predictive of normal fetal acid–base status at the time of observation. The FHR tracings may be followed in a routine manner, and no specific action is required.
- **Category II FHR tracings are indeterminate.** They are not predictive of abnormal fetal acid–base status, yet we do not have adequate evidence at present to classify these as Category I or Category III. Category II tracings require evaluation and continued surveillance and reevaluation, taking into account all of the associated clinical circumstances.
- **Category III FHR tracings are abnormal.** They are predictive of abnormal fetal acid–base status at the time of observation. They require prompt evaluation. Depending on the clinical situation, efforts to expeditiously resolve the abnormal FHR pattern may include, but are not limited to, provision of maternal oxygen, change in maternal position, discontinuation of labor stimulation, and treatment of maternal hypotension.

It is important to provide information to the laboring woman regarding the FHR pattern and the interventions that will help her fetus. Sharing information with the laboring woman reassures her that a potential or actual problem has been identified and that she is an active participant in the interventions. Occasionally, a problem arises that requires immediate intervention. In that case, the nurse can say something like “It is important for you to turn on your side right now because the baby is having a little difficulty. I’ll explain what is happening in just a few moments.” This type of response lets the woman know that although an action needs to be accomplished rapidly, information will soon be provided. In the haste to act quickly, the nurse must not forget that it is the woman’s body and her baby.

Labor and birth nurses must be skilled and competent in evaluating electronic FHR patterns and responding appropriately (see Table 33–14). Competence can be maintained through frequent in-services, formal courses, and continuing education programs.

RESPONSES TO ELECTRONIC MONITORING Responses to electronic fetal monitoring can be varied and complex. Many women have little knowledge of monitoring unless they have attended a prenatal class that dealt with this subject. Some women react to electronic monitoring positively, viewing it as a reassurance that “the baby is okay.” They may also feel the monitor helps identify problems that develop in labor. Other women may have ambivalent or even negative feelings about the monitor. They may think the monitor is interfering with a natural process, and they do not want the intrusion. They may resent the time and attention that the monitor requires—time that

could otherwise be spent providing nursing care. Some women may find that the equipment, wires, and sounds increase their anxiety. The discomfort of lying in one position and fear of injury to the baby are other objections.

Diagnosis

In the first stage of labor, appropriate nursing diagnoses may include the following:

- *Fear* related to discomfort of labor and unknown labor outcome
- *Anxiety* related to discomfort of labor and unknown labor outcome
- *Pain, Acute*, related to uterine contractions, cervical dilation, and fetal descent
- *Childbearing Process, Readiness for Enhanced*, related to the normal labor process and comfort measures.

(NANDA-I © 2014)

In the second and third stages of labor, appropriate nursing diagnoses may include the following:

- *Pain, Acute*, related to uterine contractions, the birth process, and/or perineal trauma from birth
- *Childbearing Process, Readiness for Enhanced*, related to pushing methods to assist in the birth
- *Anxiety* related to the outcome of the birth process.

(NANDA-I © 2014)

In the fourth stage of labor, possible nursing diagnoses include the following:

- *Pain, Acute*, related to perineal trauma
- *Childbearing Process, Readiness for Enhanced*, related to the involution process and self-care needs

- *Family Processes, Readiness for Enhanced*, related to incorporation of the newborn into the family.

(NANDA-I © 2014)

Planning

When a plan of care is devised for the intrapartum period, the nurse can develop a general plan that encompasses the total process, from the beginning of labor through the fourth stage, or a plan can be developed for each stage of labor and birth. It is imperative that the nurse assess the couple's understanding of the labor process and provide brief explanations as labor progresses in accordance with the couple's learning needs. The overriding goal is to provide a safe environment for the mother and fetus. Additional goals for care may include:

- Support the mother and family by offering reassurance and information as needed throughout the labor and birth experience
- Promote maternal coping behaviors
- Provide comfort measures to promote pain relief as needed
- Acknowledge and support the mother's desires and choices throughout labor, whenever possible
- Create an environment that is sensitive and supportive of the biophysical, psychosocial, spiritual, and cultural needs of the mother and her family.

Labor can be both an exciting and anxiety-producing time for the mother and her family. Feelings of ambivalence are relatively common as the laboring mother and her partner or support person experience a variety of assessments, care activities, and technologies. Orienting the mother and her family to what to expect can promote feelings of well-being during the labor and birth process (see Patient Teaching: What to Expect During Labor).

Patient Teaching

What to Expect During Labor

- Provide information on the basic assessment and care activities. Allow time for questions and discussion as the progress of labor permits. Describe aspects of the admission process, including the following:
 - Taking an abbreviated history
 - Physical assessment (maternal vital signs [VS], FHR, contraction status, status of membranes)
 - Assessment of uterine contractions (frequency, duration, intensity)
 - Orientation to surroundings
 - Introductions to other support staff
 - Determination of woman's and any support person's expectations of the nurse.
- Present aspects of ongoing physical care, such as when to expect assessment of maternal VS, FHR, and contractions.
- If the electronic fetal monitor is used, describe how it works and the information it provides. Demonstrate the fetal monitor. Orient the woman to the sights and sounds of the monitor. Explain

what "normal" data will look like and what characteristics are being watched for.

- Note that assessments will increase as the labor progresses, especially during the transition phase (usually the time the woman would like to be left alone), to help keep the mother and baby safe by noting deviations from the normal course.
- Describe the vaginal examination and the information it elicits. Use a cervical dilation chart to illustrate the amount of dilation.
- Review comfort techniques that may be used in labor, and ascertain what the woman thinks will promote comfort. Focus on open discussion.
- Review the childbirth preparation the woman has learned so that you will be able to support her in their use. Ask the woman to demonstrate the techniques she has learned.
- Review comfort and support measures, such as positioning, back rub, touch, distraction techniques, and ambulation.
- If the woman is in early labor, offer her a tour of the birthing area, and explain equipment and routines. Include the woman's partner.

Implementation

The woman in labor and her partner or support person tend to be concerned about arriving at the birth center in time for the birth. Sometimes, the labor is advanced and birth is imminent, but usually the woman is in early labor at admission. If time permits and the family is not familiar with what will occur during labor, the nurse can provide necessary information (see the Patient Teaching feature).

Integrate Cultural Beliefs

Knowledge of values, customs, and practices of various cultures is as important during labor as it is in the prenatal period. Without this knowledge, a nurse is less likely to understand a family's behavior and may attempt to impose his or her personal values and beliefs on the woman and her family. As cultural sensitivity and competence increase, so does the likelihood of providing satisfying, high-quality care (Spector, 2017). In providing culturally appropriate care, it is important to familiarize yourself with cultural beliefs from various cultures, but also important to avoid making generalizations based on a patient's perceived ethnicity, culture, or identity (Ingraham, Wingo, Foster, & Roberts, 2017). The nurse must always remain aware that an individual example of a birthing practice will never be pertinent to all women in a given group.

MODESTY Modesty is an important consideration for most women regardless of culture. Many women from a variety of backgrounds find it uncomfortable to be physically examined, so respecting the need for privacy with draping, asking the woman if she would like family members to leave the room, or making other accommodations as needed should be done whenever possible. Some women may be uncomfortable when men are present; others may be uncomfortable with exposure regardless of the gender of the healthcare providers. It is prudent to assume that embarrassment will occur with exposure and take measures to provide privacy rather than to assume that it will not matter to the woman if she is exposed.

When a woman identifies a cultural or religious preference, it is important to ask questions to gain a specific understanding of what that means to her and how she sees it impacting her care needs. For example, according to the Orthodox Jewish law of *Tznuut*, women should maintain modesty in order to preserve dignity. For some women, this may be accomplished by providing a long sleeve gown that covers her elbows and knees, whereas other Orthodox Jewish women may voice no preferences. It is important that the nurse balances knowledge of cultural and religious beliefs with verbal or behavioral cues that support a woman's preferences. For example, offering to pull the curtain while a woman changes into her patient gown shows understanding that some women prefer not to change in front of their husbands. For those who do not adhere to this belief, it provides an opportunity for the woman to verbally decline, thus providing cues on her own belief and preferences (Neis, 2017).

EXPRESSION AND MEANING OF PAIN The manner in which a woman chooses to deal with the discomfort of labor varies widely. Some women seem to turn inward and remain very quiet or cease conversation completely. Others may be

very vocal, with behaviors such as counting out loud, moaning, crying, or shouting. They may also turn from side to side or change positions frequently, often appearing restless. While some cultural influences impact the labor process, women react to labor based on a variety of factors, with culture being only a single variable; therefore, generalizations should not be used to anticipate a woman's responses.

For example, while silence may be culturally more common in some Chinese societies, it does not mean that all Chinese women will desire to labor quietly.

Different cultures also have differing beliefs about the meaning and value of labor pain. Some Latina women view pain during labor as a symbol of love toward the baby—the more intense the pain, the more intense the love. As in all cultures, beliefs that were strongly held by one generation may change over time. In the past, many Native American women viewed labor pain as natural and many used meditation, self-control, or indigenous plants or herbs, such as black cohosh, throughout their labor to aid them during birth (Spector, 2017). While some Native women may still adhere to these practices, others may no longer adhere to these beliefs and may want more modern approaches used to control pain. Labor and delivery nurses can provide culturally competent care by becoming acquainted with the beliefs and practices of the various subcultures while assessing each woman for her own unique preferences within a cultural context. In the birthing situation, the truly effective nurse supports the family's cultural practices as long as it is safe to do so.

It is important to explore each patient's desires for her labor and to inquire how she would like to manage her pain. This is important because adverse birth events increase the risk for postpartum mood disorders and can even create trauma, which can cause psychological issues that persist for future pregnancies (DeGroot & Vik, 2017).

Provide Nursing Care on Admission

The manner in which the maternity nurse greets the laboring woman and her partner influences the course of the woman's hospital stay. The arrival at the healthcare setting and the sometimes impersonal and technical aspects of admission can produce profound stress, fear, and anxiety. If women and their families are greeted in a brusque, harried manner, they are less likely to look to the nurse for support. A calm, pleasant manner indicates to the woman that she is important. It helps to instill in the couple a sense of confidence in the staff's ability to provide quality care during this critical time.

Following the initial greeting, the nurse escorts the woman and support person to the birthing room and provides a quick yet thorough orientation to the facility, including the location of the restrooms, public phones, and nurse-call or emergency-call system. These simple steps can go a long way toward helping the couple feel more at ease. The nurse also explains the monitoring equipment or other unfamiliar technology. Every effort needs to be made to demystify the environment for the laboring woman and her support person. Some women prefer that their partner remain with them during the admission process, although others prefer to have the partner wait outside.

As the nurse helps the woman undress and get into a hospital gown, he or she can start to develop rapport and begin

Focus on Diversity and Culture

Childbirth Customs

Various cultures have different customs and beliefs surrounding childbearing and childbirth. Generalizations regarding cultural perspectives are discussed with examples designed to provide students with ways to integrate cultural customs into specific individualized labor and birth options for women.

Some Hmong women from Laos may prefer to stay active during labor and to squat during the second stage of labor. It is not unusual for the partner to be present and actively involved in providing comfort. Some laboring women may prefer only “hot” foods and warm water to drink (Spector, 2017). For some Hmong women, the family may request that the mother be given a soft-boiled egg to restore her energy as soon as birth occurs. The nurse may ask the woman about her own cultural beliefs and obtain specific requests for labor positioning, ambulation in labor, who she would like to provide labor support, preferred birth positions, temperature of oral fluids preferred, and advise her that a regular diet with her own food preferences can begin immediately following a vaginal birth.

Some Vietnamese women may show a strong sense of self-control throughout labor. They may prefer to walk during labor and to give birth in a squatting position. Like many people from other Asian cultures, some may view labor as a “hot condition” and prefer cold beverages; however, during the postpartum period, which is viewed as a “cold” condition, they may prefer warm liquids (Kim, 2017). In some cultures, newborn praise can be perceived negatively, sometimes being referred to as is the “evil eye” which is associated with jealousy (Lloreda-Garcia, 2017).

Some Latina women desire to have their partners present during labor and birth to show their love and to speak using affectionate words. Many Latina women also typically want their mothers present during the birth process (Attanasio, Hardeman, Kozhimannil, & Kjerulff, 2017). Again, knowledge of traditional cultural norms can

help the nurse effectively coordinate care for the woman and her family. Cultural norms should guide, not dictate, the assessment process.

Some Muslim women may have their husband present, whereas others may desire a female friend or relative with them during childbirth. Because modesty is of great concern for many Muslim women, care must be taken to cover the woman as much as possible (Spector, 2017). Some women may want to put their *khimar* (head covering) on before a male enters the room. For some Muslim families, it may be important for a female nurse, physician, or CNM to perform examinations when possible. For women who express a preference for female care providers, it is important to discuss the possibility that a female provider may not always be present and that if a male is required, every effort to provide privacy and advanced notice will be given (Davidson, Ladewig, London, 2017). For some Muslim patients, traditions such as calling praise to Allah (*adhan*) into the newborn’s right ear may be requested (Spector, 2017).

Different religious practices are observed throughout the world. Some Orthodox Jewish women observe the law of *niddah*, which begins with the onset of regular uterine contractions or the appearance of bloody show or membrane rupture. Once this occurs, the *niddah* law mandates a physical separation of husband and wife (Neis, 2017). The nurse should inquire about specific observations so the best support and encouragement for the mother can be provided. If couples describe the preference for limited physical contact, the nurse will need to assist the woman and serve as the primary caretaker. Sometimes, the laboring woman’s mother or another female friend or relative may be present (Neis, 2017). During this time period, the father may read prayers, choose not to observe the birth, and wait to reenter the room until after the woman has completed the third stage of labor and has been assisted in resuming a comfortable position in bed.

the assessment process. The experienced labor and birth nurse can obtain essential information about the woman and her pregnancy, initiate any immediate interventions needed, and establish individualized priorities and preferences within a few minutes after admission. Forming realistic objectives for laboring women is a major challenge for nurses, because each woman has different coping mechanisms and support systems.

Laboring women often face a number of unfamiliar procedures that may seem routine for healthcare providers. It is important to remember that all patients have the right to accept or reject care measures. The patient’s informed consent is needed before any procedure that involves touching her body. The admission process, therefore, includes signing an informed consent for treatment and providing information regarding advance directives. Typically, an identification bracelet and an allergy band are attached to the expectant woman’s wrist.

Laboring families have specific expectations of the labor and birth experience, of themselves, of the nurse, and of the physician or CNM. Sometimes, families have unrealistic expectations, which can increase anxiety, create stress, and end in disappointment if expectations are not met. The nurse should encourage all families to discuss their preferences and special requests. Some families may present to the birthing center with a birth plan. Reviewing the plan provides the nurse with the opportunity to explore the family’s wishes. If requests cannot be met, explain the reasons

thoroughly. All members of the healthcare team need to be informed of the family’s requests.

Some families want the nurse present at all times, whereas others desire privacy and want to spend time alone. Couples may want a great deal of support if they have not attended childbirth education classes or if they are anxious. Others may want to enjoy the experience as a couple, with as few outside interruptions as possible. In this case, the nurse informs the couple of the nurse’s availability and of the need to make intermittent assessments.

If indicated, the nurse assists the woman into bed. A side-lying or semi-Fowler position rather than a supine position is most comfortable and prevents supine hypotensive syndrome (vena caval syndrome). After obtaining the essential information from the patient and her records, the nurse begins the intrapartum assessment. Once the assessment is complete, the nurse can make effective nursing decisions about intrapartum care, including the following:

- Should ambulation, bedrest, or a combination of the two be encouraged?
- Is more frequent or continuous electronic fetal monitoring needed?
- What preferences does the woman have for her labor and birth?
- Is a support person available?
- What special needs do this woman and her partner have?

The nurse auscultates the FHR. The nurse assesses the woman's blood pressure, pulse, respirations, oral temperature, and level of pain or discomfort. The nurse also assesses contraction frequency, duration, and intensity (possibly while gathering other data). Before the vaginal examination, the nurse informs the woman about the procedure and its purpose and obtains her consent; afterward, the nurse conveys the findings.

If signs of advanced labor are observed, a vaginal examination must be done immediately upon admission. If the woman shows signs of excessive bleeding or reports episodes of painless bleeding in the last trimester, refrain from performing a vaginal examination and notify the healthcare provider immediately.

Results of the FHR assessment, uterine contraction evaluation, and vaginal examination help determine whether the rest of the admission process can proceed at a leisurely pace or whether additional interventions are required. For example, an FHR of less than 110 beats/min on auscultation indicates that a fetal monitor should be applied immediately to obtain additional data and that continuous fetal monitoring should be performed. The patient's vital signs can be assessed once the monitor is in place.

SAFETY ALERT If the fetal monitor is no longer recording the fetal heart tracing, check for adequate gel under the transducer and reposition it before assuming there is a problem with the fetus. Maternal and fetal movement are the most common causes of an inability to trace the FHR.

The admission process includes collecting a clean, voided, midstream urine specimen. The woman with intact membranes may collect her specimen in the bathroom. Decisions regarding activity level are generally based on physical findings, clinician orders, the patient's desires, agency policy, and safety concerns.

The nurse may test the woman's urine for the presence of protein, ketones, and glucose by using a dipstick before sending the sample to the laboratory. This procedure is especially important if edema or elevated blood pressure is noted on admission. Proteinuria of +1 or more may be a sign of impending preeclampsia. Glycosuria is frequently found in pregnant women because of the increased glomerular filtration rate in the proximal tubules and the inability of these tubules to increase reabsorption of glucose. It may also be associated with gestational diabetes, however, and should not be discounted. While the woman is collecting the urine specimen, the nurse can gather the equipment for any preparation procedures ordered by the healthcare provider.

Laboratory tests are done during early admission. Hemoglobin and hematocrit values help determine the oxygen-carrying capacity of the circulatory system and the woman's ability to withstand blood loss at birth. Elevation of the hematocrit may indicate hemoconcentration of blood, which occurs with edema or dehydration. A low hemoglobin value, in the absence of other evidence of bleeding, suggests anemia. Blood may be typed and cross-matched if the woman is in a high-risk category. Platelets are evaluated as well, because low platelets can lead to bleeding problems. Low platelets are also a contraindication

for epidural anesthesia. In addition, a type and screen is performed in case an obstetric emergency arises and the woman needs to get blood products. Additional serologic testing may be performed as indicated. Offer HIV testing to all women who have not been previously screened (AIDS.gov, 2015).

Depending on how rapidly labor is progressing, the nurse notifies the healthcare provider before or after completing the admission procedures. The report includes the following information:

- Parity
- Cervical dilation and effacement
- Station
- Presenting part
- Status of the membranes
- Contraction pattern
- FHR
- Vital signs that are not in the normal range
- Any significant prenatal history
- Woman's birth preferences
- Woman's reaction to labor
- Woman's preferences for pain relief.

The nurse also enters an admission note into the computer or the charting system. The admission note should include the reason for admission, the date and time of the woman's arrival and notification of the healthcare provider, the condition of the woman and her baby, and labor and membrane status.

Provide Nursing Care During the First Stage of Labor

The nurse needs to evaluate physical parameters of the woman and her fetus. Maternal temperature is monitored every 2–4 hours unless the temperature is over 37.5°C (99.6°F), in which case it is taken every hour. When the amniotic membranes have ruptured, maternal temperature is assessed every 1–2 hours, depending on the policy of the institution. Blood pressure, pulse, respirations, and response to pain are monitored as indicated or according to unit policy. If the woman's blood pressure is greater than or equal to 140/90 mmHg or her pulse is more than 100 beats/min, the nurse must notify the healthcare provider and reevaluate the blood pressure and pulse more frequently. Monitor the woman's pain level continually, because increased pain can elevate the blood pressure and pulse, especially during contractions.

The nurse palpates uterine contractions for frequency, intensity, and duration every 30 minutes. The nurse also auscultates the FHR every 30 minutes in active labor for low-risk women and every 15 minutes for high-risk women as long as the FHR remains between 110 and 160 beats/min and is reassuring (Miller et al., 2012). Auscultate the FHR throughout one contraction and for approximately 15 seconds after the contraction to ensure there are no decelerations. If the FHR baseline is not in the range of 110–160 beats/min or if decelerations are heard, continuous electronic monitoring is recommended (see Table 33–14).

LATENT PHASE The nurse offers food and fluids as desired unless complications exist that may necessitate general anesthesia. Avoiding both liquids and solids during labor, which was once standard practice, is no longer necessary, because evidence-based practice research and new guidelines indicate that clear fluids can be consumed throughout labor and up to 2 hours before an elective cesarean birth. Recent findings suggest that consumption of clear fluids about 1 hour before cesarean section did not increase the risk of regurgitation or aspiration (Ghorashi et al., 2014). In a low-risk setting, it is not necessary to restrict intake in any way.

ACTIVE PHASE During the active phase, the contractions have a frequency of 2–5 minutes, a duration of 40–60 seconds, and a moderate to strong intensity. As the contractions become more frequent and intense, a woman who has been ambulatory may choose to sit in a chair or lie down. Contractions need to be palpated every 30 minutes.

Vaginal exams may be performed to assess cervical dilation and effacement as well as fetal station and position. Vaginal examinations should be limited, however, because they introduce bacteria, which can lead to maternal infection. During the active phase, the cervix dilates from 6 to 8 cm, and vaginal discharge and bloody show increase; thus, the nurse needs to change the perineal pads more frequently.

The FHR is auscultated and evaluated every 30 minutes for low-risk women and every 15 minutes for high-risk women (Malhotra et al., 2014). Maternal blood pressure, pulse, and respirations are monitored during the FHR assessment or more frequently if indicated. The mother's level of pain and coping mechanisms are assessed continuously.

The woman is encouraged to void because a full bladder can interfere with fetal descent. If she is unable to void, catheterization or insertion of an indwelling Foley catheter may be necessary.

If the amniotic membranes have not ruptured previously, they may do so during this phase. When the membranes rupture, the nurse notes the amount, color, odor, and consistency of the amniotic fluid and the time of rupture and immediately auscultates the FHR. The fluid should be clear, with no odor. Nonreassuring fetal status may lead to intestinal and anal sphincter relaxation. This may result in the release of meconium into the amniotic fluid, which turns the fluid greenish brown. When the nurse notes meconium-stained fluid, an electronic monitor is applied to assess the FHR continuously. Current management of membrane rupture without labor varies. Providers may opt to deliver the fetus within 24–48 hours, or allow the pregnancy to continue while administering antibiotics to the mother, or allow the pregnancy to continue with no intervention other than monitoring unless the mother develops signs of infection. In this case, the Group B streptococcus status is evaluated, and intrapartum antibiotics are administered as indicated. Labor induction may be initiated on a case-by-case basis (ACOG, 2016b).

SAFETY ALERT The highest-priority assessment following rupture of membranes is to check the fetal heart rate. As amniotic fluid is evacuated, the umbilical cord may become trapped between the fetal head and the maternal pelvis. The pressure on the umbilical cord slows or completely stops all blood flow to the fetus, which will be evidenced by a drop in FHR and ultimate fetal demise if not properly managed.

An additional potential issue during this phase is prolapse of the umbilical cord, which may occur when membranes rupture and the fetal presenting part is not well applied to the cervix. The concern is that the amniotic fluid coming through the cervix will propel the umbilical cord through the cervix (prolapsed cord). The FHR is auscultated because a drop in FHR might indicate an undetected prolapsed cord. Immediate intervention is necessary to remove pressure on a prolapsed umbilical cord.

» Visit **Pearson MyLab Nursing and eText** for Chart 8: *Deviations from Normal Labor Process Requiring Immediate Intervention*.

TRANSITION PHASE During transition, the contraction frequency may be every 1.5–2 minutes, duration is 60–90 seconds, and intensity is strong. Cervical dilation increases from 8 to 10 cm, effacement is complete (100%), and a heavy amount of bloody show is usually present. Contractions are palpated at least every 30 minutes. Sterile vaginal examinations may be done more frequently because this stage of labor usually is accompanied by rapid change. The FHR is auscultated every 30 minutes for low-risk women and every 15 minutes for high-risk women; maternal blood pressure, pulse, and respirations are monitored when the FHR is assessed or according to unit policy. Note that women may receive more frequent assessments based on individualized needs. The woman's pain level is monitored continuously.

Comfort measures become very important in this phase of labor, but continual assessment is required to ensure appropriate intervention. Women may also shake uncontrollably, feel nausea, or vomit during this stage. The woman may rapidly change from wanting a back rub and other hands-on care to wanting to be left completely alone. The support person and the nurse need to follow the woman's cues and change interventions as needed. Because the woman is breathing more rapidly, the nurse can increase the woman's comfort by offering small spoons of ice chips to moisten her mouth or applying an emollient to dry lips. The nurse can encourage the woman to rest between contractions. If analgesics have been administered, a quiet environment enhances the quality of rest between contractions.

Some women have difficulty coping during this time and need help with their breathing. Either the support person or the nurse can breathe along with the woman during each contraction to help her maintain her pattern. A gentle reminder to “slow down your breathing” can help to prevent hyperventilation. It is helpful to encourage the woman and to assure her that she is doing a good job. The woman will begin to feel increased rectal pressure as the fetal presenting part moves down the birth canal. The nurse encourages the woman to refrain from pushing until the cervix is completely dilated. To help the woman avoid involuntary

pushing during contractions, the nurse can encourage pant-blow breathing, suggesting that the woman “pant like a puppy” or “blow in short breaths as if you were blowing out a candle.” This measure helps prevent cervical edema.

The end of the transition phase and the beginning of the second stage may be indicated by a change in the woman’s voice or the sounds that she is making. As the fetus moves down and the woman feels increased pressure and a bearing-down sensation, her voice tends to deepen. If she moans during a contraction, it takes on a more guttural quality. Experienced nurses recognize this sound as a sign of changes in the woman.

PROMOTION OF COMFORT The nurse identifies factors that may contribute to discomfort for the laboring woman. These factors include uncomfortable positions or infrequent position changes, diaphoresis, continual leaking of amniotic fluid, a full bladder, a dry mouth, anxiety, and fear. The nurse and patient together plan interventions to minimize the effects of these factors.

Women in labor have many types of responses to pain. As the intensity of the contractions increases with the progress of labor, the woman becomes less aware of the environment and may have difficulty hearing and understanding verbal instructions. Some women may become irritable during this time. The pattern of coping with labor contractions varies from the use of highly structured breathing techniques to turning inward. As stated previously, the woman’s responses to pain may have a cultural basis. Low moaning that begins deep in the throat, rocking or swaying, counting, facial grimacing, and using loud vocalizations are all effective means of dealing with the discomfort of labor and birth. Some women feel that making sounds helps them cope and do the work of labor, whereas others make loud sounds only as they lose their perception of control.

The most frequent physiologic manifestations of pain are increased pulse and respiratory rates, dilated pupils, increased blood pressure, and muscle tension. During labor, these reactions are transitory because the pain is intermittent. Increased muscle tension is most significant because it may impede the labor process. Women in labor frequently tighten skeletal muscles voluntarily during a contraction and remain motionless. This method of dealing with the contractions may actually increase her discomfort, but the woman may believe it is the only acceptable way to cope with the pain.

A woman generally wants touching, massage, and other forms of physical contact during the first part of labor, but when she moves into the transition phase, she may pull away. Alternatively, the woman may beseech her partner or the nurse to hold her hand or rub her back, or she may even reach out and grasp the support person. Some women are uncomfortable with being touched at all, regardless of the phase of labor; others do not welcome touch from a nonfamily member. It is important to validate the unique strengths and coping techniques of the individual and to meet each family on their own terms, always keeping in mind that this is their experience. Cultural influences can also affect how a woman will react to support and touch in labor. The nurse

takes cues from the woman and makes adjustments in her care to meet the patient’s specific needs.

- **General comfort.** General comfort measures are of great importance during labor. By relieving minor discomforts, the nurse helps the woman optimize her coping abilities to deal with pain. The woman is encouraged to ambulate as long as there are no contraindications, such as vaginal bleeding or rupture of membranes before the fetus is engaged in the pelvis. Ambulation can increase comfort and aid in fetal descent. Even if the woman prefers not to walk around, upright positions, such as sitting in a rocker or leaning against a wall or bed, can enhance comfort. If the woman stays in bed, the nurse can encourage her to assume positions that she finds comfortable.

If the woman is more comfortable on her back, the nurse should elevate the head of the bed to relieve the pressure of the uterus on the vena cava. Pillows may be placed under each arm and under the knees to provide support. Because a pregnant woman is at increased risk for thrombophlebitis, it is important to avoid excessive pressure behind the knee and calf. The nurse needs to assess pressure points often. Frequent changes of position contribute to comfort and relaxation. The hands-and-knees posture may be used to relieve persistent back pain during labor.

Wearing socks or slippers may alleviate cold feet, and adjusting the room’s thermostat can offset excessive warmth. Attention to such details allows the woman to focus on the more important issues of giving birth. The woman may be offered a warmed or cooled facial cloth, which is placed on her forehead or across or behind her neck. Providing a toothbrush and toothpaste for oral care can also increase comfort.

Diaphoresis and the constant leaking of amniotic fluid can dampen the woman’s gown and bed linen. Offering fresh, smooth, dry bed linen promotes comfort. To avoid having to change the bottom sheet following rupture of the membranes, the nurse may replace absorbent underpads at frequent intervals (following standard precautions). To promote comfort and prevent infection, keep the perineal area as clean and dry as possible. A full bladder adds to discomfort during a contraction and may prolong labor by interfering with the descent of the fetus. The bladder should be kept as empty as possible. Even if the woman is voiding, urine may be retained because of the pressure from the fetal presenting part. The nurse can detect a full bladder by palpating directly over the symphysis pubis. Encourage the woman to empty her bladder every 1–2 hours. Some of the regional procedures for analgesia and anesthesia during labor contribute to the inability to void, and catheterization may be necessary.

The support person and any family members in attendance also need to be encouraged to maintain their own comfort. Because their attention is directed toward the laboring woman, they may forget their own needs. The nurse may have to encourage them to take breaks, to maintain food and fluid intake, and to rest. Many support persons and family members are reluctant to leave the woman unattended while they meet their own personal

needs. Offer to stay with the woman during their absence. This provides reassurance to the support person or family member that the woman will be well cared for in his or her absence.

- **Handling anxiety.** The anxiety experienced by women beginning labor is related to a combination of factors inherent to the process. A moderate amount of anxiety about pain enhances the woman's ability to deal with it. However, an excessive degree of anxiety decreases her ability to cope with the pain. Women in the latent phase of labor who are experiencing increased levels of anxiety about their ability to cope and their own personal safety are much more likely to describe their pain as unbearable. Women at risk for greater anxiety during labor include those who are young, poor, and lacking in social support. Women with preexisting mental illness, such as depression and anxiety, are at a greater risk for developing post-traumatic stress disorder related to their labor and birth experience (Modarres et al., 2012). Women with mental illness issues may need additional support to assist them with identifying effective coping mechanisms during the labor and birth process.

Ways to decrease anxiety not related to pain are to give information, which eases fear of the unknown; to establish rapport with the couple, which helps them preserve their personal integrity; and to express confidence in the couple's ability to work with the labor process. In addition to being a good listener, the nurse must demonstrate genuine concern for the laboring woman. Remaining with the woman as much as possible conveys a caring attitude and dispels fears of abandonment. Praise for breathing, relaxation, and pushing efforts not only encourages repetition of the behavior but also decreases anxiety about the ability to cope with labor.

- **Patient teaching.** Providing truthful information about the nature of the discomfort that will occur during labor is important. Stressing the intermittent nature and maximum duration of the contractions can be helpful. The woman can cope with pain better when she knows that a period of relief will follow. Describing the type of discomfort and specific sensations that will occur as labor progresses helps the woman recognize these sensations as normal and expected when she does experience them.

Advise the woman that although the strength and intensity of contractions are different for each woman, they may feel like a tightening sensation or a menstrual cramp initially. Over time, as the labor progresses, the contractions become more intense and more uncomfortable, with the uterus tightening and becoming very hard and with the pain radiating from the back around to the front. For some women, the pain takes their breath away, or they may feel anxiety and fear. As the contractions become more painful, they also occur closer together. The sensation of having to push occurs as the head progresses into the pelvis and feels like the woman has to have a bowel movement. Once the contraction goes away, this intense feeling of having to have a bowel movement usually lets up somewhat.

Descriptions of sensations are best accompanied by information on specific comfort measures. As previously

noted, some women experience the urge to push during the transition phase, when the cervix is not fully dilated and effaced. This sensation can be controlled by pant-blow breathing (it is difficult to pant or blow and bear down at the same time); the nurse should provide instructions about this technique before it is required.

Thorough orientation and explanation of surroundings, procedures, and equipment being used also decrease anxiety, thereby reducing pain. Attachment to an electronic monitor may produce fear because the woman may associate equipment of this type with people who are critically ill. It may also limit the woman's ability to move about and comfort herself with position changes and ambulation. If continuous electronic fetal monitoring is needed, the nurse can explain the beeps, clicks, and other strange noises and give a simplified explanation of the monitor strip. The nurse emphasizes that use of the fetal monitor provides a way to assess the well-being of the fetus during the course of labor. If available, a less intrusive telemetry monitor may be applied so that the woman has more freedom to move about. In addition, the nurse can show the woman and her partner or support person how the monitor can help them identify the beginnings of contractions. The nurse should encourage the woman to begin her breathing technique at the onset of each contraction; this may help lessen her perception of pain.

Labor and childbirth may be a critical time for the woman with a history of childhood physical, emotional, and/or sexual abuse or rape. To develop a competent plan of care, all laboring women should be evaluated on admission for a history of childhood abuse or rape. Depending on their cultural background, women may need specific examples of abuse to determine whether they have had these types of experiences, because some behaviors that are considered to be abusive in our society may be thought of as normal patterns of behavior in other cultures. Women may or may not be able to address this issue with the nurse because sharing such personal information is difficult and may stir up painful memories. It is therefore especially important for the nurse to be alert for nonverbal cues, such as excessive unexplained anxiety, unrelenting pain, and/or intense fear during vaginal exams, and to be prepared to offer additional teaching to help offset the woman's anxiety.

- **Supportive relaxation techniques.** Tense muscles increase resistance to the descent of the fetus and contribute to maternal fatigue. This fatigue increases pain perception and decreases the woman's ability to cope with the pain. Comfort measures, massage, techniques for decreasing anxiety, and patient teaching can contribute to relaxation. Adequate sleep and rest are also important. The laboring woman needs to be encouraged to use the period between contractions for rest and relaxation. A prolonged prodromal phase of labor (also known as false labor or Braxton Hicks contractions) may interfere with sleep. An aura of excitement naturally accompanies the onset of labor, making it difficult for the woman to sleep even though the contractions are mild and infrequent. The nurse may have to act as an advocate for the woman to limit the number of visitors, interruptions, and phone calls.

Distraction is another method of increasing relaxation and coping with discomfort. During early labor, conversation or activities such as watching television, light reading, or playing cards or other games can serve as distractions. One technique that is effective for relieving moderate pain is to have the woman concentrate on a pleasant experience she has had in the past. Other techniques include the use of a specific visual or mental focal point (e.g., a picture of a loved one), breathing techniques, counting or humming, or visualization.

Touch is another type of distraction. Although some women regard touching as an invasion of privacy or a threat to their independence, many want to touch and be touched during a painful experience. To determine whether the woman desires touch, the nurse can place a hand on the side of the bed within the woman's reach. The woman who needs touch will reach out for contact, and the nurse can follow through with this behavioral cue.

Back pain associated with labor may be relieved by firm pressure on the lower back or sacral area. To apply firm pressure, the nurse can place his or her hand or a rolled, warmed towel or blanket in the small of the woman's back or can instruct the woman's support person to do so.

In some instances, analgesics or regional anesthetic blocks may be used to enhance comfort and relaxation during labor. The nurse may also enhance the woman's relaxation by providing encouragement and support for her controlled breathing techniques.

- **Breathing techniques.** Breathing techniques may help the laboring woman. Used correctly, they raise the woman's pain threshold, permit relaxation, enhance her ability to cope with contractions, provide a sense of control, and allow the uterus to function more efficiently.

Various types of breathing techniques can be used in labor. Many women learn patterned-paced breathing during prenatal education classes. This type of controlled breathing often has three levels. The woman tends to begin with the first level and then proceed to the next when she feels the need. Regardless of the level of breathing used, a cleansing breath (involving only the chest) begins and ends each pattern. The cleansing breath consists of inhaling slowly through the nose until a sense of fullness in the lungs occurs, and then exhaling slowly through pursed lips. The first pattern may also be called slow, deep breathing or slow-paced breathing. During the breathing movements, only the chest moves. The woman inhales slowly through her nose, moves her chest up and out during the inhalation, and exhales through pursed lips. The breathing rate is 6–9 breaths per minute.

The second pattern may be called shallow or modified-paced breathing. The woman begins with a cleansing breath. At the end of the cleansing breath, she pushes out a short breath. She then inhales and exhales through the mouth at a rate of about four breaths every 5 seconds. This pattern can be altered into a more rapid rate that does not exceed 2–2.5 breaths every second.

The third pattern, introduced earlier, is called pant-blow or patterned-paced breathing. It is similar to modified-paced breathing except that the breathing is punctuated

every few breaths by a forceful exhalation through pursed lips. A pattern of four breaths may be used to begin. All breaths are kept equal and rhythmic. As the contraction becomes more intense, the woman may adjust the pattern as needed to 3:1, 2:1, and finally 1:1.

Abdominal breathing is another technique that can be effective in labor. In abdominal breathing, the woman moves the abdominal wall outward as she inhales and inward as she exhales. This method tends to lift the abdominal wall off the contracting uterus and thus helps to provide pain relief. The breathing is deep and rhythmic and typically relaxing. As transition approaches, the woman using abdominal breathing may feel the urge to breathe more rapidly. The pant-blow pattern discussed earlier can be suggested to slow the breathing and help the woman avoid the urge to bear down.

- **Hyperventilation.** Hyperventilation is the result of an imbalance of oxygen and carbon dioxide (i.e., too much carbon dioxide is exhaled, and too much oxygen remains in the body). Hyperventilation may occur when a woman breathes very rapidly over a prolonged period. The signs and symptoms of hyperventilation are tingling or numbness in the tip of the nose, lips, fingers, or toes; dizziness; spots before the eyes; or spasms of the hands or feet (carpopedal spasms). If hyperventilation occurs, the nurse encourages the woman to slow her breathing rate and take shallow breaths. With instruction and encouragement, many women are able to change their breathing to correct the problem. Encouraging the woman to relax and counting out loud for her so that she can pace her breathing during contractions are also helpful actions. If the signs and symptoms continue or become more severe, the woman is treated for hyperventilation as appropriate. The nurse remains with the woman to reassure her, because hyperventilation can increase anxiety levels.

ROLE OF THE DOULA Throughout the first stage of labor, the nurse assesses and supports the interaction between the woman and her partner. In the absence of a partner, or when the partner desires a less active role, it is becoming more common for women to employ a paid caregiver who has experience in caring for laboring women. This caregiver, often called a **doula**, has typically received special training and may even be certified. The doula's role is to enhance the laboring woman's comfort and decrease her anxiety. A doula can be a valuable advocate for the laboring woman and her family as well as an asset to the labor nurse. For example, the doula might support the woman by helping identify the beginning of each contraction and encouraging her as she breathes through it. A constant presence offering continued encouragement and support with each contraction throughout labor has immeasurable benefits.

Provide Nursing Care During the Second Stage of Labor

The second stage is reached when the cervix is completely dilated (10 cm [3.9 in.]). The uterine contractions continue as in the transition phase. Maternal pulse, blood pressure, and FHR are assessed every 5 minutes; some protocols recommend

assessment after each contraction (Anderson & Stone, 2013). Once the second stage is reached, the nurse remains with the woman continually and generally does not leave the room. Nursing care during the second stage focuses on providing care, promoting comfort, and assisting during the birth.

As the woman pushes during the second stage, she may make a variety of sounds. A low-pitched, grunting sound (“uhhh”) usually indicates that the woman is working with the pushing. The nurse who feels comfortable with maternal sounds and stays sensitive to changes in the sounds may be able to detect if the woman is losing her ability to cope. For instance, if the woman feels afraid of the sensations produced by her pushing effort, her sound may change to a high-pitched cry or whimper.

It is not uncommon for the woman to be afraid to push. In these situations, the woman may talk or cry out during the contraction instead of actively pushing. During this time, the nurse provides support, reassurance, and clear directions for the woman to follow. Often, it is helpful to direct the woman to concentrate on a single voice, listen for suggestions, and let her body do the work. Many women find this type of interaction comforting because it allows them to focus on one individual.

When teaching the effective technique for pushing, instruct the woman to bear down and push into her bottom as if she is having a bowel movement. Watch the woman’s perineum and rectum while she is pushing, and give verbal praise and encouragement when change in the perineum or rectum is seen, indicating she is successfully pushing.

During the second stage, the woman may feel intense rectal pressure. The instinctive response is to resist and to tighten muscles rather than bear down (push). A sensation of “splitting apart” or burning also occurs in the latter part of the second stage when the woman is pushing. The woman who expects these sensations and who understands that bearing down contributes to progress at this stage is more likely to do so.

When the urge to bear down becomes uncontrollable and pushing begins, the nurse can help by encouraging the woman and by supporting her efforts. Most women push spontaneously and effectively in response to messages from their body. This more natural approach, which lets the mother wait to bear down until she feels an urge to push, may shorten the pushing phase, thereby reducing the incidence of physiologic stress in the mother and acidosis in the newborn. This technique also decreases the incidence of instrument births and damage to maternal perineal tissue (Ara et al., 2015). In some settings, however, sustained, forceful pushing may be useful. In that case, when the contraction begins, the nurse tells the woman to take a cleansing breath or two, then to take a third large breath and hold it while pushing down with her abdominal muscles (called the Valsalva maneuver).

A nullipara is usually prepared for birth when perineal bulging is noted. A multipara usually progresses much more. As the birth approaches, the woman’s partner or support person also prepares.

The nurse monitors the woman’s blood pressure and the FHR between contractions, and the nurse assesses the contractions at least every 5 minutes until the birth. The nurse continually assesses the woman’s level of pain or her ability

to cope with the discomfort of labor. The nurse continues to assist the woman in her pushing efforts to keep both the woman and the support person informed of procedures and progress and to support them both throughout the birth.

PROMOTION OF COMFORT Most of the comfort measures that were used during the first stage remain appropriate during the second stage. Applying cool cloths to the face and forehead may help to cool the woman involved in the intense physical exertion of pushing. The woman may feel hot and want to remove some of her clothing or bed linens. Care still needs to be taken to provide privacy even though covers are removed. The nurse encourages the woman to rest and relax all muscles during the periods between contractions. The nurse and support person can assist the woman into a pushing position with each contraction to further conserve energy. Between contractions, the woman should be assisted into a comfortable position. Sips of fluids or ice chips may be used to provide moisture and relieve dryness of the mouth. Positive reinforcement and encouragement should be continually provided.

For some women, but especially those with epidural anesthesia, the urge to push may not occur spontaneously. The question then becomes whether to encourage passive descent of the fetus versus active pushing (see Evidence-Based Practice: Passive Descent Versus Active Pushing in Women with Epidural Anesthesia).

ASSISTING DURING BIRTH In addition to assisting the woman and her partner, the nurse assists the healthcare provider in preparing for the birth. The provider dons a sterile gown and gloves and may place sterile drapes over the woman’s abdomen and legs. An episiotomy may be performed just before the actual birth.

Shortly before the birth, the birthing room or delivery room is prepared with the equipment and materials that may be needed. These materials typically come in a prepackaged kit and contain the instruments and disposable drapes, gowns, and containers that will be used during the birth. The nurse ensures that all supplies and a pair of sterile gloves are placed on the instrument table. This table can be prepared before the birth and covered with a sterile drape. If the birth is to occur in a birthing room, family members do not need to change into other clothing; if the birth is to occur in a delivery room or surgery suite, they don a disposable scrub suit or scrubs provided by the facility. Thorough hand hygiene is required of the nurses and physician or CNM. Nurses who will be in direct contact with the mother at the time of birth need to wear protective clothing, such as an apron or gown with a splash apron, disposable gloves, and eye covering. The physician or CNM also needs to wear a plastic apron or a gown with a splash apron, eye covering, and sterile gloves.

SAFETY ALERT Some physicians and CNMs routinely use other equipment or supplies during the birth. Examples of such equipment include mineral oil, warm water, and clean washcloths for perineal massage. Gathering these supplies early can save time and enable the nurse to stay with the woman during pushing.

If for any reason the laboring woman is to give birth in a location other than the birthing room (e.g., in the case of a

Evidence-Based Practice

Passive Descent Versus Active Pushing in Women with Epidural Anesthesia

Problem

Which method of pushing—passive descent or active pushing as soon as full cervical dilation is achieved—provides the most benefit for mothers with epidural anesthesia?

Epidural analgesia is a common method of pain management during active labor, but one of its side effects is a decrease in a woman's lower body sensations. This may inhibit the natural urge to push upon full cervical dilation. Women have traditionally been directed to push immediately once cervical dilation reaches 10 cm, whether they felt the urge to push or not. The chief concern leading to this practice was that an extended second stage of labor was deleterious for both mother and baby, leading to acidosis, maternal exhaustion, and neonatal morbidity.

The natural second stage of labor includes a period of time in which the fetus descends, which the literature refers to as "passive descent." Passive descent allows the woman to delay pushing until she feels the urge to push or until the head is visible.

Evidence

Evidence to support the delay of bearing down for women without the urge to push has existed for decades. Immediate pushing does not reduce the incidence of acidosis or shorten the second stage of labor. Indeed, prolonged active pushing has been shown to increase the incidence of fetal and maternal acidosis, increase the

risk of having an instrument-assisted birth, and decrease the chance a woman would have a spontaneous vaginal birth. Immediate pushing often lengthens the second stage of labor as compared to allowing the fetus to descend via the primary power of uterine contractions (Osborne & Hanson, 2014).

Furthermore, passive descent has additional benefits in that it allows for further fetal descent and rotation, better situating the fetus in the woman's pelvis. It also causes further release of oxytocin that augments the progress of labor.

Implications

These findings suggest that the duration of active pushing should be limited, not the duration of the second stage of labor.

Critical Thinking Application

1. How can the nurse help the mother recognize the urge to push at an effective time when epidural analgesia is in place?
2. How does a rest period during pushing influence perinatal outcomes?
3. What risk factors are associated with active pushing during the second stage of labor?
4. What are the evidence-based nursing interventions related to the second stage of labor?

forceps-assisted birth where a quick transition to cesarean delivery may be necessary), she is moved on her bed or a cart shortly before birth. It is important that the woman move from one bed to another between contractions. During the contraction, the woman feels increased discomfort and may be involved in pushing efforts. Perineal bulging may be occurring, which adds to the discomfort and difficulty in moving. Take care to preserve her privacy during the transfer, and provide safety by raising the side rails. The bed itself should be placed in a locked position. The labor bed or transfer cart must be carefully braced against the delivery table to ensure the woman's safety during the transfer.

Even though the operating room setting is different from that of a birthing room, the family can still be together during the birth. It is important for nurses to provide encouragement for family members to participate, because the delivery room environment may be unfamiliar and seem intimidating. The family member may hesitate to continue providing support because of fear of interfering or being in the way. The nurse provides clear, simple directions that help the support person participate throughout the birth process. The nurse can ensure the support person is sitting as close as possible to the woman. The nurse can also encourage hand holding and touching or stroking of the woman's face.

- **Maternal birthing positions.** The upright posture for birth was considered to be normal in most societies until modern times. Women variously selected squatting, kneeling, standing, and sitting positions for birth. During the mid-20th century, the recumbent position (lithotomy

position) became common in North American hospitals because of the convenience it offered when applying new technology. In recent years, however, consumers and healthcare professionals have begun searching for alternative positions, refocusing on the comfort of the laboring woman rather than on the convenience of the physician or CNM.

» See *Pearson MyLab Nursing and eText* for Chart 9: Comparison of Birthing Positions.

Evidence-based practice research has shown that the squatting position results in fewer instrumental deliveries, fewer episiotomy extensions, and fewer perineal tears compared to the lithotomy position (Ara et al., 2015). An upright position, which has been found to be the most effective birthing position, is possible even for women who have epidural anesthesia.

The woman may be positioned for birth on a bed with use of leg supports in a squatting position, or perhaps on her hands and knees. If a birthing bed is used, the back is elevated 30–60 degrees to help the woman bear down. Stirrups, if needed and used, are padded to alleviate pressure. If the nurse is assisting the woman to place her legs in the stirrups, both the woman's legs should be lifted simultaneously to avoid strain on the abdominal, back, and perineal muscles. Stirrups are sometimes needed if the woman is unable to control her legs following epidural anesthesia, if forceps or a vacuum extractor is being used, or if a difficult birth is anticipated. The nurse should adjust the stirrups to fit the woman's legs. The feet are supported in the stirrup holders. The height and angle of the stirrups are adjusted so there is no pressure on the back

of the knees or the calves, which might cause discomfort and postpartum vascular problems. Some practitioners may opt to leave the bed assembled and, instead, lower the foot of the bed into a lower position. Many times, women are more comfortable in this position. When stirrups are not used for the birth, the woman's legs may be placed in stirrups after the birth if a repair of the perineum is needed.

- **Cleansing the perineum.** After the mother has been positioned for the birth, her vulvar and perineal area are cleansed to increase her comfort, to remove the bloody discharge that is present before the actual birth, and to prevent infection. Perineal cleansing methods range from use of warm, soapy water to aseptic technique depending on the agency protocol or on physician or CNM orders. Once the cleansing has been completed, the woman returns to the desired birthing position.
- **Supporting the couple.** Both the woman's partner or support person and the nurse who has been with the woman during the labor continue to provide support during contractions. They encourage the woman to push with each contraction, and as the fetal head emerges, ask her to take shallow breaths or to pant to prevent pushing. The physician or CNM may instruct the woman to "push and breathe, push and breathe" in an effort to ease the fetal head out to prevent perineal trauma and tearing. While supporting the head, the physician or CNM assesses whether the umbilical cord is around the fetal neck and removes it if it is, then suctions the mouth and nose with a bulb syringe if there are any obvious obstructions to spontaneous breathing. The mouth is suctioned first to prevent reflex inhalation of mucus when the sensitive nares are touched with the bulb syringe tip. The woman is encouraged to push again as the rest of the newborn's body is born.

Provide Nursing Care During the Third Stage of Labor

Nursing care during the third stage of labor focuses on initial care of the newborn, enhancing attachment, assisting with delivery of the placenta, and providing care for the mother. Newborn care is discussed in Exemplar 33.D; this section discusses maternal care.

DELIVERY OF THE PLACENTA After birth, the healthcare provider prepares for the delivery of the placenta. The following signs suggest placental separation:

- The uterus rises upward in the abdomen.
- As the placenta moves downward, the umbilical cord lengthens.
- A sudden trickle or spurt of blood appears.
- The shape of the uterus changes from a disk to a globe.

While waiting for these signs, the nurse palpates the uterus to check for boggy (soft or mushy feeling) and fullness caused by uterine relaxation and subsequent bleeding into the uterine cavity. After the placenta has separated, the woman may be asked to bear down to aid delivery of the placenta.

Oxytocics are frequently given at the time of the delivery of the placenta so that the uterus will contract and bleeding will be minimized. Oxytocin (Pitocin), 20 units, may be added to an intravenous infusion, or 10 units may be given intramuscularly. In the presence of hemorrhage caused by uterine atony, some healthcare providers may order up to 40 units of oxytocin in a liter of intravenous fluid; methylergonovine maleate (Methergine), 0.2 mg, administered intramuscularly; or carboprost tromethamine (Hemabate), 250 mcg/mL, administered intramuscularly. Cytotec has been commonly used when other pharmacologic interventions have failed. Cytotec is administered rectally in dosages of 800–1000 mcg (Hofmeyr, Gülmezoglu, & Pileggi, 2013). In addition to administering the ordered medications, the nurse assesses and records maternal blood pressure before and after administration of oxytocics and assesses the amount of bleeding.

After delivery of the placenta, the healthcare provider inspects the placenta and membranes to make sure they are intact and that all cotyledons are present. If there is a defect or a part missing from the placenta, a manual uterine examination or uterine exploration is done. The nurse notes on the birth record the time of delivery of the placenta.

Cord Blood Analysis at Birth

When significant abnormal FHR patterns have been noted, meconium-stained amniotic fluid is present, or the newborn is depressed at birth, umbilical cord blood may be analyzed immediately following the birth to determine whether acidosis is present. ACOG (2012a) recommends performing cord blood analyses when the Apgar score is below 7 at 5 minutes of age (normal Apgar score is 7–10) (see Exemplar 33.D for an in-depth discussion of the Apgar scoring system).

The cord is clamped before the neonate takes the first breath. Using a Kelly clamp, the healthcare provider clamps a 20- to 25-cm (8- to 10-in.) portion of the umbilical cord. A small amount of blood (1.0 mL is required for a full panel) is aspirated with a syringe from one of the umbilical arteries or from an artery and a vein. If the cord blood will not be analyzed immediately, a heparinized syringe should be used. Normal fetal blood pH is above 7.25 (ACOG, 2012b). Lower levels indicate acidosis and hypoxia. Many healthcare providers order cord blood analysis to minimize medicolegal exposure.

Provide Nursing Care During the Fourth Stage of Labor

The healthcare provider inspects the vagina, cervix, and perineum for lacerations and makes any necessary repairs. The episiotomy or laceration may be repaired now if it was not done previously.

The nurse assesses the uterus for firmness by palpating the fundus. The normal position is at the midline and below the umbilicus. A displaced fundus may be caused by a full bladder or by blood collected in the uterus. The clots or blood accumulation in the uterus may be expelled by grasping the uterus transabdominally with one hand anteriorly and posteriorly and then squeezing. The nurse continues to palpate the uterine fundus at frequent intervals for at least 4 hours to ensure that it remains firmly contracted (**Figure 33–56** >>), but it is not massaged unless it is soft (boggy). If the uterine fundus becomes soft (uterine atony) or

Figure 33-56 » Suggested method of palpating the fundus of the uterus during the fourth stage. The left hand is placed just above the symphysis pubis, and gentle downward pressure is exerted. The right hand is cupped around the uterine fundus.

appears to rise in the abdomen, the nurse massages it until firm; then, the nurse exerts firm pressure on the fundus in an attempt to express retained clots. During all aspects of fundal massage, the nurse uses one hand to provide support for the lower portion of the uterus and prevent damage to the round ligaments and uterine eversion. The uterus is very tender at this time; all palpation and massage should be performed as gently as possible.

The nurse washes the woman's perineum with gauze squares and warmed solution and then dries the area well with a towel before placing the sanitary pad. Many times, an ice pack is also placed against the perineum to promote comfort and decrease swelling. If stirrups have been used, the woman's legs are removed from the stirrups at the same time to avoid muscle strain. The woman is encouraged to move her legs gently up and down in a bicycle motion. The woman remains in the same bed or is transferred to a recovery room bed, and the nurse helps her don a clean gown. Soiled linens are removed, and the woman is typically offered something to drink.

During the recovery period (1–4 hours) the nurse monitors the woman closely. The perineum is inspected for edema and hematoma formation, and frequent checking of vital signs for deviations from normal is required. The maternal blood pressure is monitored at 5- to 15-minute intervals to detect any changes. Blood pressure should return to the prelabor level because an increased volume of blood is returning to the maternal circulation from the uteroplacental shunt. Pulse rate

should be slightly lower than it was during labor. Baroreceptors cause a vagal response, which slows the pulse. A rise in blood pressure may be a response to oxytocic drugs or may be caused by preeclampsia. Blood loss may be reflected by a lowered blood pressure and a rising pulse rate (**Table 33-15** »).

The nurse also monitors the woman's temperature. Frequently, women have tremors or uncontrollable shaking in the immediate postpartum period that may be caused by a difference in internal and external body temperatures (higher temperature inside the body than outside). Another theory is that the woman is reacting to the fetal cells that have entered the maternal circulation at the placental site. The nurse may place a heated blanket next to the woman's skin to alleviate the problem; this can be replaced as often as the mother desires.

The nurse assesses the mother's pain level. If the woman is experiencing any type of discomfort, pain medications can be administered as ordered. The nurse also assists with comfort measures, such as position changes, frequent ice pack changes, and administration of topical medications that are often ordered to reduce perineal edema and discomfort.

The nurse inspects the bloody vaginal discharge for amount and charts it as minimal, moderate, or heavy and as with or without clots. This discharge (lochia rubra) should be bright red. A soaked perineal pad contains approximately 100 mL of blood. If the perineal pad becomes soaked in a 15-minute period or if blood pools under the buttocks, continuous observation is necessary. When the fundus is firm, a continuous trickle of blood may signal laceration of the vagina or cervix or an unligated vessel in the episiotomy.

If the fundus rises and displaces to the right, the nurse must be concerned about two factors:

1. As the uterus rises, the uterine contractions become less effective and increased bleeding may occur.
2. The most common cause of uterine displacement is bladder distention.

The nurse palpates the bladder to determine whether it is distended. The bladder fills rapidly with the extra fluid

TABLE 33-15 Maternal Adaptations Following Birth

Characteristic	Normal Finding
Blood pressure	Returns to prelabor level
Pulse	Slightly lower than in labor
Uterine fundus	In the midline at the umbilicus, or 1–2 fingerbreadths below the umbilicus
Lochia	Red (rubra), small to moderate amount (from spotting on pads to 1/4–1/2 of pad covered in 15 minutes); does not exceed saturation of one pad in first hour
Bladder	Nonpalpable
Perineum	Without hematomas or open lacerations. Mild to moderate bruising and/or edema is common.
Appetite/Thirst	Variations possible. Increased hunger is typical due to the high level of energy expenditure during the labor and birth process. Increased thirst is due to loss of fluids (blood, sweat, urine) and fluid shifts associated with birth process.
Emotional state	Wide variation, including excited, exhilarated, smiling, crying, fatigued, verbal, quiet, pensive, and sleepy

volume returned from the uteroplacental circulation (and with any fluid received intravenously during labor and birth). The postpartum woman may not realize that her bladder is full, because trauma to the bladder and urethra during childbirth and the use of regional anesthesia decrease bladder tone and the urge to void.

All measures should be taken to enable the mother to void. The nurse may place a warm towel across the lower abdomen or pour warm water over the perineum to relax the urinary sphincter and facilitate voiding. The woman may also try running warm water over her hand. If the woman is unable to void, catheterization is necessary.

SAFETY ALERT In the immediate postbirth recovery period, report the following conditions to the healthcare provider:

- Hypotension
- Tachycardia
- Uterine atony
- Excessive bleeding
- Hematoma.

The woman and her partner or support person may be tired, hungry, and thirsty. Some agencies serve them a meal. Most women are very hungry after birth. The tired mother will probably drift off into a welcome sleep. The partner can also be encouraged to rest, because the supporting role is physically and mentally tiring. If the mother is not in a birthing room, she is usually transferred from the birthing unit to the postpartum or mother–baby area after 1 hour or more, depending on agency policy and whether the following criteria are met:

- Stable vital signs
- Stable bleeding

- Undistended bladder
- Firm fundus
- Sensations fully recovered from any anesthetic agent received during birth.

For some women, the childbirth experience has been extremely painful, filled with hours of feeling powerless or out of control. In this circumstance, the woman is at higher risk for developing posttraumatic stress disorder (Harris & Ayers, 2012).

Evaluation

Evaluation provides an opportunity to determine the effectiveness of nursing care. As a result of comprehensive nursing care during the intrapartum period, the following outcomes may be anticipated:

- The mother's physical and psychologic well-being has been maintained and supported.
- The baby's physical and psychologic well-being has been protected and supported.
- The mother and her family members have had input into the birth process and have participated as much as they desired.
- The mother and her baby have had a safe birth.

An additional purpose of care evaluation is to determine if further care is needed based on maternal or neonatal outcomes. If the outcomes are not being met, the nurse may choose to continue or revise the plan of care for optimal outcome attainment. For example, if the mother's or newborn's physical well-being is compromised, transferring them to a more intensive care setting such as an ICU or NICU may be warranted. Likewise, if the mother's psychologic well-being is compromised, a psychologic consult may be needed and safety measures initiated.

Nursing Care Plan

A Patient Requiring Induction of Labor

Lakshmi Pandey is being admitted to labor and childbirth this morning for an induction. She is accompanied by her husband, Nitya. Mrs. Pandey is a primigravida at 42 weeks of gestation. She has been experiencing Braxton Hicks contractions during the past week, but a contraction pattern has not been established. Mrs.

Pandey's membranes are intact, and her vital signs are within normal limits. Her cervix is soft and pliable, 80% effaced, and 3 cm dilated. Fetal station is –1. The nurse places an external fetal monitor to obtain a baseline fetal heart rate pattern and evaluate uterine activity.

ASSESSMENT	DIAGNOSES	PLANNING
<p>Subjective: Braxton Hicks contractions, restlessness, backache, apprehension. Pain level reported as 5 out of 10.</p> <p>Objective: Cervix is 3 cm dilated, 80% effaced; –1 station; amniotic membranes are intact. BP 120/84 mmHg, temperature 37.1°C (98.8°F), pulse 94 beats/min, respirations 14/min, FHR 144 with average variability.</p>	<ul style="list-style-type: none"> ■ <i>Risk for Injury</i> related to tachysystole of uterus caused by induction of labor ■ <i>Anxiety</i> related to discomfort of labor and unknown labor outcome <p>(NANDA-I © 2014)</p>	<ul style="list-style-type: none"> ■ The patient will progress through the stages of labor without difficulty or complications. ■ The patient will have contractions every 2–3 minutes, with duration of 40–60 seconds, and moderate intensity. ■ The patient's labor will progress with cervical dilation, effacement, and fetal descent. ■ The patient's resting tone will return to baseline between contractions. ■ The patient's vital signs will remain within normal limits.

(continued on next page)

Nursing Care Plan *(continued)*

IMPLEMENTATION

- Obtain a baseline for maternal blood pressure, pulse, respirations, temperature, and pain level.
- Confirm medical, surgical, obstetric, and prenatal history; confirm any allergies with patient.
- Place patient on external fetal monitor for 20 minutes to obtain a baseline for FHR, variability, and periodic changes (accelerations or decelerations).
- Insert intravenous line, and begin primary infusion with 1000 mL of electrolyte solution.
- Piggyback oxytocin solution into primary intravenous tubing, via pump, in the port closest to the intravenous insertion site.
- Monitor infusion pump and connections.
- Monitor and evaluate maternal blood pressure and pulse before each increase in the oxytocin infusion rate.
- Evaluate urine output.
- Evaluate and document FHR before each increase in the oxytocin infusion rate.
- Evaluate and document contraction pattern before each increase of the oxytocin infusion rate.
- Increase the oxytocin infusion dosage until adequate contractions are achieved or the maximum dose per agency protocol is reached.
- Evaluate contraction frequency, duration, and intensity before increasing the infusion rate. Discontinue the oxytocin infusion and infuse primary solution if signs of tachysystole of the uterus are detected.
- Initiate treatment measures to reverse the effects of the oxytocin infusion if fetal tachycardia or bradycardia occurs.

EVALUATION

- Contractions increased in frequency, duration, and intensity.
- Increase in cervical dilation, effacement, and intensity was achieved.
- Uterus remained soft between contractions.

CRITICAL THINKING

1. Mrs. Pandey has been receiving an oxytocin infusion for the past 4 hours and is currently receiving 6 milliunits/min. Your assessment of Mrs. Pandey's contractions includes frequency every 3 minutes, lasting 60 seconds, with moderate intensity. FHR ranges from 140 to 155 beats/min with average variability. Her cervix is now 6 cm (2.4 in.) dilated, 100% effaced, anterior, and the station is 0. Will you continue to monitor at the same infusion rate, increase the rate, or decrease the rate?
2. While monitoring a woman with an oxytocin infusion, you assess that the woman's contractions are now every 2 minutes and that the FHR has dropped to 100 beats/min with a decrease in variability. Several late decelerations are also assessed. What is your initial nursing action?

REVIEW Intrapartum Care

RELATE Link the Concepts and Exemplars

Linking the exemplar of intrapartum care with the concept of comfort:

You are caring for a mother in the transition stage of labor when she begins crying and says, "It hurts so much. I don't know if I can take this anymore." As you were admitting her, when contractions were less frequent and intense, the woman told you it was very important to her that she deliver the baby without taking any pain medication and that she would feel like a failure if she gave in and took a narcotic.

1. Will you offer her a narcotic analgesic to reduce her discomfort? Explain your answer.
2. What nonpharmacologic strategies can you implement to help her manage her pain?

Linking the exemplar of intrapartum care with the concept of culture and diversity:

3. When admitting a patient to the labor unit, what cultural assessment will you perform?
4. The woman tells you a cultural belief in her family is that a candle must be burning when the baby is born, because they believe the

baby will move toward the light, thereby making labor easier and the baby will be born faster. How will you respond to this request?

REFLECT Apply Your Knowledge

It's a busy night, and you admit two patients, one right after the other. The first patient is a 24-year-old single woman in labor with her first pregnancy. Her contractions are 8 minutes apart, she is dilated 2 cm (0.8 in.), and is at the +3 station. She tells you the pain is almost more

than she can stand during contractions and asks how soon the physician can start the epidural. The second patient is 28 years old and in labor with her fourth child. Her contractions are also 8 minutes apart, and she is dilated to 2 cm (0.8 in.) and at the +2 station. She is laughing and joking with her partner between contractions and asks if it would be okay if they play cards while they wait for labor to progress.

Overview

During the **puerperium**, or postpartum period, the woman readjusts, both physically and psychologically, from pregnancy and birth. The period begins immediately after birth and continues for approximately 6 weeks, or until the body has returned to a near pre-pregnant state.

Physical Adaptations

The physiologic changes of pregnancy are numerous and take place over several months. Likewise, after delivery, the woman's body goes through many changes as it begins to return to a nonpregnant state.

Reproductive System

Specific changes to the woman's reproductive system include involution of the uterus, discharge of lochia, cervical, vaginal, and perineal changes, the return of ovulation and menstruation, abdominal changes, and lactogenesis and breast changes. In addition, changes to the gastrointestinal, urinary, cardiovascular, neurologic, and immunologic systems occur.

Involution

The term **involution** describes the rapid reduction in size of the uterus and the return of the uterus to a nonpregnant state. Following separation of the placenta, the decidua of the uterus is irregular, jagged, and varied in thickness. The spongy layer of the decidua is cast off as lochia (uterine discharge of the debris remaining after birth), and the basal

layer of the decidua remains in the uterus to become differentiated into two layers. This occurs within the first 48–72 hours after birth. The outermost layer becomes necrotic and is sloughed off in the lochia. The layer closest to the myometrium contains the fundi of the uterine endometrial glands. These glands lay the foundation for the new endometrium. Except at the placenta site, this process is completed in approximately 3 weeks. Healing at the placenta site occurs gradually over 6 weeks, at which point the site is completely healed (Cunningham et al., 2014). Bleeding from the larger uterine vessels of the placenta site is controlled by compression of the contracted uterine muscle fibers. The clotted blood is gradually absorbed by the body. Some of these uterine vessels are eventually obliterated and replaced by new vessels with smaller lumens.

The placenta site heals by a process of exfoliation and growth of endometrial tissue. This occurs with upward endometrial growth in the decidua basalis under the placenta site, with simultaneous growth of endometrial tissue from the margins of the site. The infarcted superficial tissue then becomes necrotic and is sloughed off (Blackburn, 2013). Exfoliation is a very important aspect of involution; if healing of the placenta site leaves a fibrous scar, the area available for future implantation is limited, as is the number of possible pregnancies.

With the dramatic decrease in the levels of circulating estrogen and progesterone following placental separation, the uterine cells atrophy, and the hyperplasia of pregnancy begins to reverse. Proteolytic enzymes are released, and macrophages migrate to the uterus to promote autolysis

(self-digestion), which breaks down and absorbs protein material in the uterine wall. Factors that enhance involution include an uncomplicated labor and birth, complete expulsion of the placenta and membranes, breastfeeding, manual removal of the placenta during a cesarean birth, and early ambulation.

» Go to **Pearson MyLab Nursing and eText** for Chart 10: *Factors That Slow Uterine Involution*.

The **fundus** (top portion of the uterus) is situated in the midline and is palpable below the umbilicus (**Figure 33-57**). Following expulsion of the placenta, the uterus contracts to the size of a large grapefruit. The uterine blood vessels are firmly compressed by the myometrium. Blood and clots that remain within the uterus and changes in support of the uterus by the ligaments cause the fundus of the uterus to rise to the level of the umbilicus within 6–12 hours after birth.

A fundus that is above the umbilicus and is boggy (feels soft and spongy rather than firm and well contracted) is associated with excessive uterine bleeding. As blood collects and forms clots within the uterus, the fundus rises, interrupting firm contractions of the uterus and exacerbates **uterine atony** (relaxation of uterine muscle tone).

When the fundus is higher than expected on palpation and is not in the midline (usually deviated to the right), distention of the bladder should be suspected; the bladder should be emptied immediately and the uterus reassessed. If the woman is unable to void, in-and-out catheterization of

the bladder may be required. In the immediate postpartum period, many women may not be aware of a full bladder. Because the uterine ligaments are still stretched, a full bladder can move the uterus. By the end of the puerperium, these ligaments regain their nonpregnant length and tension.

After birth, the top of the fundus remains at the level of the umbilicus for about half a day. On the first day postpartum, the top of the fundus is located about 1 cm (0.4 in.) below the umbilicus. The top of the fundus descends approximately one fingerbreadth (width of the index, second, or third finger), or 1 cm (0.4 in.), per day until it descends into the pelvis on about the 10th day.

If the mother is breastfeeding, the release of endogenous oxytocin from the posterior pituitary in response to suckling hastens involution of the uterus. Barring complications, such as infection or retained placental fragments, the uterus approaches its prepregnant size and location by 5–6 weeks. In women who had an oversized uterus during the pregnancy (because of hydramnios, birth of a large-for-gestational-age baby, or multiple gestation), the time frame for an immediate uterine involution process is lengthened. If intra-uterine infection is present, foul-smelling lochia or vaginal discharge results. The infection irritates the uterine muscle, causing the fundus to descend much more slowly. When infection is suspected, other clinical signs, such as fever and tachycardia, and fundal tenderness must be assessed. Any slowing of descent is called **subinvolution**.

Afterpains (cramplike pains caused by intermittent contractions of the uterus that occur after childbirth) are often more severe in multiparas than in primiparas. These afterpains may cause the mother severe discomfort for 2–3 days after birth. The administration of uterotonic agents (intravenous infusion with oxytocin or oral administration of methylergonovine maleate) stimulates uterine contraction and increases the discomfort of the afterpains. A warm water bottle placed against the lower abdomen may reduce this discomfort. In addition, the breastfeeding mother may find it helpful to take a mild analgesic agent approximately 1 hour before feeding her baby. The nurse can assure the mother who is breastfeeding that the prescribed analgesics are not harmful to the newborn and help improve the quality of the breastfeeding experience. If afterpains are interfering with the mother's rest, she may find it helpful to take an analgesic at bedtime.

Lochia

The uterus rids itself of the debris remaining after birth through a discharge called **lochia**, which is classified according to its appearance and contents. These classifications are lochia rubra, lochia serosa, and lochia alba.

Lochia rubra is dark red. It occurs for the first 2–3 days and contains epithelial cells, erythrocytes, leukocytes, shreds of decidua, and occasionally fetal meconium, lanugo, and vernix. Clotting is often the result of blood pooling in the upper portion of the vagina. A few small clots (no larger than a nickel) are common, particularly in the first few days after birth. However, lochia should not contain large (plum-size) clots; if it does, the cause should be investigated without delay.

Lochia serosa is a pinkish color. It follows from approximately day 3 until day 10. Lochia serosa is composed of

Figure 33-57 » Involution of the uterus. **A**, Immediately after delivery of the placenta, the top of the fundus is in the midline and approximately halfway between the symphysis pubis and the umbilicus. Approximately 6–12 hours after birth, the fundus is at the level of the umbilicus. **B**, The height of the fundus then decreases about one fingerbreadth (~1 cm) each day.

serous exudate, shreds of degenerating decidua, erythrocytes, leukocytes, cervical mucus, and numerous microorganisms (Blackburn, 2013).

The red blood cell component decreases gradually, and a creamy or yellowish discharge persists for an additional week or two. This final discharge, termed **lochia alba** (from the Latin word for *white*), is composed primarily of leukocytes, decidual cells, epithelial cells, fat, cervical mucus, cholesterol crystals, and bacteria. Variation in the duration of lochia discharge is not uncommon; however, the trend should be toward a lighter amount of flow and a lighter color of discharge. When the lochia flow stops, the cervix is considered to be closed, and chances of infection ascending from the vagina to the uterus decrease.

Like menstrual discharge, lochia flow has a musty, stale odor that is not offensive. Microorganisms are always present in the vaginal lochia and contaminate the uterus with vaginal bacteria by the second day following birth. It is thought that infection does not develop because the organisms involved are relatively nonvirulent. Any foul smell to the lochia or used peripad suggests infection and the need for prompt additional assessment, such as white blood cell count and differential and assessment for uterine tenderness and fever.

The total average volume of lochia is approximately 225 mL, and the daily volume gradually decreases (Blackburn, 2013). Discharge is greater in the morning because of pooling in the vagina and uterus while the mother lies sleeping. The amount of lochia may also be increased by exertion or breastfeeding. Multiparous women usually have more lochia than first-time mothers. Women who undergo a cesarean birth typically have less lochia than women who give birth vaginally (Blackburn, 2013).

Evaluation of lochia is necessary not only to determine whether hemorrhage is present but also to assess uterine involution. The type, amount, and consistency of lochia determine the stage of healing of the placenta site; a progressive change from bright red at birth to dark red, then to pink, and then to white or clear discharge should be observed. Persistent discharge of lochia rubra or a return to lochia rubra may indicate subinvolution or late postpartum hemorrhage.

The nurse should exercise caution in evaluating bleeding immediately after birth. The continuous seepage of blood is more consistent with cervical or vaginal lacerations and may be effectively diagnosed when the bleeding is evaluated in conjunction with uterine consistency. Lacerations should be suspected if the uterus is firm and of expected size and if no clots can be expressed.

Cervical Changes

Following birth, the cervix is flabby, formless, and may appear bruised. The lateral aspects of the external os are sometimes lacerated during the birth process (Cunningham et al., 2014). The external os is markedly irregular and closes slowly. It admits two fingers for a few days following birth, but by the end of the first week, it admits only a fingertip.

The first childbearing permanently changes the shape of the external os. The characteristic dimple-like os of the nullipara changes to the transverse slit (fish-mouth) os of the multipara. After significant cervical laceration or several

lacerations, the cervix may appear lopsided. Because of the slight change in the size of the cervix, changes in maternal weight, muscle tone, and pelvic architecture, a diaphragm or cervical cap will need to be refitted if the woman uses one of these methods of contraception.

Vaginal Changes

The vagina appears edematous and may be bruised following birth. The apparent bruising is caused by pelvic congestion and trauma and quickly disappears. Small, superficial lacerations may be evident, and the rugae are obliterated. The hymen, torn and jagged, heals irregularly, leaving small tags called carunculae myrtiformes.

The size of the vagina decreases, and rugae return within 3–4 weeks (Blackburn, 2013; James, 2014). This facilitates the gradual return to smaller, although not nulliparous, dimensions. By 6 weeks, the vagina of a woman who is not breastfeeding usually appears normal. The lactating woman is in a hypoestrogenic state because of ovarian suppression, and her vaginal mucosa may be pale and without rugae. The effects of the lowered estrogen level may lead to dyspareunia (painful intercourse), which may be reduced by the addition of a water-soluble personal lubricant.

Tone and contractility of the vaginal orifice may be improved by perineal tightening exercises, such as Kegel exercises (discussed in Exemplar 33.A). The woman may begin these soon after birth. The labia majora and labia minora are more flaccid in the woman who has borne a child than in the nullipara.

Perineal Changes

During the early postpartum period, the soft tissue in and around the perineum may appear edematous, with some bruising. If an episiotomy or a laceration is present, the edges should be approximated. Initial healing of the episiotomy or laceration occurs in 2–3 weeks after the birth, although complete healing may take up to 4–6 months (Blackburn, 2013). Perineal discomfort may be present during this time.

Ovulation and Menstruation

The return of ovulation and menstruation varies for each postpartum woman. Menstruation generally returns as soon as 7 weeks in 70% and by 12 weeks in all nonlactating mothers or as late as 3 years in 70% of breastfeeding mothers (Pessel & Tsai, 2013). The return of ovulation is directly associated with a rise in the serum progesterone level.

The return of ovulation and menstruation in breastfeeding mothers is usually prolonged. It is associated with the length of time the woman breastfeeds and whether formula supplements are used. If a mother breastfeeds for less than 1 month, the return of menstruation and ovulation is similar to that in the woman who is not breastfeeding. Women who exclusively breastfeed usually experience a delay in menstruation of at least 3 months. Suckling by the baby typically results in alterations in the gonadotropin-releasing hormone production, which is thought to be the cause of amenorrhea (Blackburn, 2013). Although exclusive breastfeeding helps to reduce the risk of pregnancy for the first 6 months after birth, it should be relied on only temporarily and if it meets the criteria for the lactational amenorrhea

method. Furthermore, because ovulation precedes menstruation and because women often supplement breastfeeding with bottles and pacifiers, breastfeeding is not considered to be a reliable means of contraception.

Abdomen

The uterine ligaments (notably the round and broad ligaments) are stretched and require the length of the puerperium to recover. Although the stretched abdominal wall appears loose and flabby, it responds to exercise within 2–3 months. However, the abdomen may fail to regain good tone and will remain flabby in the grand multipara, in the woman whose abdomen is overdistended, or in the woman with poor muscle tone before pregnancy. **Diastasis recti abdominis** (a separation of the abdominal muscle) may occur with pregnancy, especially in women with poor abdominal muscle tone. If diastasis occurs, part of the abdominal wall has no muscular support and is formed only by skin, subcutaneous fat, fascia, and peritoneum. This may be especially pronounced in women who have undergone a cesarean section, during which the rectus abdominis muscles are manually separated to access the uterine muscle. Improvement depends on the physical condition of the mother, the total number of pregnancies, pregnancy spacing, and the type and amount of physical exercise. Diastasis may result in a pendulous abdomen and increased maternal backache. Fortunately, diastasis responds well to exercise, and abdominal muscle tone can improve significantly.

The striae (stretch marks), which occur as a result of stretching and rupture of the elastic fibers of the skin, take on different colors based on the mother's skin color. The striae of light-skinned mothers are red to purple at the time of birth, then gradually fade to silver or white. The striae of mothers with darker skin, in contrast, are darker than the surrounding skin and remain darker. Striae gradually fade after a time, but they do remain visible.

Breasts and Lactogenesis

During pregnancy, increased levels of estrogen stimulate breast duct proliferation and development, and elevated progesterone levels promote the development of lobules and alveoli in preparation for lactation. Prolactin levels rise from approximately 10 mcg/mL before pregnancy to 200 mcg/mL at term. However, lactation is suppressed during pregnancy by elevated progesterone levels secreted by the placenta. Once the placenta is expelled at birth, progesterone levels fall, and the inhibition is removed, triggering milk production. This occurs whether the mother has breast stimulation or not. If breast stimulation is not occurring by the third or fourth day, however, prolactin levels begin to drop. By 2 weeks postpartum, if there is no stimulation, prolactin levels will be back to prepregnancy levels, and milk production will cease (Walker, 2016).

Initially, lactation is under endocrine control. The hormone prolactin is released from the anterior pituitary in response to breast stimulation from suckling or the use of a breast pump. Prolactin stimulates the milk-secreting cells in the alveoli to produce milk, then rapidly drops back to baseline. If more than approximately 3 hours elapse between stimulation, prolactin levels begin to drop below baseline. To reverse the overall decline in prolactin level, the mother

can be encouraged to stimulate her breasts more frequently (e.g., every 1.5–2.0 hours). Mothers should be strongly encouraged to stimulate their breasts frequently if their babies are not effective feeders or if they are separated from their babies. Prolactin receptors are established during the first 2 weeks postpartum in response to frequency of breast stimulation (Human Milk Banking Association of North America, 2011). Inadequate development of prolactin receptors during this time is likely to negatively impact the mother's long-term milk volume.

Colostrum is the initial milk that begins to be secreted during midpregnancy and that is immediately available to the baby at birth. It provides the newborn with all the nutrition required until the mother's milk becomes more abundant in a few days. No routine supplementation of other fluids is necessary unless there is a medical indication. Colostrum is a thick, creamy, yellowish fluid with concentrated amounts of protein, fat-soluble vitamins, and minerals; it has lower amounts of fat and lactose compared with mature milk. It also contains antioxidants and high levels of lactoferrin and secretory IgA. It promotes the establishment of *Lactobacillus bifidus* flora in the digestive tract, which helps protect the baby from disease and illness. Colostrum also has a laxative effect on the newborn, which helps the baby pass meconium stools, which in turn helps decrease hyperbilirubinemia (Ladewig, London, & Davidson, 2017).

The milk that flows from the breast at the start of a feeding or pumping session is called *foremilk*. The foremilk is watery milk that is high in protein and low in fat (1–2%). This milk has trickled down from the alveoli between feedings to fill the lactiferous ducts, and it is low in fat because the fat globules made in the alveoli stick to each other and to the walls of the alveoli and do not trickle down. In addition to prolactin release, stretching of the nipple and compression of the areola signal the hypothalamus to trigger the posterior pituitary gland to release oxytocin. Oxytocin acts to cause the myoepithelial cells surrounding the alveoli in the breast tissue to contract, ejecting milk (including the fat globules present) into the ducts. This process is called the milk-ejection reflex but is better known in lay terms as the “let-down” reflex (response). The average initial let-down response occurs about 2 minutes after a baby begins to suckle, and between 4 and 10 let-down responses will occur during a feeding session. The milk that flows during “let-down” is called *hindmilk*. Hindmilk is rich in fat (which can exceed 10%) and, therefore, is high in calories. In a sample of expressed breast milk, the average total fat concentration is approximately 4% and the total caloric content is approximately 20 calories/oz.

By 6 months of breastfeeding, prolactin levels are only 5–10 mcg/mL, yet milk production continues. A whey protein called feedback inhibitor of lactation (FIL) has been identified as influencing milk production through a negative feedback loop. FIL is present in breast milk and functions to decrease milk production. The more milk that remains in the breast for a longer period of time, the more milk production is decreased. On the other hand, the more often the breasts are emptied, the lower the level of FIL and the faster milk is produced. This mechanism of regulating milk at the local level is called autocrine control. This process is key to understanding how a mother maintains or

loses her milk supply (Riordan, 2016). A number of factors can delay or impair lactogenesis. Maternal factors include the following (Janke, 2014):

- Cesarean birth
- Postpartum hemorrhage
- Type 1 diabetes
- Untreated hypothyroidism
- Obesity
- Polycystic ovary syndrome
- Retained placenta fragments
- Vitamin B₆ deficiency
- History of previous breast surgery
- Insufficient glandular breast tissue
- Significant stress.

Other factors that can interfere with breastfeeding include smoking, use of alcohol, and use of some prescription and OTC medications (e.g., antihistamines and combined birth control pills).

Stages of Human Milk

During the establishment of lactation, there are three stages of human milk:

1. Colostrum
2. Transitional milk
3. Mature milk.

After 30–72 hours of colostrum production, maternal milk production normally becomes noticeably more abundant. The milk “coming in” is called **transitional milk** and has qualities intermediate between those of colostrum and mature milk. It is still light yellow in color but is more copious than colostrum and contains more fat, lactose, water-soluble vitamins, and calories. By day 5, most mothers are producing approximately 500 mL/day.

Mature milk is white or slightly blue-tinged in color. It is present by 2 weeks postpartum and continues thereafter until lactation ceases. Mature milk contains approximately 13% solids (carbohydrates, proteins, and fats) and 87% water. Mature human milk’s appearance, similar to that of skim cow’s milk, may cause mothers to question whether their milk is “rich enough.” The nurse should reassure the mother that this is the normal appearance of mature human milk and that mature milk provides the baby with all the necessary nutrients. Although gradual changes in composition do occur continuously over periods of weeks to accommodate the needs of the growing newborn, the composition of mature milk in general is fairly consistent with the exception of the fat content as noted previously. Milk production continues to increase slowly during the first month. By 6 months postpartum, a mother produces approximately 800 mL/day (Blackburn, 2013).

Gastrointestinal System

Following birth, the mother may be hungry and may enjoy a light meal. Frequently, she is quite thirsty and will drink large amounts of fluid. Drinking fluids helps replace those lost during labor, in the urine, and through perspiration.

The bowels tend to be sluggish following birth because of the lingering effects of progesterone, decreased abdominal muscle tone, and bowel evacuation associated with the labor and birth process. Women who have had an episiotomy or who have lacerations or hemorrhoids may tend to delay elimination because they fear increasing their pain or believe their stitches will be torn if they bear down. However, refusing or delaying the bowel movement may cause increased constipation and more pain when bowel elimination finally occurs.

There is no evidence in favor of restricting oral intake following a cesarean birth. While institutional policies may vary, evidence suggests that advancing the diet as desired restores the gastrointestinal system to a normal state more quickly than withholding solids and does not lead to an increased rate of complications (King et al., 2013). The woman may experience some initial discomfort from flatulence. This can be relieved by early ambulation and use of antifatulence medications. Chamomile or peppermint tea may also be helpful in reducing discomfort from flatulence. It may take a few days for the bowel to regain its tone, especially if general anesthesia was used. The woman who has had a cesarean or a difficult birth may benefit from stool softeners.

Urinary System

The postpartum woman has increased bladder capacity, swelling and bruising of the tissue around the urethra, decreased sensitivity to fluid pressure, and decreased sensation of bladder filling. Consequently, she is at risk for overdistention, incomplete bladder emptying, and buildup of residual urine. Women who have had neuraxial anesthesia, such as an epidural or spinal, have inhibited neural functioning of the bladder and are more susceptible to bladder distention, difficulty voiding, and bladder infections. In addition, use of oxytocin to facilitate uterine contractions following expulsion of the placenta has an antidiuretic effect. Following cessation of the oxytocin, the woman will experience rapid bladder filling.

Urinary output increases during the early postpartum period (first 12–24 hours) because of postpartum diuresis. The kidneys must eliminate an estimated 2000–3000 mL of extracellular fluid with the normal pregnancy, which causes rapid filling of the bladder (Blackburn, 2013). Adequate bladder elimination is an immediate concern. Women with preeclampsia, chronic hypertension, and diabetes experience greater fluid retention than do other women, and postpartum diuresis is increased accordingly.

If urinary stasis exists, chances for urinary tract infection increase because of bacteriuria and the presence of dilated ureters and renal pelvis, which persist for approximately 6 weeks after birth. A full bladder may also increase the tendency of the uterus to relax by displacing the uterus and interfering with its contractility, leading to hemorrhage. In the absence of infection, the dilated ureters and renal pelvis return to prepregnant size by the end of the sixth week.

Vital Signs

With the possible exception of the first 24 hours after birth, the woman should be afebrile during the postpartum period. Epidural anesthesia for labor, which can interfere with heat

dissipation, has a direct effect on maternal temperature but rarely results in overt fever (Shatken, Greenough, & McPherson, 2012). A maternal temperature of up to 38°C (100.4°F) may occur after childbirth as a result of the exertion and dehydration of labor. An increase in temperature to between 37.8°C and 39°C (100° and 102.2°F) may also occur during the first 24 hours after the mother's milk comes in (Cunningham et al., 2014). However, in women not meeting these criteria, infection must be considered in the presence of an increased temperature.

Immediately following childbirth, many women experience a transient rise in both systolic and diastolic blood pressures, which spontaneously return to the prepregnancy baseline during the next few days (James, 2014). A decrease may indicate physiologic readjustment to decreased intrapelvic pressure, or it may be related to uterine hemorrhage. Orthostatic hypotension, as indicated by feelings of faintness or dizziness immediately after standing up, can develop in the first 48 hours as a result of abdominal engorgement that may occur after birth. A low or decreasing blood pressure may reflect hypovolemia secondary to hemorrhage, but it is a late sign (see discussion of hypovolemia in the module on Fluids and Electrolytes). Blood pressure elevations may result from excessive use of oxytocin or vasopressor medications. Because preeclampsia can persist into or occur first in the postpartum period, routine evaluation of blood pressure is needed. If a woman complains of headache, hypertension must be ruled out before analgesics are administered.

Puerperal bradycardia with rates of 50–70 beats/min commonly occurs during the first 6–10 days of the postpartum period. This may be related to decreased cardiac effort, decreased blood volume following placental separation and contraction of the uterus, and increased stroke volume. A pulse rate of greater than 100 beats/min may indicate hypovolemia, infection, fear, or pain and requires further assessment.

Frequently, the mother experiences intense tremors that resemble shivering from a chill immediately after birth. This shivering has been explained as a

- result of the sudden release of pressure on the pelvic nerves after birth,
- response to a fetus-to-mother transfusion that occurred during placental separation,
- reaction to maternal adrenaline production during labor and birth, or
- reaction to epidural anesthesia.

If not followed by fever, this chill is of no clinical concern, but it is uncomfortable for the woman. The nurse can increase the woman's comfort by covering her with a warmed blanket and reassuring her that the shivering is a common, self-limiting situation. If the woman allows herself to go with the shaking, the shivering will last only a short time. Some women may find a warm beverage to be helpful. Later in the puerperium, chill and fever indicate infection and require further evaluation.

Blood Values

Blood values should return to the prepregnant state by the end of the postpartum period. Pregnancy-associated activation

of coagulation factors may continue for variable amounts of time after birth. This condition, in conjunction with trauma, immobility, sepsis, obesity, African American ethnicity, diabetes, smoking, and advanced maternal age, predisposes the woman to development of thromboembolism (King et al., 2013). The incidence of thromboembolism is reduced by early ambulation.

Nonpathologic leukocytosis often occurs during labor and in the immediate postpartum period, with white blood cell counts of 25,000–30,000 cells/mm³ (Cunningham et al., 2014). These values typically return to normal levels by the end of the first postpartum week. Leukocytosis combined with the normal increase in erythrocyte sedimentation rate may obscure the diagnosis of acute infection at this time (James, 2014).

Hemoglobin and hematocrit levels may be difficult to interpret during the first 2 days after birth because of the changing blood volume. The loss of blood in the first 24 hours accounts for half the red blood cell volume gained during the course of the pregnancy. Blood loss averages 200–500 mL with a vaginal birth and nearly 1000 mL with a cesarean birth (Pessel & Tsai, 2013). Lochia constitutes less than 25% of this blood loss (James, 2014). As extracellular fluid is excreted, hemoconcentration occurs, with a concomitant rise in hematocrit. A drop in values indicates an abnormal blood loss. The following is a convenient rule to remember: A two to three percentage point drop in hematocrit equals a blood loss of 500 mL (James, 2014). After 3–4 days, mobilization of interstitial fluid leads to a slight increase in plasma volume. This hemodilution leads to a decrease in hemoglobin, hematocrit, and plasma protein by the end of the first postpartum week. Decreases in plasma volume reach nonpregnant levels by 4–6 weeks postpartum (Blackburn, 2013).

Platelet levels typically fall as a result of placental separation. They then begin to increase by the third to fourth day postpartum, gradually returning to normal by the sixth week postpartum. Fibrinolytic activity typically returns to normal during the hours following birth. The hemostatic system as a whole reaches its normal prepregnant status by 3–4 weeks postpartum; however, the diameter of deep veins can take up to 6 weeks to return to prepregnant levels (Blackburn, 2013). This explains the prolonged risk of thromboembolism in the first 6 weeks following birth.

Cardiovascular Changes

The mother's cardiovascular system undergoes dramatic changes during the birth that can result in cardiovascular instability because of an increase in cardiac output. The cardiac output typically stabilizes and returns to pregnancy levels within an hour following birth. Maternal hypervolemia acts to protect the mother from excessive blood loss. Cardiac output declines by 30% in the first 2 weeks and reaches normal levels by 6–12 weeks (Blackburn, 2013).

Diuresis in the first 2–5 days after birth assists in decreasing the extracellular fluid and results in a weight loss of 3 kg (6.6 lb) (James, 2014). Failure to have diuresis in the immediate postpartum period can lead to pulmonary edema and subsequent cardiac problems. This is seen more commonly in women with a history of preeclampsia or preexisting cardiac problems (Blackburn, 2013; James, 2014).

Neurologic and Immunologic Changes

Neurologic problems and disorders can predispose women to higher rates of morbidity and mortality during pregnancy and the postpartum period. Headaches are the most common neurologic symptoms encountered by postpartum women. Headaches may result from fluid shifts in the first week after birth, leakage of cerebrospinal fluid into the extradural space during spinal anesthesia, gestational hypertension, or stress (James, 2014). Migraine headaches may persist during pregnancy and postpartum (Hoshiyama et al., 2012). It is more likely that a woman will have a seizure during labor or in the first 24 hours after birth than during pregnancy (Sibai, 2012). Women with epilepsy also have more feeding difficulties, irritability, and lethargy.

Psychologic Adaptations

The postpartum period is a time of readjustment and adaptation for the entire childbearing family but especially for the mother. The woman experiences a variety of responses as she adjusts to a new family member, postpartum discomforts, changes in her body image, and the reality that she is no longer pregnant.

The first day or two after birth, the mother may seem passive about the event and may seem more concerned with her own needs. Food and sleep are priority needs, and she begins to process the event. By the second or third day, the new mother is ready to resume control of her mothering and of her body and life in general. At this stage, however, she may experience anxiety and require assurance that she is doing well as a mother. Difficulties with feedings may be a particular source of anxiety.

Maternal Role Attainment

Maternal role attainment (MRA) is the process by which a woman learns mothering behaviors and becomes comfortable with her identity as a mother. Formation of a maternal identity occurs with each child a woman bears. As the mother grows to know this child and forms a relationship, the mother's maternal identity gradually and systematically evolves, and she "binds in" to the newborn (Rubin, 1984).

Maternal role attainment often occurs in four stages (Mercer, 1995):

1. **The anticipatory stage** occurs during pregnancy. The woman looks to role models, especially her own mother, for examples of how to mother.
2. **The formal stage** begins when the child is born. The woman is still influenced by the guidance of others and tries to act as she believes others expect her to act.
3. **The informal stage** begins when the mother starts making her own choices about mothering. The woman begins to develop her own style of mothering and finds ways of functioning that work well for her.
4. **The personal stage** is the final stage of maternal role attainment. When the woman reaches this stage, she is comfortable with the notion of herself as "mother."

In most cases, MRA occurs within 3–10 months after birth. Social support, the woman's age and personality traits, the marital relationship, the presence of underlying anxiety or depression, the woman's previous child care experiences,

the temperament of her infant, and the family's socioeconomic status all influence the woman's success in attaining the maternal role.

The postpartum woman faces a number of challenges as she adjusts to her new role (Mercer, 1995):

- For many women, finding time for themselves is one of the greatest challenges of motherhood. It is often difficult for the new mother to find time to read a book, talk to her partner, or even eat a meal without interruption.
- Women also report feelings of incompetence because they have not mastered all aspects of the mothering role. Many times mothers find themselves unsure of what to do in a given situation.
- The next greatest challenge involves fatigue resulting from sleep deprivation. The demands of nighttime care are tremendously draining, especially when the woman has other children.
- Another challenge for the new mother involves the feeling of responsibility that having a child brings. A woman experiences a sense of lost freedom, an awareness that she will never again be quite as carefree as she was before becoming a mother.
- Finding time for older children following the birth of a new baby also presents challenges. Many women feel guilty because the new baby takes up so much of their time. Sibling rivalry or ill feelings about the baby from other children can put additional stress on the mother.
- Mothers sometimes cite the infant's behavior as a challenge, especially when the child is about 8 months old. The baby develops stranger anxiety, begins crawling and getting into things, and may be fussy from teething. In addition, the baby's tendency to put things in the mouth requires constant vigilance by the parent.

In 2004, Mercer proposed replacing the term *maternal role attainment (MRA)* with the term *becoming a mother (BAM)*. She stated that BAM "more accurately encompasses the dynamic transformation and evolution of a woman's persona than does MRA, and the term MRA should be discontinued."

A mother's first interaction with her newborn is influenced by many factors, including her involvement with her family of origin, her relationships, the stability of her home environment, the communication patterns she has developed, and the degree of nurturing she received as a child. These factors shaped the person she has become. The following personal characteristics are also important:

- **Level of trust.** What level of trust has this mother developed in response to her life experiences? What is her philosophy of childrearing? Will she be able to treat her baby as a unique individual with changing needs that should be met as much as possible?
- **Level of self-esteem.** How much does she value herself as a woman and a mother? Is she generally able to cope with the adjustments of life?
- **Capacity for enjoying herself.** Is the mother able to find pleasure in everyday activities and human relationships?
- **Adequacy of knowledge about childbearing and childrearing.** What beliefs about the course of pregnancy, the

capabilities of newborns, previous experiences with infants or children, and the nature of her emotions may influence her behavior at first contact with her newborn and later?

- **Prevailing mood or usual feeling tone.** Is the woman predominantly content, angry, depressed, or anxious? Is she sensitive to her own feelings and those of others? Will she be able to accept her own needs and to obtain support in meeting them?
- **Reactions to the present pregnancy.** Was the pregnancy planned? Did it go smoothly? Were there ongoing life events that enhanced her pregnancy or depleted her reserves of energy? How have other life roles changed because of her pregnancy and motherhood?

By the time of birth, each mother has developed some kind of emotional orientation to the baby based on these factors.

Initially after birth during the *taking-in* period, the woman tends to be passive and somewhat dependent. She follows suggestions, hesitates to make decisions, and is still rather preoccupied with her needs (Rubin, 1984). She may have a great need to talk about her perceptions of her labor and birth. This helps her work through the process, sort out the reality from her fantasized experience, and clarify anything that she did not understand. Food and sleep are major needs.

By the second or third day after birth, the new mother is often ready to resume control of her body, her mothering, and her life in general. Rubin (1984) labeled this the *taking-hold* period. If she is breastfeeding, she may worry about her technique or the quality of her milk. If her baby spits up after a feeding, she may view it as a personal failure. She may also feel demoralized by the fact that the nurse or an older family member handles her baby proficiently while she feels unsure and tentative. She requires assurance that she is doing well as a mother. Today's mothers seem to be more independent and adjust more rapidly, exhibiting behaviors of "taking-in" and "taking-hold" in shorter periods of time than those previously identified.

Development of Family Attachment

Nurses caring for families in the postpartum stage need to be aware of the long-term adjustments and stresses that the family faces as its members adjust to new and different roles. Nurses can help by providing anticipatory guidance about the realities of being a parent and by giving the postpartum family parenting literature for reference at home. Ongoing parenting groups give parents an opportunity to discuss problems and become comfortable in new roles.

Father–Newborn Interactions

In Western cultures, commitment to family-centered maternity care has fostered interest in understanding the feelings and experiences of the new father. Evidence suggests that the father has a strong attraction to his newborn and that the feelings he experiences are similar to the mother's feelings of attachment. The father's characteristic sense of absorption, preoccupation, and interests in the newborn demonstrated during early contact is termed *engrossment*. Engrossment occurs after birth when the father and the

newborn bond. Engrossment is not only the effect of the father caring for the baby, such as holding and comforting, but the emotional effect that the baby has on the father (Sears & Sears, 2016). Differences in involvement still exist among fathers in Western culture and may be influenced by factors other than culture (e.g., previous experience with paternal role or exposure to male/father role models).

Siblings and Others

Babies are capable of maintaining a number of strong attachments without loss of quality. These attachments may include siblings, grandparents, aunts, and uncles. The social setting and personality of the individual seem to be significant factors in the development of multiple attachments. Birth centers are especially geared toward the family's inclusion in the birth process. In the hospital setting, the advent of open visiting hours and rooming-in permits siblings and others to participate in the attachment process.

Initial Maternal Attachment Behavior

After labor and birth, a new mother demonstrates a fairly regular pattern of maternal behaviors as she continues to familiarize herself with her newborn. In a progression of touching activities, the mother proceeds from fingertip exploration of the newborn's extremities toward palmar contact with larger body areas and finally to enfolding the newborn with the whole hand and arm. The time she takes to accomplish these steps varies from minutes to days. The mother increases the proportion of time spent in the *en face* position—she arranges herself or the newborn so that she has direct face-to-face and eye-to-eye contact (**Figure 33–58** >>). There is an intense interest in having the newborn's eyes open. When the newborn's eyes are open, the mother characteristically greets and talks to the baby in high-pitched tones.

In most instances, the mother relies heavily on her senses of sight, touch, and hearing in getting to know what her baby is really like. She also tends to respond verbally to any sounds emitted by the newborn, such as cries, coughs, sneezes, and grunts. The sense of smell may be involved as well.

Figure 33–58 >> A mother *en face* with her newborn.

The nurse plays a key role in assessing and assisting the mother–newborn bond. As discussed in detail in Exemplar 33.D, the nurse facilitates a number of activities that help strengthen maternal attachment, including feeding, bathing, and recognizing the baby’s specific cues related to sleep and activity. Ongoing assessment of the mother’s psychologic adaptation is critical because it allows the nurse to evaluate what patient teaching needs to be provided. Nursing interventions that foster the process of becoming a mother include the following categories:

- Instructing for newborn/infant caregiving
- Building awareness of and responsiveness to newborn/infant interactive capabilities
- Promoting maternal–newborn attachment
- Preparing the woman for the maternal social role preparation
- Encouraging interactive therapeutic nurse–patient relationships

Maternal/social role preparation and interactive therapeutic nurse–patient relationships may have a greater impact on the progress of becoming a mother than formal teaching. A detailed discussion of psychologic assessment of the postpartum mother is included in the Nursing Process section of this exemplar.

Postpartum Weight and Nutrition

An initial weight loss of approximately 4.5–5.4 kg (10–12 lb) occurs as a result of birth of the baby and expulsion of the placenta and amniotic fluid. Diuresis accounts for the loss of an additional 2.3 kg (5 lb) during the early puerperium. By the sixth to eighth week after birth, many women have returned to approximately their prepregnant weight if they had gained the average 11.4–13.6 kg (25–30 lb) during pregnancy. For others, a return to prepregnant weight may take longer. Women often express concern about the slow pace of their postpartum weight loss. Multiparas tend to be more positive than primiparas, probably because a multipara’s previous experience has prepared her for the fact that the body does not immediately return to a prepregnant state.

Nutritional needs change following childbirth. Nutrient requirements vary depending on whether the mother decides to breastfeed. An assessment of postpartum nutritional status is necessary before giving nutritional guidance. Postpartum nutritional status is determined primarily by assessing the new mother’s weight, hemoglobin and hematocrit levels, clinical signs, and dietary history.

Postpartum Nutritional Status

The amount of weight gained during pregnancy is a major determinant of weight loss after childbirth. Generally, women who gain excessive weight during pregnancy are more likely to sustain a weight gain 1 year following childbirth, putting them at increased risk of long-term overweight or obesity. The mother’s weight should be considered in terms of ideal weight, prepregnancy weight, and weight gain during pregnancy. Women who desire information about weight reduction can be referred to a dietitian or nutritionist for individual counseling or to community-based

educational programs. Educational programs need to address a variety of issues, such as the significance of the quality of food eaten rather than its quantity; the importance of regular physical activity in improving health, building lean muscle mass, and increasing metabolism; and the value of meal planning to ensure that healthy foods are readily available and to avoid pitfalls such as opting for fast foods, which are often high in fat.

Hemoglobin and erythrocyte levels should return to normal within 2–6 weeks after childbirth. Hematocrit levels gradually rise because of hemoconcentration as extracellular fluid is excreted. Iron supplements are generally continued for 2–3 months following childbirth to replenish stores depleted by pregnancy.

The nurse assesses clinical symptoms the new mother may be experiencing. Constipation is a common problem following birth. The nurse can encourage the woman to maintain a high fluid intake to keep the stool soft. Dietary sources of fiber, such as whole grains, fruits, and vegetables, are also helpful in preventing constipation.

The nurse obtains specific information on dietary intake and eating habits directly from the woman. Visiting the mother during mealtimes provides an opportunity for unobtrusive nutritional assessment. Which foods has the woman selected? Is her diet nutritionally sound? A comment focusing on a positive aspect of her meal selection may initiate a discussion of nutrition.

The nurse needs to inform the dietitian if a woman’s cultural or religious beliefs require specific foods so that appropriate meals can be prepared for her. The nurse may also refer women with unusual eating habits or numerous questions about good nutrition. In addition, the nurse provides literature on nutrition so that the woman will have a source of appropriate information at home.

During the childbearing years, the risk for obesity becomes especially problematic for women. Consequently, it is critical to use the postpartum period to change behaviors and help promote effective weight management in women.

Nutritional Care of Formula-feeding Mothers

After birth, the formula-feeding mother’s dietary requirements return to prepregnancy levels. If the mother has a good understanding of nutritional principles, it is sufficient to advise her to reduce her daily caloric intake by approximately 300 kcal and to return to prepregnancy levels for other nutrients.

If the mother has a limited understanding of nutrition, now is the time to teach her the basic principles and importance of a well-balanced diet. Her eating habits and dietary practices will eventually be reflected in the diet of her child.

If the mother has gained excessive weight during pregnancy (or perhaps was overweight before pregnancy) and wishes to lose weight, the nurse should refer her to a dietitian or a nutritionist. A weight-reduction diet can be designed to meet nutritional needs and food preferences. Weight loss goals of 0.45–0.9 kg (1–2 lb) per week are usually suggested.

In addition to meeting her own nutritional needs, the new mother is usually interested in learning how to provide for

her baby's nutritional needs. A discussion of newborn/infant feeding that includes topics such as selecting newborn/infant formulas, formula preparation, and vitamin and mineral supplementation is appropriate and generally well received.

Nutritional Care of Breastfeeding Mothers

The nutritional needs of the mother are increased during breastfeeding. In Exemplar 33.A, Table 33–4 lists the Dietary Reference Intakes during breastfeeding for specific nutrients, and Table 33–5 provides a sample daily food plan for lactating women. It is especially important for the breastfeeding mother to consume sufficient calories because inadequate caloric intake can reduce milk volume. However, milk quality generally remains unaffected. The breastfeeding mother should increase her calories by approximately 200 kcal over her pregnancy requirement or 500 kcal over her prepregnancy requirement. This results in a total of approximately 2500–2700 kcal/day for most women.

Because protein is an important ingredient in breast milk, an adequate intake while breastfeeding is essential. An intake of 65 g/day during the first 6 months of breastfeeding, and of 62 g/day during the second 6 months, is recommended. As in pregnancy, it is important for the mother to consume adequate nonprotein calories to prevent the use of protein as an energy source.

Calcium is an important ingredient in milk production, and requirements during lactation remain the same as those during pregnancy—that is, an increase of 1000 mg/day. If the intake of calcium from food sources is not adequate, calcium supplements are recommended.

Liquids are especially important during lactation, because inadequate fluid intake may decrease milk volume. Fluid recommendations while breastfeeding are eight to ten 8-oz glasses daily, including water, juice, milk, and soups.

In addition to counseling nursing mothers on how to meet their increased nutrient needs during breastfeeding, it is important to discuss a few issues related to newborn/infant feeding. For example, many breastfeeding mothers are concerned about how specific foods they eat may affect their babies. Generally, the nursing mother need not avoid any foods except those to which she might be allergic. Occasionally, however, some nursing mothers find that certain foods may cause the baby to be colicky or to develop a skin rash. Onions, turnips, cabbage, chocolate, spices, and seasonings are common offenders. The best advice to give the nursing mother is to avoid those foods that she suspects cause distress in her baby. For the most part, however, she should be able to eat any nourishing food she wants without fear that her baby will be affected.

Alterations in the Postpartum Period

Two common postpartum alterations are hemorrhage and endometritis. **Early (primary) postpartum hemorrhage** occurs in the first 24 hours after childbirth and is the more common of the two types of postpartum hemorrhage. **Late (secondary) postpartum hemorrhage** occurs from 24 hours to 6 weeks after birth. Postpartum hemorrhage (PPH) continues to be a cause of significant maternal mortality and

morbidity, although there has been a decrease in the Western world over recent years.

The traditional definition of PPH has been a blood loss of greater than 500 mL following childbirth. That definition is currently being questioned, however, because careful quantification indicates that the average blood loss in a vaginal birth is actually greater than 500 mL, and the average blood loss after a cesarean childbirth exceeds 1000 mL (Harvey & Dildy, 2013). Clinically, PPH can be defined as a drop in maternal hematocrit levels of 10% or more from predelivery baseline or excessive bleeding that causes hemodynamic instability or the need for a blood transfusion (Sosa, 2014). Some common causes of PPH include overdistention of the uterus, abruptio placentae, placenta previa, precipitous labor, prolonged labor, retained placental tissue, and birth trauma.

Uterine atony (relaxation of the uterus) is the leading cause of early PPH. If external or internal uterine massage is not effective in controlling excessive bleeding, uterine stimulants such as oxytocin, misoprostol, ergotamine, and prostaglandin analog and will be administered (Thorpe & Laughton, 2014).

» Go to **Pearson MyLab Nursing and eText** for Chart 11: Uterine Stimulants Used to Prevent and Manage Uterine Atony.

Postpartum endometritis (metritis), an inflammation of the endometrium portion of the uterine lining occurring anytime up to 6 weeks postpartum, may occur in 30–35% of those who give birth by cesarean after an extended period of labor and ruptured membranes (Duff, 2014). Postpartum infection from vaginal delivery primarily affects the placental implantation site, the decidua, and adjacent myometrium. Bacteria that colonize the cervix and vagina gain access to the amniotic fluid during labor and postpartum and begin to invade devitalized tissue (the lower uterine segment, lacerations, and incisions). The same pathogenesis, polymicrobial proliferation and tissue invasion, is associated with cesarean delivery, but surgical trauma, additional devitalization of tissue, blood and serum accumulation, and foreign bodies (suture, staples) provide additional favorable anaerobic bacterial conditions.

Assessment findings consistent with endometritis are foul-smelling lochia, sawtooth fever (usually between 38.3°C [101.0°F] and 40°C [104°F]), uterine tenderness on palpation, lower abdominal pain, tachycardia that parallels the temperature increase, and chills (James, 2014).

Alterations in health during the antepartum and intrapartum period may cause increased risk during the postpartum period. **Table 33–16** » lists risks associated with various conditions.

Lifespan Considerations

Although the nurse considers all new mothers' physical and psychosocial needs, the adolescent mother and the mother over the age of 35 may require specific care and guidance.

Nursing Care of the Postpartum Adolescent

The adolescent mother may have special postpartum needs, depending on her level of maturity and her support system. The nurse needs to assess maternal–newborn interaction, roles of support people, plans for discharge, knowledge of childrearing, and plans for follow-up care. It is imperative

TABLE 33–16 Postpartum High-Risk Factors

Risk Factor	Condition
Preeclampsia	↑ Blood pressure ↑ Central nervous system irritability ↑ Need for bedrest → ↑ risk thrombophlebitis ↑ Risk of seizures
Diabetes	Need for insulin regulation Episodes of hypoglycemia or hyperglycemia ↓ Healing
Cardiac disease	↑ Maternal exhaustion
Cesarean birth	↑ Recovery time ↑ Pain from incision ↑ Risk of infection ↑ Length of hospitalization
Overdistention of uterus (multiple gestation, hydramnios)	↑ Risk of hemorrhage ↑ Risk of thrombophlebitis ↑ Risk of anemia ↑ Risk of breastfeeding problems (cesarean section risk) ↑ Stretching of abdominal muscles ↑ Incidence and severity of afterpains
Abruptio placentae, placenta previa	Hemorrhage → anemia ↑ Uterine contractility after birth → ↑ infection risk
Precipitous labor (<3 hours)	↑ Risk of lacerations to birth canal → hemorrhage
Prolonged labor (>24 hours)	Exhaustion ↑ Risk of hemorrhage Nutritional and fluid depletion ↑ Bladder atony and/or trauma Endometritis Uterine inversion
Trauma due to difficult birth	Exhaustion ↑ Risk of perineal lacerations ↑ Risk of hematomas ↑ Risk of hemorrhage → anemia
Extended period of time in stirrups at birth	↑ Risk of thrombophlebitis ↑ Risk of muscle, tendon, ligament, and nerve injury
Retained placenta	↑ Risk of hemorrhage ↑ Risk of infection
Uterine atony	↑ Risk of hemorrhage

that a community health service contact the adolescent shortly after discharge.

Contraception counseling is an important part of teaching the adolescent mother. The incidence of repeat pregnancies during adolescence is high. The younger the adolescent, the more likely she is to become pregnant again, and the more likely the mother is to experience complicated pregnancy and birth (Sedgh et al., 2015; Torvie et al., 2015). Nurses should be aware of the state laws that govern their jurisdiction in order to determine if providing contraception without parental consent is allowed. In states where adolescents can obtain birth control without parental consent, it is often more comfortable for the adolescent to address these issues without others being present. Adolescents also may encounter obstacles when attempting to obtain contraceptives

themselves. These may include embarrassment about discussing the topic; concerns about confidentiality, such as not wanting their parents to know or having to give permission; and lack of knowledge regarding available methods. Nurses can play a key role in overcoming these obstacles by providing teaching and referrals that address these barriers. See the exemplar on Family Planning in the module on Sexuality.

The nurse has many opportunities for teaching the adolescent about her newborn in the postpartum unit. Because the nurse is a role model, the manner in which the nurse handles a newborn greatly influences the young mother. If the father is present, he should be included in as much of the teaching as possible. If the grandparents are going to take an active role in caring for the baby, they should also be included in teaching if this is desired by the new mother.

As with older parents, a newborn examination done at the bedside gives adolescents information about their baby's health and shows possible positions for handling the baby. The nurse can also use this time to provide information about newborn and infant behavior. Parents who have some idea of what to expect from their baby are less frustrated with the baby's behavior.

The adolescent mother appreciates positive feedback about her newborn and her developing maternal responses. Praise and encouragement will increase her confidence and self-esteem. Young mothers with low self-esteem, family conflict, and few social supports are more likely to encounter postpartum depression (Cherry & Dillon, 2014). Careful assessment of these factors should be made during the postpartum period so that appropriate referrals can be provided before discharge.

Group classes for adolescent mothers should include information about newborn/infant care skills, such as taking the baby's temperature, clearing the nose and mouth, monitoring growth and development, feeding the baby, providing well-baby care, and identifying danger signals in the ill newborn. These classes can also address unique needs of teen mothers, such as peer relationships, added responsibilities, and goal setting.

Ideally, teenage mothers should visit adolescent clinics for assessments of themselves and their children for several years after birth. In this way, the adolescent's enrollment in classes on parenting, need for vocational guidance, and school attendance can be supported and followed closely. Classes in the school system for young mothers are an excellent way of helping adolescents finish school and learn how to parent at the same time. Some public high schools have on-site child care centers to assist adolescent mothers and to provide an opportunity for them to learn important child development principles and child-care tasks.

Nursing Care of the Postpartum Mother Over Age 35

The mother over age 35 may have special postpartum needs based on her birth experience, personal expectation, and lifestyle choices. Women may delay childbearing for a variety of reasons such as relationship choices, educational opportunities, career options, and financial considerations. In addition, physiologic conditions may impair normal reproductive processes. Because of their greater life experiences, older parents may also be more aware of the realities of having a child and what it means to have a baby at their age (Ladewig et al., 2017).

Although women over 35 experience the same involution process as younger mothers, they may have life experiences and education that better prepare them for parenthood. Despite the potential advantage of more life experiences, older couples must be made aware that the addition of a newborn will alter established routines and practices. In addition to routine postpartum follow-up, some women over 35 with pre-existing conditions or complications may need additional follow-up with healthcare providers other than their obstetrician.

NURSING PROCESS

During the first several postpartum weeks, the woman must accomplish the following physical and developmental tasks:

- Restore physical condition.
- Develop competence in caring for and meeting the needs of her baby.
- Establish a relationship with her new child.
- Adapt to altered lifestyles and family structure resulting from the addition of a new member.

Assessment

Postpartum Physical Examination

Comprehensive care is based on a thorough assessment that identifies individual needs or potential problems. The nurse should remember the following principles in preparing for and completing the assessment of the postpartum woman:

- Use universal precautions, including wearing gloves during this exam.
- Select a time that will provide the most accurate data. Palpating the fundus when the woman has a full bladder, for example, may give false information about the progress of involution. Ask the woman to void before assessment.
- Explain the purpose of regular assessment.
- Ensure that the woman is relaxed before starting. Perform the procedures as gently as possible to avoid unnecessary discomfort.
- Record and report the results as clearly as possible.
- Take appropriate precautions to prevent exposure to body fluids.

While performing the physical assessment, the nurse should also be teaching the woman. The assessment provides an excellent time to provide information about the body's postpartum physical and anatomic changes as well as the danger signs to report. Because the time that new mothers spend in the postpartum unit is limited, nurses need to use every available opportunity for patient education about self-care. To assist nurses in recognizing these opportunities, examples of patient teaching during the assessment are provided throughout the following discussion. See Postpartum Assessment: First 24 Hours After Birth.

Psychologic Assessment

Adequate assessment of the mother's psychologic adjustment is an integral part of postpartum evaluation. This assessment focuses on the mother's general attitude, feelings of competence, available support systems, and caregiving skills. It also evaluates her fatigue level, sense of satisfaction, and ability to accomplish her developmental tasks.

PSYCHOLOGIC ASSESSMENT RISK FACTORS Some new mothers have little or no experience with newborns and may feel totally overwhelmed. They may show these feelings by asking questions and reading all available material or by becoming passive and quiet, because they simply cannot deal with their feelings of inadequacy. Unless a nurse questions the woman about her plans and previous experience in a supportive, nonjudgmental way, the nurse might conclude that the woman is uninterested, withdrawn, or depressed. Clues indicating adjustment difficulties include the following:

- Excessive continued fatigue
- Marked depression
- Excessive preoccupation with physical status or discomfort
- Evidence of low self-esteem
- Lack of support systems
- Marital problems
- Inability to care for or nurture the newborn
- Current family crises, such as illness or unemployment.

These characteristics frequently indicate a potential for maladaptive parenting, which may lead to child abuse or neglect (physical, emotional, or intellectual) and cannot be ignored. Referrals to public health nurses or other available community resources may provide greatly needed assistance and alleviate potentially dangerous situations.

ASSESSMENT OF EARLY ATTACHMENT A nurse in any postpartum setting can periodically observe and note progress toward attachment. Research shows that fathers experience attachment feelings similar to those experienced by mothers, and the assessment should include both parents when possible. This section, however, focuses primarily on the mother's attachment process.

The following questions can be addressed in the course of nurse-patient interaction:

- Is the mother demonstrating attachment behaviors toward her newborn? To what extent does she seek face-to-face contact and eye contact? Has she progressed from fingertip touch, to palmar contact, to enfolding the baby close to her own body? Is attachment increasing or decreasing? If the mother does not exhibit increasing attachment, why not? Do the reasons lie primarily within her, the baby, or the environment?
- Is the mother inclined to nurture her baby by feeding every 2–3 hours?
- Is she progressing in her interactions with her newborn?
- Does the mother act consistently? If not, is the source of unpredictability within her or her baby?
- Does she seek information and evaluate it objectively? Does she develop solutions based on adequate knowledge of valid data? Does she evaluate the effectiveness of her maternal care and adjust appropriately?
- Is the mother sensitive to the newborn's needs as they arise? How quickly does she interpret her baby's behavior and react to cues? Does she seem happy and satisfied with the baby's responses to her efforts? Is she pleased

Postpartum Assessment: First 24 Hours After Birth

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA [†]
Vital Signs		
Blood pressure (BP): should remain consistent with baseline BP during pregnancy	High BP (preeclampsia, essential hypertension, renal disease, anxiety); drop in BP (may be normal; uterine hemorrhage)	Evaluate history of preexisting disorders and check for other signs of preeclampsia (edema, proteinuria). Assess for other signs of hemorrhage (↑ pulse, cool clammy skin).
Pulse: 60–100 beats/min	Tachycardia (difficult labor and birth, hemorrhage)	Evaluate for other signs of hemorrhage (↓ BP; cool, clammy skin).
Respirations: 12–20 breaths/min	Marked tachypnea (respiratory disease)	Assess for other signs of respiratory disease.
Temperature: 36.6°–38.0°C (98°–100.4°F)	After first 24 hours, temperature of 38.0°C (100.4°F) or higher suggests infection	Assess for other signs of infection; notify healthcare provider.
Breasts		
General appearance: smooth, even pigmentation; changes of pregnancy still apparent; one may appear larger	Reddened area (mastitis)	Assess further for signs of infection.
Palpation: depending on postpartum day, may be soft, filling, full, or engorged	Palpable mass (caked breast, mastitis); engorgement (venous stasis); tenderness, heat, edema (engorgement, caked breast, mastitis)	Assess for other signs of infection: If blocked duct, consider heat, massage, and position change for breastfeeding. Assess for further signs. Report mastitis to healthcare provider.
Nipples: supple, pigmented, intact; become erect when stimulated	Fissures, cracks, soreness (problems with breastfeeding); not erectile with stimulation (inverted nipples)	Reassess technique; recommend appropriate interventions.
Lungs		
Sounds: clear to bases bilaterally	Diminished (fluid overload, asthma, pulmonary embolus, pulmonary edema)	Assess for other signs of respiratory distress.
Abdomen		
Musculature: abdomen may be soft, have a “doughy” texture; rectus muscle intact	Separation in musculature (diastasis recti abdominis)	Evaluate size of diastasis; teach appropriate exercises for decreasing the separation.
Fundus: firm, midline; following expected process of involution	Boggy (full bladder, uterine bleeding, retained products of conception)	Massage until firm. Assess bladder, and have woman void if needed. Attempt to express clots when firm. If bogginess remains or recurs, report to healthcare provider.
May be tender when palpated	Constant tenderness (infection)	Assess for evidence of endometritis.
Cesarean section incision dressing: dry and intact	Moderate to large amount of blood or serosanguineous drainage on dressing	Assess for hemorrhage. Reinforce dressing and notify healthcare provider.
Lochia		
Scant to moderate amount, earthy odor; no clots	Large amount, clots (hemorrhage) Foul-smelling lochia (infection)	Assess for firmness and express additional clots. Begin peripad count. Assess for other signs of infection; report to healthcare provider.
Normal progression: first 1–3 days: rubra	Failure to progress normally or return to rubra from serosa (subinvolution)	Report to healthcare provider.
Following rubra: days 3–10: serosa (alba seldom seen in hospital)		
	*Possible causes of alterations are identified in parentheses.	[†] This column provides guidelines for further assessment and initial nursing actions.

(continued on next page)

Postpartum Assessment: First 24 Hours After Birth *(continued)*

PHYSICAL ASSESSMENT/ NORMAL FINDINGS	ALTERATIONS AND POSSIBLE CAUSES*	NURSING RESPONSES TO DATA†
Perineum		
Slight edema and bruising in intact perineum	Marked fullness, bruising, increasing pain (vulvar hematoma)	Assess size. Apply ice glove or ice pack. Report to healthcare provider.
Episiotomy: no redness, edema, ecchymosis, or discharge; edges well approximated	Redness, edema, ecchymosis, discharge, or gaping stitches (infection)	Encourage sitz baths; review perineal care and appropriate wiping techniques.
Hemorrhoids: none present (if present, should be small and nontender)	Full, tender, inflamed hemorrhoids	Encourage sitz baths, side-lying position, Tucks pads, anesthetic ointments, manual replacement of hemorrhoids, stool softeners, and increased fluid intake.
Costovertebral Angle (CVA) Tenderness		
None	Present (kidney infection)	Assess for other symptoms of urinary tract infection (UTI); obtain clean-catch urine. Report to healthcare provider.
Lower Extremities		
No pain with palpation; negative calf pain on ambulation	Positive findings (thrombophlebitis)	Report to healthcare provider.
Elimination		
Urinary output: voiding in sufficient quantities at least every 4–6 hours; bladder not palpable	Inability to void (urinary retention); symptoms of urgency, frequency, dysuria (UTI)	Employ nursing interventions to promote voiding; if not successful, obtain order for catheterization.
		Report symptoms of UTI to healthcare provider.
Bowel elimination: should have normal bowel movement by second or third day after birth	Inability to pass feces (constipation caused by fear of pain from episiotomy, hemorrhoids, perineal trauma)	Encourage fluids, ambulation, roughage in diet, and sitz baths to promote healing of perineum; obtain order for stool softener.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing actions.
CULTURAL ASSESSMENT§	VARIATIONS TO CONSIDER	NURSING RESPONSES TO DATA§§
Determine customs and practices regarding postpartum care. Ask the mother whether she would like fluids, and ask what temperature she prefers.	Individual preference may include room-temperature or warmed fluids rather than iced drinks.	Provide for specific request if possible. If woman is unable to provide specific information, the nurse may draw from general information regarding cultural variation.
Ask the mother what foods she would like.	Special foods or fluids to hasten healing after childbirth.	Mexican women may want food and fluids that restore hot–cold balance to the body. Women of European background may ask for iced fluids.
Ask the mother whether she would prefer to be alone during breastfeeding.	Some women may be hesitant to have someone with them when their breast is exposed.	Provide privacy as desired by the mother.
§These are only a few suggestions. We do not mean to imply this is a comprehensive cultural assessment; rather, it is a tool to encourage cultural competence.		§§This column provides guidelines for further assessment and initial nursing intervention.

Postpartum Assessment: First 24 Hours After Birth *(continued)*

PSYCHOSOCIAL ASSESSMENT/NORMAL FINDINGS	VARIATIONS TO CONSIDER*	NURSING RESPONSES TO DATA†
Psychologic Adaptation		
During first 24 hours: passive; preoccupied with own needs; may talk about her labor and birth experience; may be talkative, elated, or very quiet (the taking-in phase)	Very quiet and passive; sleeps frequently (fatigue from long labor; feelings of disappointment about some aspect of the experience; may be following cultural expectation)	Provide opportunities for adequate rest, nutritious meals and snacks that are consistent with what the woman desires to eat and drink, and opportunities to discuss birth experience in nonjudgmental atmosphere if the woman desires to do so.
Usually by 12 hours: beginning to assume responsibility; some women eager to learn; easily feels overwhelmed (the taking-hold phase)	Excessive weepiness, mood swings, pronounced irritability (postpartum blues, feelings of inadequacy, culturally proscribed behavior)	Explain postpartum blues; provide supportive atmosphere. Determine support available for mother. Consider referral for evidence of profound depression.
Attachment		
<i>En face</i> position, holds baby close, cuddles and soothes, calls by name, identifies characteristics of family members in newborn, may be awkward in providing care. Initially may express disappointment over gender or appearance of baby but within 1–2 days demonstrates attachment behaviors.	Continued expressions of disappointment with gender, appearance of baby; refusal to care for baby; derogatory comments; lack of bonding behaviors (difficulty in attachment, following expectations of cultural/ethnic group)	Provide reinforcement and support for newborn caregiving behaviors; maintain nonjudgmental approach and gather more information if caregiving behaviors are not evident.
Patient Education		
Has basic understanding of self-care activities and newborn care needs; can identify signs of complications that should be reported.	Unable to demonstrate basic self-care and newborn care activities (deficient knowledge; postpartum blues; following prescribed cultural behavior; may be cared for by grandmother or other family member)	Identify predominant learning style. Determine whether woman understands English, and provide interpreter if needed. Provide reinforcement of information through conversation and written material (remember that some women and their families may not be able to understand written materials because of language difficulties or inability to read). Provide information regarding newborn/infant care skills that are culturally consistent. Give woman an opportunity to express her feelings. Consider social service home referral for women who have no family or other support, are unable to take in information about self-care and baby care, and demonstrate no caregiving activities.
	*Possible causes of alterations are identified in parentheses.	†This column provides guidelines for further assessment and initial nursing actions.

with feeding behaviors? How much of this ability and willingness to respond is related to the baby's nature and how much to her own?

- Does the woman state that she is pleased with her baby's appearance and gender? Is she reporting experiencing pleasure during interactions with her newborn? What interferes with the enjoyment? Does she speak to the baby frequently and affectionately? Does she call him or her by name? Does she point out family traits or characteristics she sees in the newborn?
- Are there any cultural factors that might modify the mother's response? For instance, is it customary for the

grandmother to assume most of the child care responsibilities while the mother recovers from childbirth?

When these questions have been addressed and the facts assembled, the nurse's intuition and knowledge should combine to answer three more questions:

1. Is there a problem in attachment?
2. If so, what is the problem?
3. What is its source?

The nurse can then devise a creative approach to the problem as it presents itself in the context of a unique, developing mother–newborn relationship.

Diagnosis

Typical diagnoses related to the mother's needs may include any of the following:

- *Urinary Elimination, Impaired*
- *Breastfeeding, Ineffective*
- *Constipation*
- *Pain, Acute*
- *Sleep Pattern, Disturbed*

(NANDA-I © 2014)

The postpartum family's needs, which should be identified during assessment, are also frequently used for developing nursing diagnoses. Examples of these diagnoses include the following:

- *Deficient Knowledge* related to information about newborn/infant care
- *Anxiety* related to role transition
- *Family Processes, Readiness for Enhanced*

(NANDA-I © 2014)

Planning

Goals for care may include:

- The mother will demonstrate bonding with newborn as evidenced by using the *en face* position.
- The mother will meet the baby's needs as they arise.
- The mother will demonstrate adequate self-care to meet her needs as they arise.
- The mother will seek assistance as needed to care for self and newborn.
- The mother's physical condition returns to a nonpregnant state.
- The mother will gain competence in caregiving and confidence in herself as a parent.

Implementation

Care of the mother during the postpartum period requires a great deal of patient teaching in order to prepare her for discharge.

Provide Patient Teaching

An important component of postpartum nursing care is patient teaching, which must be individualized to the learning capability and readiness of the parents. Meeting the educational needs of the new mother and her family can be challenging. Each woman's educational needs will depend on her age, background, educational level, experience, and expectations. However, because the mother spends only a brief period of time in the postpartum area, it can be difficult for the nurse to identify and address individual instructional needs. Effective education provides the childbearing family with sufficient knowledge to meet many of its own health needs and to seek assistance if necessary. The nurse should have the mother exercise her choices when possible and support those choices, with the help of cultural awareness and a sound knowledge base (see Focus on Diversity and Culture: Postpartum Care).

The nurse first assesses the learning needs of the new mother through observation, sensitivity to nonverbal cues,

Focus on Diversity and Culture

Postpartum Care

In many cultures, women and their families may embrace practices involving rest, seclusion, and dietary restraint, designed to assist the woman and her baby during the period of postpartum vulnerability. Chou (2017) notes a systematic review of over 50 studies concluded that globally, most cultures identify a specified postpartum period, ranging 7 and 42 days, in which these practices are common threads. In some cultures, there is also a period of seclusion which coincides with the period of lochial flow or postpartum bleeding. It should be noted that there are multifaceted variables that formulate a woman's personal beliefs and while cultural traditions will vary, the period of physiological recovery appears to coincide with the need for physical recovery in most cultures (Chou, 2017).

and tactfully phrased questions. For example, "What plans have you made for handling things when you get home?" may elicit a response of several words and provide the opportunity for some information sharing and guidance. Some agencies also use checklists of common concerns for new mothers. The woman can check the concerns that are of interest to her.

Teaching during the postpartum period is a continuous process in which the nurse takes opportunities during interactions with the new parents to identify learning opportunities and offer teaching interventions. The nurse can also plan and implement teaching in a logical, nonthreatening way based on knowledge of and respect for the family's cultural values and beliefs. Unless the nurse believes a culturally related activity would be harmful, it can be supported and encouraged.

Nurses need to consider the mother's physical and psychosocial needs when conducting postpartum teaching. Initially, the woman may be exhausted from the birth experience, and her concentration may be impaired. Later, the new mother may be preoccupied with visitors and phone calls. Information should be delivered a little at a time and repeated to make sure that the parents understand what the nurse has discussed with them. Repetition is a valuable tool in the postpartum environment. In addition, many women are discharged during the first 48 hours after birth, making postpartum education difficult.

When the nurse is performing teaching sessions, the schedule of the woman's partner must also be considered. If the partner returns to work during the immediate postpartum period, teaching sessions in the late afternoon or early evening may be more convenient. In some cultures, such as the Hispanic culture, female relatives often assist the new mother and baby, so it is important to include any care providers in the teaching session.

Postpartum units use a variety of instructional methods, including handouts, formal classes, videos, and individual interaction. Printed materials are helpful for new mothers to consult if questions arise at home. Some facilities offer a hotline service that new mothers can call with questions or concerns. As the cultural diversity in the United States continues to grow, the need for culturally competent information is imperative. Along with culturally diverse material, teaching aids should be presented in the woman's native language when possible. Written materials should be available, and translators or language lines should be used. Many patients are now accustomed to using the internet and may prefer to

visit support groups and access educational materials online. As technology expands, the nurse must remain current with the changing technology and the resources it creates. Evaluation of learning may also take several forms, such as return demonstrations, question-and-answer sessions, and even formal evaluation tools. Follow-up phone calls after discharge provide additional evaluative information and continue the helping process for the family.

Teaching content should include information on role changes and psychologic adjustments as well as skills. Risk factors and signs of postpartum depression should be reviewed with every woman. Information is also essential for women with specialized educational needs, such as mothers who have had a cesarean birth, parents of twins, parents of a newborn with congenital anomalies, parents with other young children, parents with a child who will require long-term hospitalization, and so on. More and more women with disabilities are now having children, and they may require additional support and education. Anticipatory guidance can help prepare parents for the many changes they will experience with a new family member.

Following discharge, various services are available in most communities to meet the needs of the postpartum family. These services range from educational, such as classes on nutrition, exercise, newborn/infant care, and parenting, to specific healthcare programs, such as well-baby checks, immunization clinics, family-planning services, new-mother support groups, and more. Some are offered by private caregivers, whereas others are the domain of city, county, state, or federal agencies. In all cases, the goal is to help ensure that all family members have the opportunity to meet healthcare needs, regardless of their resources.

Home healthcare is an important form of community-based nursing care offered to postpartum families. Home care visits and phone contacts help ensure that new parents have the necessary skills and resources to care for their baby.

Promote Comfort and Well-Being

The nurse can promote and restore maternal physical well-being by monitoring uterine status, vital signs, cardiovascular status, elimination patterns, nutritional needs, sleep and rest, and learning needs. Some women also require medication to relieve pain, treat anemia, provide immunity to rubella, and prevent development of antibodies in the non-sensitized Rh-negative woman. To promote immunization status, the CDC (2014a) recommends that postpartum patients receive Tdap, and, depending on the time of year, the flu vaccine as indicated. Most postpartum women need nursing interventions to promote their comfort and relieve stress.

» Go to **Pearson MyLab Nursing and eText** for Chart 12: Essential Information for Common Postpartum Drugs.

It is important to ask the woman if she believes any special measures will be particularly effective and to offer her choices when possible. It is also important to remember that in some cultures or religions, such as Orthodox Judaism, women are prohibited from certain activities during the Sabbath, such as turning on electric lights and signing consent forms, and may need assistance with opening the wrappers of sanitary pads, tearing toilet paper, and using the call button to summon the nurse. The nurse and patient should discuss this prior to the start of the Sabbath.

Focus on Integrative Health

Lysine

Lysine, an essential amino acid, has been identified as a supplement that decreases the incidence of pain following an episiotomy. Lysine is available as a supplement. The recommended adult dosage is 12 mg/kg per day. It is also present in dietary sources, including meat, cheese, fish, eggs, soybeans, and nuts.

Many nursing interventions are available for the relief of perineal discomfort. Before selecting a method, the nurse needs to assess the perineum to determine the degree of edema and other problems. Application of ice to an episiotomy can promote comfort. The warmth of the water in the sitz bath provides comfort, decreases pain, and promotes circulation to the tissues, which promotes healing and reduces the incidence of infection. Gel pads, ice packs, and cool sitz baths have been found to be effective in reducing perineal edema and reducing the response of nerve endings that cause perineal discomfort (Brincat et al., 2015).

Complementary health approaches such as the use of lysine may be helpful in decreasing discomfort associated with an episiotomy (see Focus on Integrative Health: Lysine). In addition, patient teaching is imperative to promote healing of the perineum following delivery (see Patient Teaching: Perineal Care).

Some mothers experience hemorrhoidal pain after giving birth. Relief measures include the use of sitz baths, topical anesthetic ointments, rectal suppositories, or witch hazel pads applied directly to the anal area. The woman may be taught to digitally replace external hemorrhoids back into

Patient Teaching

Perineal Care

Many women do not consider the episiotomy to be a surgical incision. Discussion helps them understand the importance of good wound care.

- Describe the process of wound healing. Discuss the risk of contamination of the episiotomy or laceration repair by bacteria from the anal area.
- Explain techniques that are used to keep the episiotomy clean and promote healing, such as
 - a. sitz bath, or
 - b. use of a peribottle following each voiding or defecation. Wash with soap and water at least once every 24 hours. Change peripads at least four times per day.
- Demonstrate correct use of the peribottle or sitz bath if necessary.
- Describe comfort measures:
 - a. Ice pack, glove, or tea pad immediately following birth
 - b. Sitz bath
 - c. Judicious use of analgesics or topical anesthetics
 - d. Tightening buttocks before sitting.
- Identify signs of suture line infection. Advise the woman to contact her caregiver if infection develops.
- Encourage discussion, and provide printed handouts. Some of this content may also be covered during a small postpartum class.

Patient Teaching

Common Postpartum Concerns

Several postpartum occurrences cause special concern for mothers. The nurse will frequently be asked about the following events:

Source of Concern	Explanation
Gush of blood that sometimes occurs when she first arises	Result of normal pooling of blood in the vagina when the woman lies down to rest or sleep. Gravity causes blood to flow out when she stands.
Passing clots	Blood pools at the top of the vagina and forms clots that are passed upon rising or sitting on the toilet.
Night sweats	Normal physiologic occurrence that results as the body attempts to eliminate excess fluids that were present during pregnancy. May be aggravated by a plastic mattress pad.
Afterpains	More common in multiparas. Caused by contractions and relaxation of uterus. Increased by oxytocin and breastfeeding. Relieved with mild analgesics and time.
"Large stomach" after birth and failure to lose all weight gained during pregnancy	The baby, amniotic fluid, and placenta account for only a portion of the weight gained during pregnancy. The remainder takes approximately 6 weeks to lose. Abdomen also appears large because of decreased muscle tone. Postpartum exercises will help.

her rectum. Hand washing to prevent contamination to the vagina is essential. The woman may also find it helpful to maintain a side-lying position when possible and to avoid prolonged sitting. The mother is encouraged to maintain an adequate fluid intake, and stool softeners are administered to ensure greater comfort with bowel movements. Mothers should be advised to avoid straining with bowel movements, because this can increase the severity and discomfort associated with hemorrhoids. The hemorrhoids usually disappear a few weeks after birth if the woman did not have them before her pregnancy.

To reduce afterpains, the nurse can suggest that the woman lie prone, with a small pillow under her lower abdomen, and explain that the discomfort may feel intensified for approximately 5 minutes but then diminishes greatly, if not completely. The prone position applies pressure to the uterus and, therefore, stimulates contractions. When the uterus maintains a constant contraction, the afterpains cease. Additional nursing interventions include a sitz bath (for warmth), positioning, ambulation, or administration of an analgesic agent. For breastfeeding mothers, an analgesic administered 30 minutes to an hour before nursing helps promote comfort and enhances maternal–newborn interaction.

Discomfort may be caused by immobility. The woman who has been in stirrups or has pulled back on her legs for an extended period of time may experience muscular aches from such extreme positioning. It is not unusual for women to experience joint pains and muscular pain in both arms and legs, depending on the effort exerted during the second stage of labor. Early ambulation is encouraged to help reduce the incidence of complications, such as constipation and thrombophlebitis. It also helps promote a feeling of general well-being. The nurse provides information about ambulation and the importance of monitoring any signs of dizziness or weakness. Despite best efforts by the nurse to teach the mother about postpartum care and anticipated changes following delivery, certain occurrences may cause concern for mothers (see Patient Teaching: Common Postpartum Concerns).

Enhance Attachment

The first few hours—and even minutes—after birth are an important period for the attachment of mother and newborn.

If contact can occur during the first hour after birth, the newborn will be in a quiet state and able to interact with parents by looking at them. Newborns also turn their heads in response to a voice. If possible and desired by the mother, the nurse may place the newborn on the woman's chest so that she can directly see her baby (**Figure 33–59** ). This early interaction, particularly skin-to-skin contact between mother and baby, promotes attachment, early breastfeeding, and family interaction.

Source: Courtesy of Brigitte Hall, RNC, MSN, IBCLC.

Figure 33–59  Mother and newborn skin-to-skin.

The first parent–newborn contact may be brief (a few minutes), and it may be followed by a more extended contact after the mother completes other uncomfortable procedures (expulsion of the placenta and suturing of the episiotomy or laceration). When the newborn is returned to the mother, the nurse can assist her to begin breastfeeding if the woman so desires. The baby may seek out the mother's breast, and early contact between mother and newborn can greatly affect breastfeeding success. Even if the newborn does not actively nurse, he or she can lick, taste, and smell the mother's skin. This activity by the newborn stimulates the maternal release of prolactin, which promotes the onset of lactation. These early interactions are associated with greater breastfeeding success.

Darkening the birthing room by turning out most of the lights causes newborns to open their eyes and gaze around. This in turn enhances eye-to-eye contact with the parents. (*Note:* If the healthcare provider needs a light source, the spotlight can be left on.) Treatment of the newborn's eyes with antibiotic eye ointment may also be delayed up to an hour after birth (AAP, 2016a). Many parents who establish eye contact with the newborn are content to quietly gaze at their baby. Others may show more active involvement by touching or inspecting the newborn. Some mothers talk to their babies in a high-pitched voice, which seems to be soothing to newborns. Some couples verbally express amazement and pride when they see they have produced a beautiful, healthy baby. Their verbalization enhances feelings of accomplishment and ecstasy.

Encourage both parents to do whatever they feel most comfortable doing. Some parents prefer only limited contact with the newborn immediately after birth and, instead, desire private time together in a quiet environment. In spite of the current zeal for providing immediate attachment opportunities, nursing personnel need to be aware of parents' wishes. The desire to delay interaction with the newborn does not necessarily imply a decreased ability of the parents to bond with their newborn.

Discuss Suppression of Lactation

For the woman who chooses not to breastfeed, lactation may be suppressed by mechanical inhibition. Although signs of engorgement do not usually appear until the second or third day postpartum, engorgement is best prevented by beginning mechanical methods of lactation suppression as soon as possible after birth. Ideally, this involves having the woman begin wearing a supportive, well-fitting bra within 6 hours after birth. Some women may prefer a tight-fitting sports bra. The woman should wear the bra continuously until lactation is suppressed (usually 5–7 days) and remove it only to shower. The bra provides support and eases the discomfort that can occur with tension on the breasts because of fullness. Ice packs should be applied over the axillary area of each breast for 20 minutes four times daily. This practice should begin soon after birth. In addition, ice is useful in relieving discomfort if engorgement occurs.

The nurse should advise the mother to avoid any stimulation of her breasts by her baby, herself, breast pumps, or her sexual partner until the sensation of fullness has passed. Such stimulation increases milk production and delays the suppression process. Heat is avoided for the same reason;

therefore, the mother is encouraged to let shower water flow over her back rather than her breasts.

Some mothers may inquire about suppression medications used in the past for nonnursing mothers. The nurse should inform these patients that because of concerns related to side effects, such medications are no longer used. Mechanical, rather than pharmacologic, methods are now employed.

Relieve Emotional Stress

The birth of a child, with the changes in role and the increased responsibilities it produces, is a time of emotional stress for the new mother. During the early postpartum period, the mother may be emotionally labile; mood swings and tearfulness are common. Initially the mother may repeatedly discuss her experiences of labor and birth. This allows the mother to integrate her experiences. If she believes that she did not cope well with labor, she may have feelings of inadequacy and may benefit from reassurance that she did well. Some women feel that they did not have any perception of time during the labor and birth and want to know how long it really lasted, or they may not remember the entire experience. In this case, it is helpful for the nurse to talk with the woman and provide the information that she is missing and desires.

During this time, the new mother must also adjust to the loss of her fantasized child and accept the child she actually has. This task may be more difficult if the child is not of the desired gender or if the baby has birth defects. Women who gave birth prematurely may experience guilt or have feelings of inadequacy. Immediately after the birth (the taking-in period), the mother is focused on bodily concerns and may not be fully ready to learn about personal and newborn care. Following the initial dependent period, the mother becomes very concerned about her ability to be a successful parent (the taking-hold period). During this time, the mother requires reassurance that she is effective. She also tends to be receptive to teaching and demonstration designed to assist her in mothering successfully.

The depression, weepiness, and "let-down feeling" that characterize the postpartum blues are often a surprise for the new mother. She requires reassurance that these feelings are normal, an explanation of why they occur, and a supportive environment that permits her to cry without feeling guilty. The Edinburgh Postnatal Depression Scale (EPDS) (see Box 28–4 in the exemplar on Postpartum Depression in the module on Mood and Affect) is a widely used, validated screening tool that provides the nurse with clear information differentiating normal postpartum adjustment from postpartum depression. It consists of a 10-item questionnaire in which each patient response is given a score from 0 to 3. A total score greater than 12 is strongly associated with depression and indicates a need for intervention (Roy-Burne, 2016). See the exemplar on Postpartum Depression in the module on Mood and Affect for an in-depth discussion of postpartum depression.

Promote Rest

Energy is needed to make the psychologic adjustments to a new baby and to assume new roles, so it is helpful for the new mother to know that fatigue may persist for several weeks or even months. Although most new mothers feel tired, if they have perceived the pregnancy and birth as a natural process, they tend to view themselves as healthy and

well. Mothers who have other children may feel overwhelmed trying to meet the needs of the larger family.

Physical fatigue can affect other adjustments and functions of the new mother as well. For example, fatigue can reduce milk flow, thereby increasing problems with establishing breastfeeding. Persistent fatigue is especially common when mothers attempt to perform activities while the baby is napping instead of resting themselves. The nurse teaches women that failure to get adequate rest can lead to chronic fatigue and should be avoided. Fatigue can be a symptom of postpartum depression and should be discussed with the healthcare provider if symptoms continue or are accompanied by other signs of depression. Severe ongoing fatigue can also be a symptom of a thyroid disorder and should be evaluated by a healthcare provider (Gabbe et al., 2012).

Most mothers view the postpartum period as a time for recuperation. In many non-Western cultures, the 40 days following the birth are a time of recovery, when female relatives or friends assist the new mother in her daily activities (Zerwekh & Garneau, 2014). In Mexico, during the first 7 days, non-household members are not permitted to visit or enter the home. Mothers receive help with housework and

eat special foods. It is recommended that they not be exposed to wind, and bathing is prohibited.

Specific groups of mothers at a higher risk for postpartum fatigue include the following:

- Mothers of multiples
- Mothers with babies who are still hospitalized and who engage in multiple trips to the hospital to visit their babies
- Mothers of newborns with birth defects or special needs
- Mothers who lack social and familial support
- Mothers who return to work before the advised 6-week time period
- Mothers who have been on extended bedrest during the pregnancy.

Discuss Sexual Activity and Contraception

Typically, postpartum couples resume sexual intercourse once the episiotomy is healed and the lochial flow has stopped (Leeman & Rogers, 2012). Because this usually occurs by the end of the third week, before the 6-week follow-up, it is important that the woman and her partner have

Evidence-Based Practice

Optimizing Adherence to the Postpartum Plan of Care

Problem

In the weeks following birth, the plan for postpartum care may become fragmented among healthcare providers due to inconsistent communication between the inpatient and outpatient settings. As a result, as many as 40% of women do not attend a postpartum visit (ACOG, 2016c).

Evidence

The postpartum visit provides the opportunity for the patient and the healthcare provider to discuss both physical and psychosocial concerns, to establish a plan for contraception, and to determine which healthcare provider will assume primary care. In addition, a full physical examination is conducted, including a gynecologic exam, Pap smear, breast exam, and evaluation of general health after delivery (Haran et al., 2014). Women diagnosed with gestational diabetes, hypertensive disorders of pregnancy, or preterm birth should be counseled about these disorders and the associated risks for future pregnancies. The postpartum visit provides an opportunity for women to ask questions about their labor experience, the childbirth process, and any complications that may have occurred (ACOG, 2016c).

Implications

The American College of Obstetricians and Gynecologists (ACOG, 2016c) make the following recommendations regarding optimizing postpartum care:

- Provide anticipatory guidance during antenatal visits to initiate the postpartum plan of care
- Establish a single healthcare provider to assume responsibility for coordinating the woman's postpartum care, including contact information and written instructions
- Discuss pregnancy complications with respect to risks for future pregnancies and recommendations to optimize maternal health

- Emphasize the need for early postpartum follow-up for women with hypertensive disorders and other complications of pregnancy
- Explain the need for a comprehensive postpartum visit within the first 6 weeks after birth, including a full assessment of physical, social, and psychological well-being
- Establish a system to ensure that women who desire long-acting reversible contraception, or any other form of contraception, receive it during the postpartum visit
- Recommend anticipatory guidance at the postpartum visit that includes newborn/infant feeding, expressing breast milk if returning to work or school, postpartum weight retention, sexuality, physical activity, and nutrition
- Determine who will assume primary responsibility for the woman's ongoing care (Ob-Gyn or other healthcare provider)

Critical Thinking Application

1. Do you have any biases that may hinder your ability to provide adequate anticipatory guidance for optimization of postpartum care? Think about a variety of situations that may present opportunities for bias, including caring for patients of different cultures and spiritual backgrounds, patients from different age groups, patients from different sexual orientations and marital status, and patients experiencing dysfunctional family dynamics.
2. How will you act as an advocate for a woman who chooses to either breastfeed or bottle feed her baby?
3. How would you approach postpartum teaching about contraceptives for a 17-year-old single mother and a 27-year-old married mother with two children?
4. What are some strategies to improve adherence to the postpartum plan of care? Consider the nurse-patient relationship and how it relates to communication, patient teaching, and collaboration.

information about what to expect. The nurse may inform the couple that because the vaginal vault is “dry” (lacking estrogen), some form of water-soluble lubrication, such as K-Y jelly or Astroglide, may be necessary during intercourse. The woman-superior and side-lying coital positions may be preferable, because they allow the woman to control the depth of penile penetration. Couples should be counseled that intercourse may be uncomfortable for the woman for some time and that patience is imperative.

Breastfeeding couples should be cautioned that during orgasm, milk may spurt from the nipples because of the release of oxytocin. Some couples find this spurt to be pleasurable or amusing, but others choose to have the woman wear a bra during sexual activity. Nursing the baby before lovemaking reduces the chance of milk release.

Other factors may inhibit satisfactory sexual experiences. For example, the baby’s crying may be a distraction, the woman’s changed body may seem unattractive to her or her partner, maternal sleep deprivation may reduce the woman’s desire, or the woman’s physiologic response to sexual stimulation may be altered because of hormonal changes. By 3 months postpartum, many couples return to prepregnant levels of sexual interest and activity; however, this is highly variable. It is not abnormal for women, especially when breastfeeding, to experience decreased libido for several months. Decreased libido can be associated with hormonal changes, fatigue, stress, and lack of time because of family and work demands.

With anticipatory guidance during the prenatal and postpartum periods, the couple can be forewarned of potential temporary problems. Anticipatory guidance is enhanced if the couple can discuss their feelings and reactions as they experience them.

» Go to **Pearson MyLab Nursing and eText** for Chart 13: *Resuming Sexual Activity After Childbirth*.

Information on contraception should be provided as part of discharge teaching if it is permissible within the healthcare agency. The nurse can also be an important resource for the woman and her partner during postpartum follow-up. Couples typically choose to use contraception to control the number of children they will have or to determine the spacing of future children. Some religious-based hospital facilities prohibit nurses and other healthcare providers from discussing contraception. If the nurse is discussing birth control, it is important to emphasize that in choosing a specific method, consistency of use is essential. The nurse needs to identify the advantages, disadvantages, risks, and contraindications of the various methods to help the couple, or the single mother, make an informed choice about the most practical and compatible method. Breastfeeding women are commonly concerned that a contraceptive method will interfere with their ability to breastfeed. Breastfeeding women should be given available options and choose the method that best fits their lifestyle, financial situation, and personal preference.

Promote Well-being After Cesarean Birth

The mother who has a cesarean birth usually does extremely well postoperatively. Most women are ambulating by the day after the surgery. By the second postpartum day, the woman usually can shower, which seems to provide a mental as well as physical lift. Most women are discharged by the third day after birth.

The chances of pulmonary infection, however, are increased after a cesarean birth because of immobility after the use of narcotics and sedatives and because of the altered immune response in postoperative patients. Therefore, nurses should encourage the woman to cough and deep breathe every 2–4 hours while awake until she is ambulating frequently.

Nurses should also encourage leg exercises every 2 hours until the woman is ambulating. These exercises increase circulation, help prevent thrombophlebitis, and aid intestinal motility by tightening abdominal muscles.

Many of the complications that historically occurred after a cesarean birth were related to postpartum care practices in which mothers were encouraged to stay in bed for prolonged periods of time. Early ambulation, eating a low-roughage diet shortly after birth, and breastfeeding or newborn feeding soon after birth all enhance the recovery of the mother and decrease complications in the postoperative period. Even though a cesarean birth is an operative procedure, most women giving birth are relatively healthy and, therefore, are less likely to experience postoperative complications when compared with other surgical patients.

The nurse monitors and manages the woman’s pain experience during the postpartum period. Sources of pain include incisional pain, gas pain, referred shoulder pain, periodic uterine contractions (afterbirth pains), discomfort related to breastfeeding, and pain from voiding, defecation, or constipation. Nursing interventions are oriented toward preventing or alleviating pain or helping the woman cope with pain and include the following:

- Administer analgesics as needed, especially during the first 24–72 hours after childbirth. Use of analgesics relieves the woman’s pain and enables her to be more mobile and active. Some facilities administer ibuprofen on a continuous basis in the early postpartum period to decrease swelling, reduce pain, and lower the need for, or frequency of, narcotic agents.
- Promote comfort through proper positioning, frequent changes of position, massage, back rubs, oral care, and reduction of noxious stimuli, such as noise and unpleasant odors.
- Encourage visits by significant others, including the newborn and older children. These visits distract the woman from the painful sensations and help reduce her fear and anxiety.
- Encourage the use of breathing, relaxation, guided imagery, and distraction (e.g., stimulation of cutaneous tissue) techniques taught in childbirth preparation class.

Epidural analgesia administered just after the cesarean birth is an effective method of pain relief for most women in the first 24 hours following birth. Other methods of pain relief that may be ordered by the physician include patient-controlled analgesia and a continuous peripheral nerve block. A continuous epidural infusion is administered via an electric pump through an epidural catheter that is left in place following birth. The device has a button the woman can depress if additional pain relief is needed. Nursing assessments are hourly for women with a continuous epidural infusion in place and include vital signs, level of pain, amount of drug received, and amount of self-administration. The tubing is inspected to ensure that connections are

maintained, because movement by the woman in bed could disrupt the line. The epidural site should also be assessed to ensure that the catheter has not been displaced.

Although the use of general anesthesia continues to decline, women who receive general anesthesia warrant additional assessments in the immediate postpartum period. Vital signs should be monitored continually until the woman has regained consciousness. Cardiopulmonary equipment should be in close range, with cardiac monitoring available as needed. The pulse oximeter should be used to determine the woman's oxygen status.

If a general anesthetic was used, abdominal distention may produce marked discomfort for the woman during the first few postpartum days. Measures to prevent or minimize abdominal distention include leg exercises, abdominal tightening, ambulation, avoiding carbonated or very hot or cold beverages, and avoiding the use of straws. Medical intervention for gas pain includes using rectal suppositories and enemas to stimulate passage of flatus and stool and encouraging the woman to lie on her left side. Lying on the left side allows the gas to pass from the descending colon to the sigmoid colon so that it can be expelled more readily.

Many physicians also order a nonsteroidal anti-inflammatory drug (NSAID) in addition to the previously mentioned agents once the woman is tolerating oral fluids well. NSAIDs assist with decreasing inflammation and do not have the negative side effects associated with many narcotics, such as sedation and constipation. NSAIDs are often given in combination with narcotic agents during the immediate postpartum period and often result in a decreased intake of narcotic agents.

Sometimes, women who have a cesarean birth have other discomforts that can be relieved with pharmacologic interventions. The nurse assesses the woman for other symptoms, such as nausea, itching (typically related to the morphine used in the epidural), and headache. If the woman is experiencing nausea, an antiemetic can be administered. Itching can also be relieved with pharmacologic interventions. NSAIDs are effective in managing headaches and other body aches.

The nurse can minimize discomfort and promote satisfaction as the mother assumes the activities of her new role. Instruction and assistance in assuming comfortable positions when holding or breastfeeding the baby will do much to increase the mother's sense of competence and comfort. The nurse should teach the woman to splint her incision when she ambulates to decrease pulling on the incision and the discomfort created by contraction of the abdominal muscles.

Other measures are aimed at needs that are unique to the woman who has had an operative birth. These measures include the following:

- Assess for the return of bowel sounds in all four quadrants every 4 hours, and assess the consistency of the abdomen. Women with a firm, distended abdomen may have difficulty passing flatus or stool.
- Assess the intravenous site, flow rate, and patency of the intravenous tubing.
- Monitor the condition of surgical dressings or the incision site using the REEDA scale (redness, edema, ecchymosis, discharge, and approximation of the suture line) along with skin temperature at and around the incision line.

Provide Care for the Woman Who Places Newborn for Adoption

Women who choose to place their babies for adoption are more likely to be single, Caucasian, never married adolescents than Hispanic or African American women of any age. The majority of women who relinquish their children have higher education and income levels, higher future educational or career goals, and mothers and fathers who favor adoption. Still others may feel that they are not emotionally ready for the responsibilities of parenthood, or their partner may strongly disapprove of the pregnancy. These and many other reasons may prompt the woman to relinquish her baby. The number of women who give their babies up voluntarily, however, is shrinking because of an increase in the acceptability of single motherhood and teenage parenting (Martin et al., 2015). Less than 1% of all births in the United States result in an adoption (Center for American Progress, 2015).

Increasingly, babies are being placed in foster care because of the mother's illicit drug use, past history of abusing children, or incarceration. The number of babies placed for adoption because of these circumstances is unknown, but several factors must be met, including clear evidence that the parent is unfit and that severing the parental rights is in the best interest of the child (Child Welfare Information Gateway, 2013a). Many of these babies may be placed with relatives or in long-term foster care.

In the 1990s, a number of babies were abandoned and left to die because the mothers did not want them and did not want others to know of their pregnancies. Starting in 1997, Infant Safe Haven Acts were passed that provided a means for a mother to place her baby up for adoption anonymously. The legislation was enacted to protect newborns from death caused by abandonment. Today, all 50 states plus the District of Columbia and Puerto Rico have legislation in place to ensure that relinquished babies are left with safe providers who can care for them and provide medical services. The relinquishing mother is protected from prosecution for neglect or abandonment under the law (Child Welfare Information Gateway, 2013b).

The mother who places her baby for adoption usually experiences intense ambivalence. Several factors contribute to this. First, there are social pressures against giving up one's child. In addition, the woman has usually made considerable adjustments in her lifestyle to carry and give birth to this child, and she may be unaware of the growing bond between her and her child. Her attachment feelings may peak upon seeing her baby. At the same time, she may not have told friends and relatives about the pregnancy and, therefore, may lack a support system to help her work through her feelings and support her decision making. After childbirth, the mother needs to complete a grieving process to work through her loss and its accompanying grief, loneliness, guilt, and other feelings. Mothers who relinquish their newborns and have open adoptions experience less grief than those who have closed adoptions (Castle, 2012). When the relinquishing mother is admitted to the birthing unit, the nurse should be informed about the mother's decision to relinquish the baby. The nurse needs to respect any special requests for the birth and encourage

the woman to express her emotions. After the birth, the mother should be allowed access to the baby; she is the one who will decide whether she wants to see the newborn. Seeing the newborn often aids in the grieving process and provides an opportunity for the birth mother to say good-bye. When the mother sees her baby, she may feel strong attachment and love. The nurse needs to assure the woman that these feelings do not mean that her decision to relinquish the child is wrong; relinquishment is often a painful act of love.

Postpartum nursing care also includes arranging ongoing care for the relinquishing mother. Some mothers may request an early discharge or a transfer to another medical unit. When possible, the nurse supports these requests.

Evaluation

Anticipated outcomes of comprehensive nursing care of the postpartum family include the following:

- The mother is reasonably comfortable and has learned pain relief measures.

- The mother is rested and understands how to add more activity during the next few days and weeks.
- The mother's physiologic and psychologic well-being have been supported.
- The mother verbalizes her understanding of self-care measures.
- The new parents demonstrate how to care for their baby.
- The new parents have had opportunities to form attachment with their baby.
- The new parents have information and access to community resources. This includes adoptive and relinquishing parents.

An additional purpose of care evaluation is to determine if further care is needed based on the postpartum family's outcomes. If the outcomes are not being met, the nurse may choose to continue or revise the plan of care for optimal outcome attainment (see Nursing Care Plan: A Postpartum Patient).

Nursing Care Plan

A Postpartum Patient

Cathy McGhee delivered Callie, a healthy girl, 4 days ago. At the time of birth, Ms. McGhee was able to put the newborn to breast within the first hour. Callie was very alert at birth, latching on without difficulty. Ms. McGhee was able to breastfeed successfully

during the remainder of her hospital stay. Today, Ms. McGhee has returned to the clinic complaining of pain and swelling in both breasts and a low-grade fever. She has also had trouble getting Callie to latch on.

ASSESSMENT	DIAGNOSIS	PLANNING
<p>Subjective: Breast pain and tenderness, anxiety</p> <p>Objective: Temperature 38°C (100.4°F). Breast tissue is firm, warm, and skin is shiny and taut. Swelling in axillary area and flat-tened nipples.</p>	<ul style="list-style-type: none"> ■ <i>Acute Pain</i> related to increased breast fullness secondary to increased blood supply to breast tissue causing swelling of tissue around milk ducts <p>(NANDA-I © 2014)</p>	<ul style="list-style-type: none"> ■ The patient will remain free of breast fullness and pain. ■ The patient will experience decreased swelling of breast tissue. ■ The patient will exhibit no signs of breast tenderness or firmness.

IMPLEMENTATION

- Instruct woman to breastfeed frequently.
- Instruct woman to breastfeed at least 10–15 minutes on each breast per feeding.
- Assist woman to pre-express milk onto nipple or baby's lips.
- Initiate pumping or manually express milk at the beginning of the feeding.
- Instruct woman to pump, hand express, or massage to empty breast when feedings are missed.
- Administer analgesics before breastfeeding.
- Apply warm and/or cold compresses before breastfeeding.
- Apply fresh cabbage leaves to the breast between feedings.

EVALUATION

- No evidence of swelling found in breast tissue.
- Pain has decreased.
- Breast tissue is soft and without tenderness.

CRITICAL THINKING

1. The nurse preparing Ms. McGhee for discharge notices that Callie was breastfed 3 hours ago but for only 3–4 minutes on each breast. Ms. McGhee states that the baby is very sleepy and has slept most of the day. She says she will wait to breastfeed again until she is home and more comfortable, because her breasts hurt and are swollen. The nurse assesses the woman's breasts, which are firm and tender, with some swelling under the arm. What should the nurse instruct the patient to do before discharge? What can Ms. McGhee do to minimize the breast fullness and discomfort?
2. A postpartum nurse is teaching a breastfeeding class to new mothers. During the class, one woman states she had a problem with engorgement after the birth of her first child and wants to know what she can do differently this time in order to avoid the problem again. What strategies can the nurse suggest to help prevent engorgement?

REVIEW Postpartum Care

RELATE Link the Concepts and Exemplars

Linking the exemplar of postpartum care with the concept of family:

1. What challenges would you anticipate for the new family following the delivery of twins or triplets?
2. How might you assess a family's ability to incorporate a newborn into the family unit?

Linking the exemplar of postpartum care with the concept of stress and coping:

3. What stressors must the mother of a newborn cope with after discharge?
4. How do these stressors impact the risk for child abuse? What nursing implementations and strategies can the nurse offer the new family to reduce this risk?

REFLECT Apply Your Knowledge

Jessica Riley is a single, 18-year-old mother with a 1-year-old son, Ryan. Jessica has had no contact with Ryan's father since before Ryan was born. Jessica and Ryan live in a small, one-bedroom apartment with Jessica's boyfriend, Casey. She is currently pregnant with Casey's baby.

Jessica took the evening off from work because she was feeling very tired. She fixes dinner for Casey before he has to go to work. While she is fixing dinner, Ryan begins crying in the other room, and Jessica interrupts making dinner to attend to his needs.

When they all finally sit down to eat, Casey throws his plate against the wall and screams at her for making a "lousy dinner." He then proceeds to yank her out of her chair, hit her in the back, and knock her to the floor. She gets up crying, and he hits her in the abdomen and says, "You care more about these damn brats than me and what I want." She falls to the floor, and he kicks her in the abdomen. Jessica screams in

pain. She somehow gets off the floor and makes it into the bedroom. The neighbor in the next apartment hears the commotion and calls the police.

When the police arrive, they find Jessica on the bed doubled over and crying, Ryan in his crib crying, and Casey watching TV while smoking a joint. The police note that Jessica is pregnant and call for an ambulance. They ask her whether she was hit, and she tells them no. The police tell Jessica they are taking Casey in for drug possession and further questioning. Jessica calls her mother and asks her to come get Ryan and then meet her at the hospital.

When the paramedics arrive, they start an intravenous line, place Jessica on oxygen, and transport her to the hospital. At the hospital, the OB triage nurse sends her directly to the labor and delivery unit. Jessica delivers a healthy baby girl later in the evening. Because Jessica sustained a small abruption to the placenta, the midwife and physician suspect trauma from abuse.

In the immediate postpartum period, the midwife talks with Jessica privately. Jessica is told that she had a small abruption and that the placenta had an infarct. The midwife tells Jessica that in these situations, trauma is suspected. The midwife also shares with Jessica that sometimes women in abusive relationships get hit or kicked in the abdomen. Jessica cries and admits to the midwife that this is what happened, but she insists that Casey didn't mean to do it and is sure he will never do it again. She tells the midwife she will not press charges.

Social work is called for referral before Jessica goes home. The nurse midwife tells Jessica that a social work referral is required because of the risk of intimate partner violence and drug charges against Casey. Jessica worries about this, fearing that Casey will be angry. The social worker makes a visit the day after Jessica and the baby are discharged; Jessica is relieved that Casey is not home. Jessica tells the social worker everything is fine and that there are really no problems.

1. As the nurse caring for Jessica, what nursing diagnosis would be appropriate for the plan of care?
2. What risks to parental attachment do you anticipate for Jessica and her new daughter?
3. Create a teaching plan for Jessica before discharge.

Exemplar 33.D Newborn Care

Exemplar Learning Outcomes

33.D Summarize care of newborns.

- Summarize the adaptations of the newborn to extrauterine life.
- Outline alterations found in newborns.
- Summarize collaborative therapies used by interprofessional teams for newborns with alterations.
- Illustrate the nursing process in providing culturally competent care to the newborn.

Overview

The newborn (neonatal) period is the time from birth through the 28th day of life. During this period, the newborn adjusts from intrauterine to extrauterine life. The transition from fetus to newborn is the most complex physiologic adaptation that occurs in the human experience and involves virtually every organ system of the body (Hillman, Kallapur, & Jobe, 2012). The nurse needs to be knowledgeable about a newborn's normal physiologic and behavioral adaptations and be able to recognize alterations.

Adaptations to Extrauterine Life

The first 6 hours of life, in which the newborn's body systems adapt to extrauterine life, is called the period of **neonatal transition**. The respiratory and cardiac systems undergo the most dramatic changes within the first minutes after birth.

Respiratory Adaptations

To begin life as a separate being, the newborn must immediately establish respiratory gas exchange in conjunction with marked circulatory changes. These radical and rapid changes are crucial to the maintenance of extrauterine life.

Initiation of Respiration

To maintain life, the lungs must function immediately after birth. Two changes are necessary for this to happen:

1. Pulmonary ventilation must be established through lung expansion.
2. A marked increase in the pulmonary circulation must occur.

The first breath of life—the gasp in response to mechanical and reabsorptive, chemical, thermal, and sensory changes associated with birth—initiates the serial opening of the alveoli. So begins the transition of the newborn from a fluid-filled environment to an air-breathing, independent, extrauterine life. **Figure 33–60** » summarizes the initiation of respiration.

During the latter half of gestation, the fetal lungs continuously produce fluid. This fluid expands the lungs almost completely, filling the air spaces. Production and maintenance

of a normal volume of fetal lung fluid are essential for normal lung growth (Fraser, 2014). Through intermittent fetal breathing movements, the fetus practices respiration, develops the chest wall muscles and the diaphragm, and regulates lung fluid volume. Some of the lung fluid moves up into the trachea and into the amniotic fluid; it is then swallowed by the fetus.

During delivery, the fetal chest is compressed, increasing intrathoracic pressure and squeezing a small amount of the fluid out of the lungs. After the birth of the newborn's trunk, the chest wall recoils. This chest recoil creates a negative intrathoracic pressure, which is thought to produce a small, passive inspiration of air that replaces the fluid in the large airways that is squeezed out.

After this first inspiration, the newborn exhales, with crying, against a partially closed glottis, creating positive intrathoracic pressure. The high positive intrathoracic pressure distributes the inspired air throughout the alveoli and begins to establish functional residual capacity (FRC), which is the air left in the lungs at the end of a normal expiration. The higher intrathoracic pressure also increases absorption of fluid via the capillaries and lymphatic system. The negative intrathoracic pressure created when the diaphragm moves down with inspiration causes lung fluid to flow from the alveoli across the alveolar membranes into the pulmonary interstitial tissue.

At birth, the alveolar epithelium is temporarily more permeable. This permeability, combined with decreased cellular resistance at the onset of breathing, may facilitate passive liquid absorption. With each succeeding breath, the lungs continue to expand, stretching the alveolar walls and increasing the alveolar volume.

Protein molecules are too large to pass through capillary walls. The presence of more protein molecules in the pulmonary capillaries than in the interstitial tissue creates oncotic pressure. This pressure draws the interstitial fluid into the capillaries and lymphatic tissue to balance the concentration of protein. Lung expansion helps the remaining lung fluid move into the interstitial tissue. As pulmonary vascular resistance decreases, pulmonary blood flow increases, and more interstitial fluid is absorbed into the bloodstream. In the healthy term newborn, lung fluid moves rapidly into the

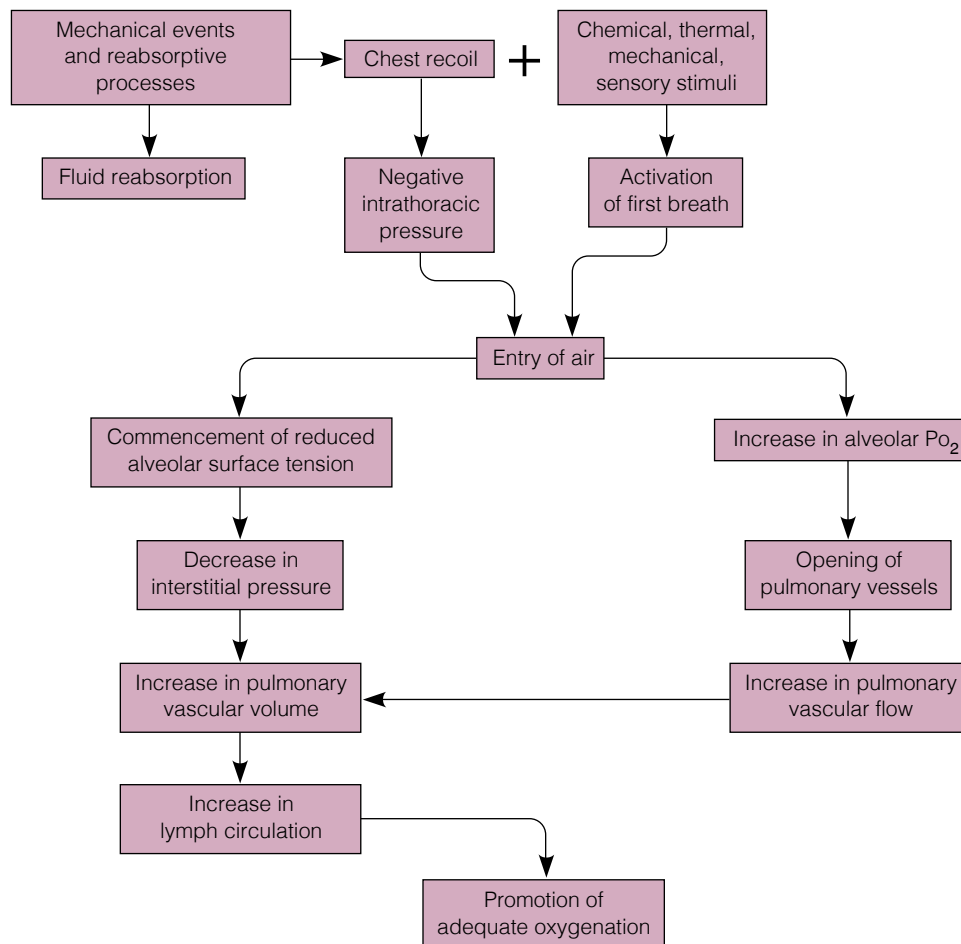

Figure 33-60 >> Initiation of respiration in the newborn.

interstitial tissue, but it may take several hours to move into the lymph and blood vessels. By 30 minutes of age most newborns have a normal FRC with uniform lung expansion. Surfactant is essential for a normal FRC (Rosenberg, 2013).

Although the initial chest recoil assists in clearing the airways of accumulated fluid and permits further inspiration, most healthcare providers believe mucus and fluid should be suctioned from the newborn's mouth, nose, and throat. These providers use a bulb syringe to suction the mouth and nose as soon as the newborn's head and shoulders are delivered and again as the newborn adapts to extrauterine life and stabilizes.

Newborns may have problems clearing the fluid in the lungs and beginning respiration for a variety of reasons:

- The lymphatic system may be underdeveloped, thus decreasing the rate at which the fluid is absorbed from the lungs.
- Complications may occur before or during labor and birth that interfere with adequate lung expansion; thus, the decrease in pulmonary vascular resistance fails to occur, resulting in decreased pulmonary blood flow. These complications include the following:
 - a. Inadequate compression of the chest wall in very small newborns (small for gestational age or very low birth weight) because of immature muscular development

- b. The absence of chest wall compression in a neonate born by cesarean birth, although this compression can be externally applied by skilled healthcare providers as they deliver the newborn from the uterus
- c. Respiratory depression because of maternal analgesia or anesthesia agents
- d. Aspiration of amniotic fluid, meconium, or blood.

Several chemical factors contribute to the onset of breathing. One of the most important is asphyxia of the fetus and newborn. The first breath is an inspiratory gasp, the result of central nervous system (CNS) reaction to sudden pressure, temperature change, and other external stimuli. This first breath is triggered by the slight elevation in partial pressure of carbon dioxide and decrease in pH and partial pressure of oxygen (PO_2), which are the natural result of a vaginal labor and birth. These changes, which are present in all newborns to some degree, stimulate the aortic and carotid chemoreceptors, initiating impulses that trigger the medulla's respiratory center. Although this brief period of asphyxia is a significant stimulator, prolonged asphyxia is abnormal and depresses respiration. Early cord clamping before the initiation of respirations may result in reflex bradycardia and the need for resuscitative efforts (Gruneberg & Crozier, 2015). As a result, it is appropriate for newborns to

vigorously cry and be active before the cord is clamped or the placenta separates.

A significant decrease in environmental temperature after birth, from 37°C to between 21° and 23.9°C (98.6°F to 70°–75°F), results in sudden chilling of the moist newborn (Blackburn, 2013). The cold stimulates skin nerve endings, and the newborn responds with rhythmic respirations. Normal temperature changes that occur at birth are within acceptable physiologic limits. Excessive cooling may result in profound respiratory depression and evidence of cold stress.

Upon birth the newborn experiences light, new sounds, and the full effects of gravity for the first time. As the fetus moves from the womb's familiar, comfortable, and quiet environment to one of sensory abundance, a number of physical and sensory influences help respiration begin. These stimuli include the following:

- The actual experience of birth, with its numerous tactile, auditory, and visual stimuli
- Joint movement, which results in enhanced proprioceptor stimulation to the respiratory center to sustain respirations
- Thorough drying of the newborn and placing the baby on the mother's chest and abdomen for skin-to-skin contact provides ample stimulation in a comforting way and also decreases heat loss.

Factors Opposing Initiation of Respiration

Three major factors may inhibit the initiation of respiratory activity:

- The contracting force between alveoli (alveolar surface tension)
- Viscosity of lung fluid within the respiratory tract, which is influenced by surfactant levels
- The ease with which the lungs are able to fill with air (lung compliance).

Alveolar surface tension is the contracting force between the moist surfaces of the alveoli. This tension, which is necessary for healthy respiratory function, would nevertheless cause the small airways and alveoli to collapse between each inspiration were it not for the presence of surfactant. By reducing the attracting force between alveoli, surfactant prevents the alveoli from completely collapsing with each expiration and thus promotes lung expansion. Similarly, surfactant promotes lung compliance (the ability of the lung to fill with air easily). When surfactant decreases, compliance also decreases. Decreased compliance, combined with the small radii of the newborn's airway, results in an increase in the pressure needed to expand the alveoli with air.

The first breath usually establishes a functional residual capacity that is 30–40% of the fully expanded lung volume. This functional residual capacity allows alveolar sacs to remain partially expanded on expiration, decreasing the need for continuous high pressures for each of the following breaths. Subsequent breaths require only 6–8 cm H₂O of pressure to open alveoli during inspiration. Therefore, the first breath of life is usually the most difficult.

Cardiopulmonary Physiology

As air enters the lungs, PO₂ rises in the alveoli, which stimulates the relaxation of the pulmonary arteries and triggers a decrease in pulmonary vascular resistance. As pulmonary vascular resistance decreases, the vascular flow in the lung increases rapidly and achieves 100% normal flow at 24 hours of life. This delivery of greater blood volume to the lungs contributes to the conversion from fetal circulation to newborn circulation.

After pulmonary circulation is established, blood is distributed throughout the lungs, although the alveoli may or may not be fully open. For adequate oxygenation to occur, the heart must deliver sufficient blood to functional, open alveoli. Shunting of blood is common in the early newborn period. Bidirectional blood flow, or right-to-left shunting through the ductus arteriosus, may divert a significant amount of blood away from the lungs, depending on the pressure changes of respiration, crying, and the cardiac cycle. This shunting in the newborn period is also responsible for the unstable transitional period in cardiopulmonary function.

Oxygen Transport

The transportation of oxygen to the peripheral tissues depends on the type of hemoglobin in the red blood cells (RBCs). In the fetus and newborn, a variety of hemoglobins exist, the most significant being fetal hemoglobin (HbF) and adult hemoglobin (HbA). Approximately 70–90% of the hemoglobin in the fetus and newborn is of the fetal variety. The greatest difference between HbF and HbA relates to the transport of oxygen.

Because HbF has a greater affinity for oxygen than does HbA, the oxygen saturation in the newborn's blood is greater than that in the adult's, but the amount of oxygen available to the tissues is less. This situation is beneficial prenatally because the fetus must maintain adequate oxygen uptake in the presence of very low oxygen tension (umbilical venous PO₂ cannot exceed uterine venous PO₂). However, this high concentration of oxygen in the blood makes hypoxia in the newborn particularly difficult to recognize. Clinical manifestations of cyanosis (bluish discoloration of skin and mucous membranes) do not appear until low blood levels of oxygen are present. In addition, alkalosis (increased pH) and hypothermia can result in less oxygen being available to the body tissues, whereas acidosis, hypercarbia, and hyperthermia can result in less oxygen being bound to hemoglobin and more oxygen being released to the body tissues. (See the module on Acid–Base Balance.)

Maintaining Respiratory Function

The lung's ability to maintain oxygenation and ventilation (the exchange of oxygen and carbon dioxide) is influenced by such factors as lung compliance and airway resistance. Lung compliance is influenced by the elastic recoil of the lung tissue and anatomic differences in the newborn. The newborn has a relatively large heart and mediastinal structures that reduce available lung space. Also, the newborn chest is equipped with weak intercostal muscles and a rigid rib cage, with horizontal ribs and a high diaphragm, which restrict the space available for lung expansion. The large abdomen further encroaches on the high diaphragm to

decrease lung space. Another factor that limits ventilation is airway resistance, which depends on the radii, length, and number of airways. Airway resistance is increased in the newborn compared with that in adults.

Characteristics of Newborn Respiration

Initial respirations may be largely diaphragmatic, shallow, and irregular in depth and rhythm. The abdomen's movements are synchronous with the chest movements. When the breathing pattern is characterized by pauses lasting 5–15 seconds, **periodic breathing** is occurring. Periodic breathing is rarely associated with differences in skin color or heart rate changes, and it has no prognostic significance. Tactile or other sensory stimulation increases the inspired oxygen and converts periodic breathing patterns to normal breathing patterns during neonatal transition. With deep sleep, the pattern is reasonably regular. Periodic breathing occurs with rapid-eye-movement (REM) sleep, and grossly irregular breathing is evident with motor activity, sucking, and crying. Cessation of breathing lasting more than 20 seconds is defined as apnea and is abnormal in term newborns. Apnea may or may not be associated with changes in skin color or bradycardia (drop below 100 beats/min). Apnea always needs to be further evaluated.

Newborns tend to be obligatory nose breathers: The nasal route is the primary route of air entry because of the high position of the epiglottis and the position of the soft palate (Blackburn, 2013). Although many term newborns can breathe orally, nasal obstructions can cause respiratory distress. Therefore, it is important to keep the nose and throat clear.

Immediately after birth, and for approximately the next 2 hours, respiratory rates of 60–70 breaths/minute are normal.

Some cyanosis and **acrocyanosis** (bluish discoloration of hands and feet) are normal for several hours; thereafter, the newborn's color improves steadily. If respirations drop below 30 or exceed 60 breaths/min when the neonate is at rest, or if retractions, cyanosis, or nasal flaring and expiratory grunting occur, the healthcare provider should be notified. Any increased use of the intercostal muscles (retractions) may indicate respiratory distress, which should be reported immediately.

Cardiovascular Adaptations

During fetal life, blood with higher oxygen content is diverted to the heart and brain. Blood in the descending aorta is less oxygenated and supplies the kidney and intestinal tract before it is returned to the placenta. Limited amounts of blood, pumped from the right ventricle toward the lungs, enter the pulmonary vessels. In the fetus, increased pulmonary resistance forces most of this blood through the ductus arteriosus into the descending aorta.

» Go to **Pearson MyLab Nursing and eText** to see Chart 14: *Fetal and Neonatal Circulation*.

Marked changes occur in the cardiovascular system at birth. Expansion of the lungs with the first breath decreases pulmonary vascular resistance and increases pulmonary blood flow. Pressure in the left atrium increases as blood returns from the pulmonary veins. Pressure in the right atrium drops, and systematic vascular resistance increases as umbilical venous blood flow is halted when the cord is clamped. These physiologic mechanisms mark the transition from fetal to neonatal circulation and show the interplay of cardiovascular and respiratory systems (**Figure 33–61** »).

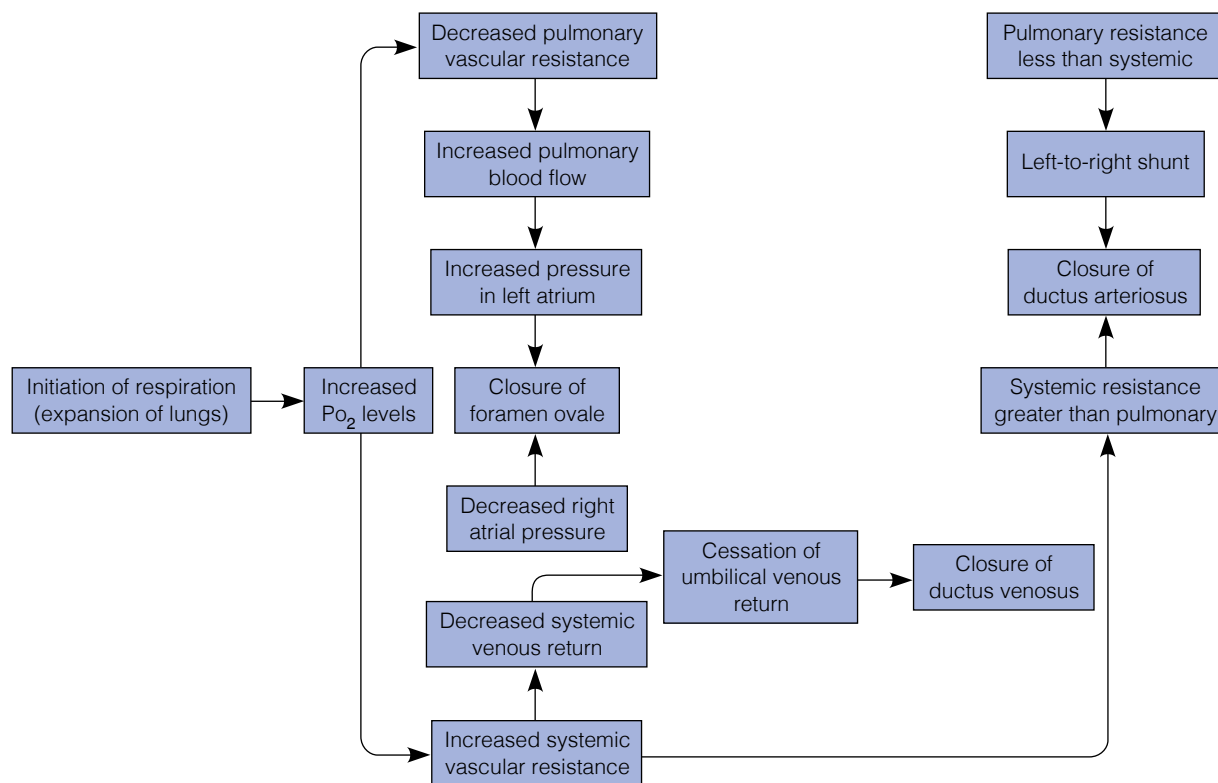

Figure 33–61 » Transitional circulation: conversion from fetal to neonatal circulation.

Five major areas of change occur in cardiopulmonary adaptation:

1. **Increased aortic pressure and decreased venous pressure.** Clamping of the umbilical cord eliminates the placental vascular bed and reduces the intravascular space. Consequently, aortic (systemic) blood pressure increases. At the same time, blood return via the inferior vena cava decreases, resulting in a decreased right atrial pressure and a small decrease in pressure within the venous circulation.
2. **Increased systemic pressure and decreased pulmonary artery pressure.** With loss of the low-resistance placenta, systemic resistance pressure increases, resulting in greater systemic pressure. At the same time, lung expansion increases pulmonary blood flow, and the increased blood PO₂ associated with initiation of respirations dilates pulmonary blood vessels. The combination of vasodilation and increased pulmonary blood flow decreases pulmonary artery resistance. As the pulmonary vascular beds open, the systemic vascular pressure increases, enhancing perfusion of the other body systems.
3. **Closure of the foramen ovale.** Closure of the foramen ovale is a function of changing atrial pressures. In utero, pressure is greater in the right atrium, and the foramen ovale is open after birth. Decreased pulmonary resistance and increased pulmonary blood flow increase the pulmonary venous return into the left atrium, thereby increasing left atrial pressure slightly. The decreased pulmonary vascular resistance and the decreased umbilical venous return to the right atrium also decrease right atrial pressure. The pressure gradients across the atria are now reversed, with the left atrial pressure now greater, and the foramen ovale is functionally closed 1–2 hours after birth. However, a slight right-to-left shunting may occur in the early newborn period. Any increase in pulmonary resistance or right atrial pressure, such as occurs with crying, acidosis, or cold stress, may cause the foramen ovale to reopen, resulting in a temporary right-to-left shunt. Anatomic closure occurs within 30 months (Blackburn, 2013).
4. **Closure of the ductus arteriosus.** Initial elevation of the systemic vascular pressure above the pulmonary vascular pressure increases pulmonary blood flow by reversing the flow through the ductus arteriosus. Blood now flows from the aorta into the pulmonary artery. Furthermore, although the presence of oxygen causes the pulmonary arterioles to dilate, an increase in blood PO₂ triggers the opposite response in the ductus arteriosus—that is, it constricts.

In utero, the placenta provides prostaglandin E₂, which causes ductus vasodilation. With the loss of the placenta and increased pulmonary blood flow, prostaglandin E₂ levels drop, leaving the active constriction by PO₂ unopposed. If the lungs fail to expand or if PO₂ levels drop, the ductus remains patent. Functional closure starts within 18 hours after birth, and fibrosis of the ductus occurs within 2–3 weeks after birth (Blackburn, 2013; Fraser, 2014).

5. **Closure of the ductus venosus.** Although the mechanism initiating closure of the ductus venosus is not known, it appears to be related to mechanical pressure changes after severing of the cord, redistribution of blood, and cardiac output. Closure of the bypass forces perfusion of the liver. Fibrosis of the ductus venosus occurs within 2 months.

Assessment of the newborn's heart rate, blood pressure, heart sounds, and cardiac workload provides data for evaluating cardiac function. The newborn's blood pressure tends to be highest immediately after birth and then descends to its lowest level at about 3 hours of age. By days 4–6, the blood pressure rises and then plateaus at a level approximately the same as the initial level. Blood pressure is sensitive to the changes in blood volume that occur in the transition to newborn circulation. Peripheral perfusion pressure is a particularly sensitive indicator of the newborn's ability to compensate for alterations in blood volume before changes in blood pressure. Capillary refill should be less than 3 seconds when the skin is blanched.

Blood pressure values during the first 12 hours of life vary with the birth weight and gestational age. The average mean blood pressure is 31–61 mmHg in the full-term, resting newborn over 3 kg (6.6 lb) during the first 12 hours of life (Gomella, 2013). Crying may cause an elevation of in both the systolic and diastolic blood pressure; thus, accuracy is more likely in the quiet newborn. Currently two-point pulse oximetry (right hand and either foot) is recommended to screen for congenital heart disease. An SpO₂ of <95% needs to be referred to a cardiology clinic (Bradshaw et al., 2012; Goetz & Hokanson, 2011).

Shortly after the first cry and the start of changes in cardiopulmonary circulation, the newborn heart rate can accelerate to 180 beats/min. The average resting heart rate in the first week of life is 110 to 160 beats/min in a healthy full-term newborn but may vary significantly during deep sleep or active awake states. In full-term newborns, the heart rate may drop to a low of 80 to 100 beats/min during deep sleep (Van Woudenberg, Wills, & Rubarth, 2012).

Murmurs are produced by turbulent blood flow. Murmurs may be heard when blood flows across an abnormal valve or across a stenosed valve, when an atrial or ventricular septal defect is present, or when the flow across a normal valve is increased.

In newborns, 90% of all murmurs are transient and not associated with anomalies. These murmurs usually involve incomplete closure of the ductus arteriosus or foramen ovale. Soft murmurs may be heard as the pulmonary branch arteries increase their blood flow from 7% to 50% of the combined ventricular output during transition, causing a physiologic peripheral pulmonary stenosis. Clicks may normally be heard at the lower left sternal border as the great vessels dilate to accommodate systolic blood flow in the first few hours of life. Murmurs are sometimes absent even in seriously malformed hearts.

Before birth, the right ventricle does approximately two thirds of the cardiac work, resulting in increased size and thickness of the right ventricle at birth. In the first 2 hours after birth, when the ductus arteriosus remains mostly patent, about one third of the left ventricular output is returned

to the pulmonary circulation. As a result, the left ventricle has a significantly greater increase in volume load than the right ventricle after birth, and it needs to progressively increase in both size and thickness. This may explain why right-sided heart defects are better tolerated than left-sided ones and why left-sided heart defects rapidly become symptomatic after birth.

Hematopoietic Adaptations

In the first days of life, hematocrit may rise 1–2 g/dL above fetal levels as a result of placental transfusion, low oral fluid intake, and diminished extracellular fluid volume. By 1 week after birth, peripheral hemoglobin is comparable to fetal blood counts. The hemoglobin level declines progressively over the first 2 months of life (Blackburn, 2013). This initial decline in hemoglobin creates a phenomenon known as **physiologic anemia of infancy**. A factor that influences the degree of physiologic anemia is the nutritional status of the newborn. Supplies of vitamin E, folic acid, and iron may be inadequate given the amount of growth in the later part of the first year of life. Hemoglobin values fall, mainly from a decrease in red cell mass rather than from the dilutional effect of increasing plasma volume. The facts that red cell survival is lower in newborns than in adults and that red cell production is less also contribute to this anemia. Neonatal RBCs have a lifespan of 60–70 days, approximately one-half to two-thirds the lifespan of adult RBCs (Bagwell, 2014). The normal RBC count in a term newborn is in the range of 5.1–5.3 million per milliliter during the first 24–48 hours of life (Bagwell, 2014).

Leukocytosis is a normal finding, because the stress of birth stimulates increased production of neutrophils during the first few days of life. Neutrophils then decrease to 35% of the total leukocyte count by 2 weeks of age. Lymphocytes play a role in antibody formation and eventually become the predominant type of leukocyte, and the total WBC count falls.

Blood volume is approximately 85 mL/kg for a term neonate (Diab & Luchtman-Jones, 2015). For example, a 3.6-kg (8-lb) newborn has a blood volume of 306 mL. Blood volume varies based on the amount of placental transfusion received during the delivery of the placenta as well as other factors, including the following:

- Delayed cord clamping and the normal shift of plasma to the extravascular spaces
- Gestational age
- Prenatal and/or perinatal hemorrhage
- Site of the blood sample.

SAFETY ALERT Laboratory results may vary between capillary collection and venous collection. Greater variances can be expected if capillary collection was difficult or good blood flow was not obtained and the heel was squeezed excessively, which increases the risk of cellular damage within the specimen, increased serum levels, and micro blood clots.

Temperature Regulation

Newborns are homeothermic: They attempt to stabilize their internal (core) body temperatures within a narrow range in spite of significant temperature variations in their environment.

Thermoregulation in the newborn is closely related to the rate of metabolism and oxygen consumption. Within a specific environmental temperature range, called the **neutral thermal environment (NTE)**, the rates of oxygen consumption and metabolism are minimal, and internal body temperature is maintained because of thermal balance (Blackburn, 2013). Thus, the normal newborn requires higher environmental temperatures to maintain a thermoneutral environment.

Several newborn characteristics affect the establishment of thermal stability:

- The newborn has a thinner epidermis and less subcutaneous fat than an adult.
- Blood vessels in the newborn are closer to the skin than the blood vessels of an adult. Therefore, the circulating blood is influenced by changes in environmental temperature and, in turn, influences the hypothalamic temperature-regulating center.
- The flexed posture of the term newborn decreases the surface area exposed to the environment, thereby reducing heat loss.
- Shivering, a form of muscular activity that generates body heat, is common in the cold adult, but is rarely seen in the newborn.

Size and age may also affect the establishment of an NTE. For example, the small-for-gestational-age newborn has less adipose tissue and is hypoflexed and, therefore, requires higher environmental temperatures to achieve an NTE. Larger, well-insulated newborns may be able to cope with lower environmental temperatures. If the environmental temperature falls below the lower limits of the NTE, the newborn responds with increased oxygen consumption and metabolism, which results in greater heat production. As a result, prolonged exposure to the cold may result in depleted glycogen stores and acidosis. Oxygen consumption also increases if the environmental temperature is above the NTE.

A newborn is at a distinct disadvantage in maintaining a normal temperature. With a large body surface in relation to mass and a limited amount of insulating subcutaneous fat, the term newborn loses heat at about four times the rate of an adult. The newborn's poor thermal stability is primarily because of excessive heat loss rather than impaired heat production. Because of the risk of hypothermia and possible cold stress, minimizing heat loss in the newborn after birth is essential (see Evidence-Based Practice: Thermoregulation and Heat Loss Prevention in Newborns). This topic is covered in more detail in the module on Thermoregulation.

Hepatic Adaptations

In the newborn, the liver is frequently palpable 2–3 cm (0.8–1.2 in.) below the right costal margin. It is relatively large and occupies approximately 40% of the abdominal cavity. The newborn liver plays a significant role in iron storage, carbohydrate metabolism, conjugation of bilirubin, and coagulation. Additional essential functions of the liver include the production of bile, regulation of plasma proteins and glucose, and the biotransformation of drugs and toxins. The neonate has less than 20% of the hepatocytes that are

Evidence-Based Practice

Thermoregulation and Heat Loss Prevention in Newborns

Problem

What is the best way to support thermoregulation in the newborn immediately after birth?

Evidence

Newborns have several risk factors for hypothermia after birth: a large surface-to-mass ratio, minimal subcutaneous tissue, and wet skin. The challenge of thermoregulation is increased if the newborn is low birth weight, preterm, or sick. Cold stress can lead to harmful side effects or even death. Several systematic reviews of research on newborn thermoregulation have been published by professional groups interested in neonatal health: AWHONN, the American College of Nurse-Midwives, and the American College of Pediatricians (Lunze & Hamer, 2012; Moore et al., 2012; Turnbull & Petty, 2013). These reviews have focused on healthy newborns as well as on newborns at risk. Multiple systematic reviews of multi-site, randomized trials provide the strongest level of evidence for nursing practice.

Skin-to-skin contact of the newborn with its mother after birth is recommended as the mainstay of thermoregulation for most healthy newborns. When placed skin to skin, the baby gets heat directly from its mother via conduction. Skin-to-skin care is associated with both short- and long-term benefits, and it has been shown to be an effective method of thermoregulation for babies as small as 1200 g. For smaller babies, or babies who are too ill to be placed on their mother's skin, resuscitation and other treatments may allow evaporative heat loss. Prewarming the delivery suite to 80°F and placing the newborn in a plastic bag up to the neck during physiologic stabilization prevents heat loss in high-risk babies. Heated mattresses are also effective in preventing hypothermia.

While plastic barriers have been shown to avoid hypothermia in high-risk newborns, no studies have demonstrated that these interventions reduce the long-term risk of death, brain injury, mean duration of oxygen therapy, or hospitalization. Some barrier methods (e.g., occlusive dressings) result in hyperthermia. Continuous monitoring of the newborn's body temperature should accompany any of the heat loss barrier methods.

Implications

Family-centered birth care provides the best environment for the newborn, including support of thermoregulation. You can avoid hypothermia in healthy newborns by drying the baby with a towel, placing the bare newborn in direct contact with the mother's bare skin, and placing a blanket over them both. Babies who are too small or too sick for skin-to-skin contact should be dried, placed on a heated mattress, and wrapped in plastic wrap up to the neck. A small cut can be made in the plastic for access to the umbilicus. In the case of plastic barriers, continuous monitoring of the baby's temperature is necessary to avoid overheating. Temperature can be continuously monitored using a temperature probe on the newborn's skin connected to a monitoring device.

Critical Thinking Application

1. Discuss the evidence related to thermoregulation with skin-to-skin contact immediately after birth.
2. Identify nursing interventions that promote thermoregulation in the newborn.
3. Describe complications of cold stress in each physiologic system in the newborn.

present in the adult liver, and liver growth continues after birth until it reaches its mature size.

Iron Storage

As RBCs are destroyed after birth, the iron is stored in the liver until needed for new RBC production. Newborn iron stores are determined by total body hemoglobin content and length of gestation. The term newborn has approximately 270 mg of iron at birth, and approximately 140–170 mg of this amount is in the hemoglobin. If the mother's iron intake has been adequate, enough iron will be stored to last until the baby is about 5 months of age. After about 6 months of age, the infant requires foods containing iron or iron supplements to prevent anemia.

Carbohydrate Metabolism

At term, the newborn's cord blood glucose level is 15 mg/dL lower than the maternal blood glucose level (Rosenberg, 2013). Newborn carbohydrate reserves are relatively low. One third of this reserve is in the form of liver glycogen. Newborn glycogen stores are twice those of the adult. The newborn enters an energy crunch at the time of birth, with the removal of the maternal glucose supply and the increased energy expenditure associated with the birth process and extrauterine life. The newborn consumes fuel sources at a faster rate because of the work of breathing, loss of heat when exposed to cold, activity, and activation of muscle

tone. Glucose is the main source of energy in the first 4–6 hours after birth. During the first 2 hours of life, the serum blood glucose level declines, then rises, and finally reaches a steady state by 3 hours after birth (Rosenberg, 2013).

The nurse may assess the newborn's glucose level on admission if risk factors are present or per agency protocol. As stores of liver and muscle glycogen and blood glucose decrease, the newborn compensates by changing from a predominantly carbohydrate metabolism to fat metabolism. This allows the newborn to derive energy from fat and protein as well as from carbohydrates. The amount and availability of each of these "fuel substrates" depend on the ability of immature metabolic pathways, which lack specific enzymes or hormones, to function in the first few days of life.

Conjugation of Bilirubin

Conjugation of bilirubin is the conversion of yellow lipid-soluble pigment into water-soluble pigment. Unconjugated (indirect) bilirubin is a breakdown product derived from hemoglobin released primarily from destroyed RBCs. Unconjugated bilirubin is not in an excretable form and is a potential toxin. Total serum bilirubin is the sum of conjugated (direct) and unconjugated (indirect) bilirubin.

Fetal unconjugated bilirubin crosses the placenta to be excreted, so the fetus does not need to conjugate bilirubin. Total bilirubin at birth is usually less than 3 mg/dL unless an abnormal hemolytic process has been present in utero.

After birth, the newborn's liver must begin to conjugate bilirubin. This produces a normal rise in serum bilirubin levels in the first few days of life.

The bilirubin formed after RBCs are destroyed is transported in the blood bound to albumin. The bilirubin is transferred into the hepatocytes and bound to intracellular proteins. These proteins determine the amount of bilirubin held in a liver cell for processing and, consequently, the amount of bilirubin uptake into the liver. Direct bilirubin is excreted into the tiny bile ducts, then into the common duct and duodenum. The conjugated (direct) bilirubin then progresses down the intestines, where bacteria transform it into urobilinogen (urine bilirubin) and stercobilinogen. Stercobilinogen is not reabsorbed; rather, it is excreted as a yellow-brown pigment in the stools.

Even after the bilirubin has been conjugated and bound, it can be changed back to unconjugated bilirubin via the enterohepatic circulation. In the intestines, beta-glucuronidase enzyme acts to split off (deconjugate) the bilirubin from glucuronic acid if it has not first been acted on by gut bacteria to produce urobilinogen. The free bilirubin is then reabsorbed through the intestinal wall and brought back to the liver via portal vein circulation. This recycling of the bilirubin and decreased ability to clear bilirubin from the system are prevalent in babies with very high beta-D-glucuronidase activity levels, those who are exclusively breastfed, and those with delayed bacterial colonization of the gut (e.g., because of the use of antibiotics). Very high beta-D-glucuronidase activity levels further increase the newborn's susceptibility to jaundice (yellow pigmentation of body tissues due to high bilirubin levels).

The newborn liver has relatively less glucuronyl transferase activity in the first few weeks of life than an adult liver. This reduction in hepatic activity, along with a relatively large bilirubin load, decreases the liver's ability to conjugate bilirubin and increases susceptibility to jaundice.

Coagulation

The liver plays an important part in blood coagulation during fetal life, and it continues this function following birth. Coagulation factors II, VII, IX, and X (synthesized in the liver) are activated under the influence of vitamin K and, therefore, are considered to be vitamin K dependent. The absence of normal flora needed to synthesize vitamin K in the newborn gut results in low levels of vitamin K, which in turn results in a transient blood coagulation alteration between the second and fifth day of life. From a low point at approximately 2–3 days after birth, these coagulation factors rise slowly, but they do not approach adult levels until 9 months of age or later (Bagwell, 2014). Other coagulation factors with low umbilical cord blood levels are factors XI, XII, and XIII. Fibrinogen and factors V and VII are near adult levels. Although newborn bleeding problems are rare, an injection of vitamin K (AquaMEPHYTON) is given prophylactically on the day of birth to combat potential clinical bleeding problems.

Platelet counts at birth are in the same range as for older children, but newborns may manifest mild transient difficulty in platelet aggregation functioning. This platelet problem is accentuated by phototherapy. Prenatal maternal therapy with phenytoin sodium (Dilantin) or phenobarbital also causes abnormal clotting studies and newborn bleeding in the first

24 hours after birth. Neonates born to mothers receiving warfarin (Coumadin) compounds may bleed because these agents cross the placenta and accentuate existing vitamin K-dependent factor deficiencies; therefore, most pregnant women in need of anticoagulant therapy receive heparin, which does not cross the placental barrier (Yarrington, Valente, & Economy, 2015). Transient neonatal thrombocytopenia may occur in newborns born to mothers with severe hypertension or HELLP (*hemolysis, elevated liver enzymes, and low platelet count*) syndrome and in newborns born to mothers who have idiopathic isoimmune thrombocytopenic purpura.

Physiologic Jaundice

Physiologic jaundice (nonpathologic unconjugated hyperbilirubinemia) is caused by accelerated destruction of fetal RBCs, impaired conjugation of bilirubin, and increased bilirubin reabsorption from the intestinal tract. This condition does not have a pathologic basis but is a normal biological response of the newborn.

Muchowski (2014) describes six factors—several of which can also be related to pathologic events—whose interaction may give rise to physiologic jaundice:

1. **Increased amounts of bilirubin delivered to the liver.** The increased blood volume because of delayed cord clamping combined with faster RBC destruction in the newborn leads to an increased bilirubin level in the blood. A proportionately larger amount of non-erythrocyte bilirubin forms in the newborn. Therefore, newborns have two to three times greater production or breakdown of bilirubin than adults. The use of forceps or vacuum extraction, which sometimes causes facial bruising or cephalohematoma (entrapped hemorrhage), can increase the amount of bilirubin to be handled by the liver.
2. **Defective hepatic uptake of bilirubin from the plasma.** If the newborn does not ingest adequate calories, the formation of hepatic binding proteins diminishes, resulting in higher bilirubin levels.
3. **Defective conjugation of bilirubin.** Decreased uridine-diphosphoglucuronosyl activity, as in hypothyroidism or inadequate caloric intake, causes the intracellular binding proteins to remain saturated and results in greater unconjugated bilirubin levels in the blood. The fatty acids in breast milk are thought to compete with bilirubin for albumin-binding sites and, therefore, to impede bilirubin processing.
4. **Defective excretion of bilirubin.** A congenital infection may cause impaired excretion of conjugated bilirubin. Delay in introduction of bacterial flora and decreased intestinal motility can also delay excretion and increase enterohepatic circulation of bilirubin.
5. **Inadequate hepatic circulation.** Decreased oxygen supplies to the liver associated with neonatal hypoxia or congenital heart disease lead to a rise in the bilirubin level.
6. **Increased reabsorption of bilirubin from the intestine.** Reduced bowel motility, intestinal obstruction, or delayed passage of meconium (the first stool) increases the circulation of bilirubin in the enterohepatic pathway, thereby resulting in higher bilirubin values.

Approximately 40% of full-term newborns exhibit physiologic jaundice on about the second or third day after birth, and it may last as long as 5 days (Zaja et al., 2014). This condition does not have a pathologic basis, but rather is a normal biologic response of the newborn. The characteristic yellow color results from increased levels of unconjugated (indirect) bilirubin, which are a normal product of RBC breakdown and reflect the body's temporary inability to eliminate bilirubin. Bruising, feeding patterns, and gastrointestinal activity can influence serum bilirubin levels (Ladewig et al., 2017). Serum levels of bilirubin reach approximately 4–6 mg/dL before the yellow coloration of the skin and sclera appear. The signs of physiologic jaundice appear after the first 24 hours postnatally. This time frame differentiates physiologic jaundice from pathologic jaundice, which is clinically seen at birth or within the first 24 hours of postnatal life. Generally, physiologic jaundice is more prevalent than pathologic jaundice. Hypothermia, hypoglycemia, maternal use of medications such as sulfa drugs and salicylates, and prematurity contribute to the development of physiologic jaundice (Ladewig et al., 2017). A major risk factor for developing severe hyperbilirubinemia in term neonates is a total serum or transcutaneous level in the high-risk zone on a bilirubin nomogram. The nomogram created by Bhutani, Johnson, and Sivieri (1999) and approved by the American Academy of Pediatrics (2004) is frequently used, as are bilirubin calculation tools available via the internet.

» **Stay Current:** Visit www.bilitool.org to see a bilirubin calculation tool based on the nomogram by Bhutani et al. (1999).

There is no consistent definition of neonatal hyperbilirubinemia; what is considered to be in that range varies with population characteristics and age (Blackburn, 2013). Peak bilirubin levels are reached between days 3 and 5 in the full-term newborn. These values are established for European and American White newborns. Chinese, Japanese, Korean, and Native American newborns have considerably higher bilirubin levels that are not as apparent and that persist for longer periods with no apparent ill effects (Blackburn, 2013).

The nursery or postpartum room environment, including lighting, may hinder early detection of the degree and type of jaundice. Pink walls and artificial lights mask the beginning of jaundice in newborns. Daylight assists the observer in early recognition by eliminating distortions caused by artificial light.

If jaundice is suspected, the nurse can quickly assess the newborn's coloring by pressing the skin, generally on the forehead or nose, with a finger. As blanching occurs, the nurse can observe the icterus (yellow coloring).

Several newborn care procedures will decrease the probability of high bilirubin levels:

- Maintain the newborn's skin temperature at 36.5°C (97.8°F) or above, because cold stress results in acidosis. Acidosis in turn decreases available serum albumin-binding sites, weakens albumin-binding powers, and causes elevated unconjugated bilirubin levels.
- Monitor stool for amount and characteristics. Bilirubin is eliminated in the feces; inadequate stooling may result in reabsorption and recycling of bilirubin. Encourage early

breastfeeding, because the laxative effect of colostrum increases the excretion of meconium and transitional stool.

- Encourage early feedings to promote intestinal elimination and bacterial colonization and provide the caloric intake necessary for formation of hepatic binding proteins.

If jaundice becomes apparent, nursing care is directed toward keeping the newborn well hydrated and promoting intestinal elimination.

Physiologic jaundice may be very upsetting to parents; they require emotional support and a thorough explanation of the condition. If the baby is placed under phototherapy, a few additional days of hospitalization may be required; this may also be disturbing to parents. The nurse can encourage parents to provide for the emotional needs of their newborn by continuing to feed, hold, and caress the baby. If the mother is discharged, the parents are encouraged to return for feedings and to telephone or visit when possible. In many instances, the mother, especially if she is breastfeeding, may elect to remain hospitalized with her newborn; the nurse should support this decision. If insurance limitations make this unrealistic, it may be possible to find an empty room for the discharged mother and her family to use while visiting the newborn. As an alternative to continued hospitalization, the newborn may be treated with home phototherapy.

Breastfeeding and Breast Milk Jaundice

Breastfeeding is implicated in prolonged jaundice in some newborns. *Breastfeeding jaundice* occurs during the first days of life in breastfed newborns. It appears to be related to inadequate fluid intake with some element of dehydration and not with any abnormality in milk composition (Hardy, D'Agata, & McGrath, 2016). Prevention of early breastfeeding jaundice includes encouraging frequent (every 2–3 hours) breastfeeding, avoiding supplementation if the newborn is not dehydrated, and accessing maternal lactation counseling. Breastfeeding jaundice is self-limiting; it peaks around day 3 as enteral intake increases, then resolves.

In *breast milk jaundice*, the bilirubin level begins to rise after the first week of life, when physiologic jaundice is waning after the mother's milk has come in. The level peaks at 5–10 mg/dL at 2–3 weeks of age and then declines over the first several months of life (Hardy et al., 2016).

In contrast to breastfeeding jaundice, breast milk jaundice is related to milk composition. Some women's breast milk contains several times the normal concentration of certain free fatty acids. These free fatty acids may compete with bilirubin for binding sites on albumin and inhibit the conjugation of bilirubin or increase lipase activity, which disrupts the RBC membrane. Increased lipase activity enhances absorption of bile across the gastrointestinal tract membrane, thereby increasing the enterohepatic circulation of bilirubin. Newborns with breastfeeding jaundice appear well, and at present, development of kernicterus (toxic levels of bilirubin in the brain) has not been documented. Temporary cessation of breastfeeding may be advised if bilirubin reaches presumed toxic levels of approximately 20 mg/dL or if the interruption is necessary to establish the cause of the hyperbilirubinemia. Most providers believe that breastfeeding

may be resumed once other causes of jaundice have been ruled out and as long as serum bilirubin levels remain below 20 mg/dL. In cases of breast milk jaundice, the newborn's serum bilirubin levels begin to fall dramatically within 24–36 hours after breastfeeding is discontinued. With resumption of breastfeeding, the bilirubin concentration may have a slight rise of 2–3 mg/dL, with a subsequent decline. Breastfeeding mothers need encouragement and support in their desire to breastfeed their babies, assistance and instruction regarding pumping and expressing milk during the interrupted nursing period, and reassurance that they are capable of feeding and nurturing their babies (Lauwers & Swisher, 2016). To diminish misunderstandings by mothers from a variety of cultural backgrounds, careful explanations about newborn jaundice are warranted (see Focus on Diversity and Culture: Interpreting Illness Through Cultural Beliefs).

Gastrointestinal Adaptations

The term newborn has sufficient intestinal and pancreatic enzymes to digest most simple carbohydrates, proteins, and fats. The carbohydrates requiring digestion in the newborn are usually disaccharides (lactose, maltose, and sucrose), which are split into monosaccharides (galactose, fructose, and glucose) by the enzymes of the intestinal mucosa. Lactose is the primary carbohydrate in the breastfeeding newborn and generally is easily digested and well absorbed. The only enzyme lacking in the newborn is pancreatic amylase, which remains relatively deficient during the first few months of life. Newborns have trouble digesting starches (changing more complex carbohydrates into maltose), so they should not be fed solid foods until at least 4 to 6 months of age (AAP, 2016b; Mayo Clinic, 2016).

Although proteins require more digestion than carbohydrates, they are well digested and absorbed from the newborn intestine. The newborn digests and absorbs fats less efficiently because of the minimal activity of the pancreatic enzyme lipase. The newborn excretes approximately 10–20% of the dietary fat intake, compared with 10% for the adult. The newborn absorbs the fat in breast milk more completely than the fat in cow's milk because breast milk consists of more medium-chain triglycerides and contains lipase.

By birth, the newborn has experienced swallowing, gastric emptying, and intestinal propulsion. In utero, fetal swallowing is accompanied by gastric emptying and peristalsis of the fetal intestinal tract. By the end of gestation, peristalsis becomes much more active in preparation for extrauterine life. Fetal peristalsis is also stimulated by anoxia, causing the expulsion of meconium into the amniotic fluid by more mature fetuses.

Air enters the stomach immediately after birth. The small intestine is filled with air within 2–12 hours, and the large bowel is filled within 24 hours. The salivary glands are immature at birth, and the newborn produces little saliva until about 3 months of age. The newborn's stomach has a capacity of approximately 50–60 mL. It empties intermittently, starting within a few minutes of the beginning of a feeding and ending 2–4 hours after a feeding. Bowel sounds are present within the first 30–60 minutes of birth; the newborn can successfully feed during this time. The newborn's gastric pH becomes less acidic about a week after birth and remains less acidic than that of adults for the next 2–3 months.

The cardiac sphincter is immature, as is neural control of the stomach. Therefore, some regurgitation may be noted in the newborn period. Regurgitation of the first few feedings during the first day or two of life can usually be lessened by avoiding overfeeding and by burping the newborn well both during and after the feeding.

When no other signs and symptoms are evident, vomiting is limited and ceases within the first few days of life. Continuous vomiting or regurgitation should be observed closely. If the newborn has swallowed bloody or purulent amniotic fluid, lavage of the stomach may be indicated in the term newborn to relieve the problem. Bilious vomiting is abnormal and must be evaluated thoroughly; it may represent a condition that warrants prompt surgical intervention.

Adequate digestion and absorption are essential for newborn growth and development. If optimal nutritional support is available, postnatal growth should parallel intrauterine growth; that is, after 30 weeks of gestation, the fetus gains 30 g per day and adds 1.2 cm (0.5 in.) to body length daily. To gain weight at the intrauterine rate, the term newborn requires 120 calories/kg per day. After birth, caloric intake is often insufficient for weight gain until the newborn is 5–10 days old. During this time, the term newborn may experience a weight loss of 5–10%. Because insensible water loss and a shift of intracellular water to extracellular space account for the 5–10% weight loss, failure to lose weight when caloric intake is inadequate may indicate fluid retention.

Term newborns usually pass **meconium** (their first stool) within 8–24 hours of life and almost always within 48 hours. Meconium is formed in utero from the amniotic fluid and its constituents, intestinal secretions, and shed mucosal cells. It is recognized by its thick, tarry-black or dark green appearance (**Figure 33–62A** >>). Transitional (thin brown to green) stools consisting of part meconium and part fecal material are passed for the next day or two (**Figure 33–62B**), and then the stools become entirely fecal (**Figure 33–62C**). Generally, the stools of a breastfed newborn are pale yellow (but may be pasty green); they are more liquid and more frequent

Focus on Diversity and Culture

Interpreting Illness Through Cultural Beliefs

Cultural beliefs lead mothers to interpret illness within their cultural framework, especially when instructions are not given clearly or are not understood by the mother (Lauderdale, 2012; Andrews & Boyle, 2016). For example, different cultures have different beliefs and practices about activity during pregnancy. These may influence when to have the baby shower, what position the mother sleeps in, and even what foods the mother eats during pregnancy. Careful assessment of the mother's cultural beliefs and practices can minimize misunderstandings as well as negative or unrealistic maternal reactions.

than those of formula-fed newborns, whose stools are paler. Frequency of bowel movement varies but ranges from one every 2–3 days to as many as 10 daily. Mothers should be counseled that the newborn is not constipated as long as the bowel movement remains soft.

Urinary Tract Adaptations

Certain physiologic features of the newborn's kidneys influence the newborn's ability to handle body fluids and excrete urine:

- The term newborn's kidneys have a full complement of functioning nephrons by 34–36 weeks of gestation.
- The glomerular filtration rate of the newborn's kidney is low in comparison with the adult rate. Because of this physiologic decrease in kidney glomerular filtration, the newborn's kidney is unable to dispose of water rapidly when necessary.
- The juxtamedullary portion of the nephron has limited capacity to reabsorb HCO_3^- and H^+ and to concentrate urine (reabsorb water back into the blood). The limitation of tubular reabsorption can lead to inappropriate loss of substances present in the glomerular filtrate, such as amino acids, bicarbonate, glucose, and sodium.

Full-term newborns are less able than adults to concentrate urine because their tubules are short and narrow. The limited tubular reabsorption of water and limited excretion of solutes (principally sodium, potassium, chloride, bicarbonate, urea, and phosphate) in growing newborns also reduce their ability to concentrate urine. Although feeding practices may affect the osmolarity of the urine, they have limited effect on the concentration of the urine. The ability to concentrate urine fully is attained by 3 months of age.

The newborn's difficulty concentrating urine makes the effect of excessive insensible water loss or restricted fluid intake unpredictable. The newborn kidney is also limited in its dilutional capabilities. Concentrating and dilutional limitations of renal function are important considerations in monitoring fluid therapy to prevent dehydration or overhydration.

Many newborns void immediately after birth; this voiding frequently goes unnoticed. A newborn who has not voided by 48 hours should be assessed for adequacy of fluid intake, bladder distention, restlessness, and symptoms of pain. The appropriate clinical personnel should be notified if indicated (Gabbe et al., 2012).

The initial bladder volume is 6–44 mL of urine. Unless edema is present, normal urinary output is often limited, and voidings are scanty until fluid intake increases. (The fluid of edema is eliminated by the kidneys, so newborns with edema have a much higher urinary output.) During the first 2 days after birth, the newborn voids 2–6 times daily, with a urine output of 15 mL/kg per day. The newborn subsequently voids 5–25 times every 24 hours, with a volume of 25 mL/kg per day.

Following the first voiding, the newborn's urine frequently appears cloudy (because of mucus content) and has a high specific gravity, which decreases as fluid intake increases. Occasionally, pink stains ("brick dust spots") appear on the diaper. These are caused by urates and are innocuous. Blood or whitish discharge may occasionally be observed on the diapers of female newborns; this **pseudo-menstruation** is related to the withdrawal of maternal hormones. Males who are circumcised may have bloody spotting following the procedure. In the absence of apparent causes for bleeding, the healthcare provider should be

- White blood cells: <2–3 cells/high-power field
- Red blood cells: 0
- Casts: 0
- Bacteria: 0
- Color: pale yellow

notified. During the early neonatal period, normal urine is straw colored and almost odorless, although odor does occur when certain drugs are given, metabolic disorders exist, or infection is present. **Box 33–7** » contains urinalysis values for the normal newborn.

Immunologic Adaptations

The newborn's immune system is not fully activated until sometime after birth. Limitations in the newborn's inflammatory response result in failure to recognize, localize, and destroy invasive bacteria. As a result, the signs and symptoms of infection are often subtle and nonspecific in the newborn. The newborn also has a poor hypothalamic response to pyrogens; therefore, fever is not a reliable indicator of infection. In the neonatal period, hypothermia is a more reliable sign of infection.

Of the three major types of immunoglobulins that are primarily involved in immunity—IgG, IgA, and IgM—only IgG crosses the placenta. When the pregnant woman forms antibodies in response to illness or immunization, this process is called **active acquired immunity**. When IgG antibodies are transferred from the pregnant woman to the fetus in utero, **passive acquired immunity** results because the fetus does not produce the antibodies itself. IgG antibodies are very active against bacterial toxins.

Because the maternal IgG is transferred primarily during the third trimester, preterm newborns (especially those born before 34 weeks of gestation) may be more susceptible to infection than term newborns. In general, newborns have immunity to tetanus, diphtheria, smallpox, measles, mumps, poliomyelitis, and a variety of other bacterial and viral diseases. The period of resistance varies: Immunity against common viral infections, such as measles, may last 4–8 months; immunity to certain bacteria may disappear within 4–8 weeks.

The normal newborn can produce a protective immune response to vaccines, such as hepatitis B immunoglobulin vaccine, when given as early as a few hours after birth. It is customary to begin the majority of routine immunizations at 2 months of age so that the infant can develop active acquired immunity.

The IgM antibodies are produced in response to blood group antigens, gram-negative enteric organisms, and some viruses in the expectant mother. Because IgM does not normally cross the placenta, most or all of it is produced by the fetus beginning at 10–15 weeks of gestation. Elevated levels of IgM at birth may indicate placental leaks or, more commonly, antigenic stimulation in utero. Consequently, elevations of IgM suggest that the newborn was exposed to an

intrauterine infection, such as syphilis or TORCH syndrome (*toxoplasmosis, rubella, cytomegalovirus, herpesvirus hominis* type 2 infection). The lack of available maternal IgM in the newborn also accounts for the susceptibility to gram-negative enteric organisms, such as *Escherichia coli*.

The functions of IgA immunoglobulins are not fully understood. IgA appears to provide protection mainly on secreting surfaces, such as the respiratory tract, gastrointestinal tract, and eyes. Serum IgA does not cross the placenta and is not normally produced by the fetus in utero. Unlike the other immunoglobulins, IgA is not affected by gastric action. Colostrum (the forerunner of breast milk) is very high in the secretory form of IgA. Consequently, it may be of significance in providing some passive immunity to the neonate of a breastfeeding mother. Newborns begin to produce secretory IgA in their intestinal mucosa approximately 4 weeks after birth.

Neurologic and Sensory–Perceptual Function

The newborn's brain is about one quarter the size of an adult's, and myelination of nerve fibers is incomplete. Unlike the cardiovascular and respiratory systems, which undergo tremendous changes at birth, the nervous system is minimally influenced by the actual birth process.

Because many biochemical and histologic changes have yet to occur in the newborn's brain, the postnatal period is considered to be a time of risk with regard to development of the brain and nervous system. For neurologic development—including development of intellect—to proceed, the brain and other nervous system structures must mature in an orderly, unhampered fashion.

Intrauterine Experience

Newborns respond to and interact with the environment in a predictable pattern of behavior that is somewhat shaped by their intrauterine experience. This intrauterine experience is affected by intrinsic factors, such as maternal nutrition, and by external factors, such as the mother's physical environment. Depending on the newborn's intrauterine experience and individual temperament, neonatal behavioral responses to different stresses vary. Some newborns react quietly to stimulation, others become over-reactive and tense, and still others exhibit a combination of the two.

Factors such as exposure to intense auditory stimuli in utero may eventually manifest in the behavior of the newborn. For example, the fetal heart rate initially increases when the pregnant woman is exposed to auditory stimuli, but repetition of the stimuli leads to decreased fetal heart rate. Thus, the newborn who was exposed to intense noise during fetal life is significantly less reactive to loud sounds after birth.

Characteristics of Newborn Neurologic Function

Normal newborns are usually in a position of partially flexed extremities, with the legs near the abdomen. When awake, the newborn may exhibit purposeless, uncoordinated bilateral movements of the extremities. The organization and

quality of the newborn's motor activity are influenced by a number of factors, including the following (Nugent, 2013):

- Intrauterine growth restriction
- Prenatal stress
- Environmental chemicals
- Obstetric medications
- Acute fetal distress
- Gestational and pregestational diabetes
- Intrauterine drug exposure
- Prematurity and low birth weight.

Eye movements are observable during the first few days of life. An alert newborn is able to fixate on faces and geometric objects or patterns, such as black-and-white stripes. A bright light shining in the newborn's eyes elicits the blinking reflex.

The cry of the newborn should be lusty and vigorous. High-pitched cries, weak cries, and no cries are causes for concern.

The newborn's body growth progresses in a cephalocaudal (head-to-toe), proximal-distal fashion. The newborn is somewhat hypertonic—that is, there is resistance to extending the elbow and knee joints. Muscle tone should be symmetric. Diminished muscle tone and flaccidity may indicate neurologic dysfunction.

Specific symmetric deep tendon reflexes can be elicited in the newborn. The knee-jerk reflex is brisk; a normal ankle clonus may involve three to four beats. Plantar flexion is present. Other reflexes, including the Moro, grasping, Babinski, rooting, and sucking reflexes, are characteristic of neurologic integrity. **Table 33-17** » provides a summary of stimulus, and response, for the common newborn reflexes.

Performance of complex behavioral patterns reflects the newborn's neurologic maturation and integration. Newborns who can bring a hand to their mouth may be demonstrating motor coordination as well as a self-quieting technique, thus increasing the complexity of the behavioral response. Newborns also possess complex, organized, defensive motor patterns, as exhibited by the ability to remove an obstruction, such as a cloth across the face.

Periods of Reactivity

The behavior of the newborn can be divided into three categories, the sleep state, the transitional state, and the alert state (McGrath & Vittner, 2015). These postnatal behavioral states are similar to those that have been identified during pregnancy. Subcategories are identified under each major category.

Sleep States

The sleep states are as follows:

- **Deep or quiet sleep.** Deep sleep is characterized by closed eyes with no eye movements; regular, even breathing; and jerky motions or startles at regular intervals. Behavioral responses to external stimuli are likely to be delayed. Startles are rapidly suppressed, and changes in state are not likely to occur. Heart rate may range from 100 to 120 beats/min.
- **Active or light sleep (rapid eye movement [REM] sleep).** The baby has irregular respirations; eyes closed,

with REM; irregular sucking motions; minimal activity; and irregular but smooth movement of the extremities. Environmental and internal stimuli may initiate a startle reaction and a change of state.

Newborn sleep cycles have been recognized and defined according to duration. The length of the sleep cycle depends on the age of the newborn. At term, REM active sleep and quiet sleep occur in intervals of 50–60 minutes (Gardner, Goldson, & Hernandez, 2016). Approximately 45–50% of the newborn's total sleep is active sleep, 35–45% is quiet sleep, and 10% is transitional between these two periods. Growth hormone secretion depends on regular sleep patterns. Any disturbance of the sleep–wake cycle can result in irregular spikes of growth hormone. REM sleep stimulates the highest peaks of growth hormone and the growth of the neural system. Over a period of time, the newborn's sleep–wake patterns become diurnal (the newborn sleeps at night and stays awake during the day).

Alert States

In the first 30–60 minutes after birth, many newborns display a quiet alert state. After a sleep phase that lasts from a few minutes to between 2 and 4 hours, a second alert state occurs. This second alert period lasts 4 to 6 hours in the normal newborn. The nurse should use these alert states to encourage bonding and breastfeeding.

The newborn's periods of alertness tend to be shorter during the first 2 days after birth; this allows the baby to recover from the birth process. Subsequent alert states are of choice or of necessity. Increasing choice of wakefulness by the newborn indicates a maturing capacity to achieve and maintain consciousness. Heat, cold, and hunger are but a few of the stimuli that can cause wakefulness by necessity. Once the disturbing stimuli have been removed, the baby tends to fall back asleep.

The following are subcategories of the alert state (McGrath & Vittner, 2015):

- **Drowsy.** The behaviors common to the drowsy state are open or closed eyes; fluttering eyelids; semidozing appearance; and slow, regular movements of the extremities. Mild startles may be noted from time to time. Although the reaction to a sensory stimulus is delayed, a change of state often results.
- **Quiet alert.** In the quiet-alert state, the newborn is alert and follows and fixates on attractive objects, faces, or auditory stimuli. Motor activity is minimal, and the response to external stimuli is delayed.
- **Active alert.** In the active-alert state, the newborn's eyes are open, and motor activity is quite intense, with thrusting movements of the extremities. Environmental stimuli increase startles or motor activity, but individual reactions are difficult to distinguish because of the generally high activity level (**Figure 33-63** »).
- **Crying.** Intense crying is accompanied by jerky motor movements. Crying serves several purposes for the newborn. It may be a distraction from disturbing stimuli, such as hunger and pain. Fussiness often allows the newborn to discharge energy and reorganize behavior. Most important, crying elicits an appropriate response of help from the parents.

TABLE 33–17 Common Reflexes of the Newborn

Reflex	Stimulus and Response	Visual
Rooting	Elicited when the side of the newborn’s mouth or cheek is touched. In response, the newborn turns toward that side and opens the lips to suck (if not fed recently).	
Sucking	Elicited when an object is placed in the newborn’s mouth or anything touches the lips. Newborns suck even while sleeping; this is called <i>nonnutritive sucking</i> , and it can have a quieting effect on the baby. Disappears by 12 months.	
Moro	Elicited when the newborn is startled by a loud noise or lifted slightly above the crib and then suddenly lowered. In response, the newborn straightens arms and hands outward while the knees flex. Slowly the arms return to the chest, as in an embrace. The fingers spread, forming a C, and the newborn may cry. This reflex may persist until about 6 months of age.	
Tonic neck (fencer position)	Elicited when the newborn is supine and the head is turned to one side. In response, the extremities on the same side straighten, whereas on the opposite side they flex. This reflex may not be seen during the early newborn period, but once it appears it persists until about the third month.	
Stepping	When held upright with one foot touching a flat surface, the newborn puts one foot in front of the other and “walks” (<i>stepping reflex</i>). This reflex is more pronounced at birth and is lost in 4–8 weeks.	

TABLE 33–17 Common Reflexes of the Newborn (*continued*)

Reflex	Stimulus and Response	Visual
Palmar grasping	Elicited by stimulating the newborn's palm with a finger or an object; the newborn grasps and holds the object or finger firmly enough to be lifted momentarily from the crib.	
Babinski	Fanning and hyperextension of all toes and dorsiflexion of the big toe occurs when the lateral aspect of the sole is stroked from the heel upward across the ball of the foot. In children older than 24 months, an abnormal response is extension or fanning of the toes; this Babinski response indicates upper motor neuron abnormalities.	
Blinking	Flash of light causes eyelids to close.	
Pupillary	Flash of light causes pupils to constrict.	
Startle	Loud noise evokes flexion in arms with fists clenched.	
Abdominal	Tactile stimulation causes abdominal muscles to contract.	
Withdrawal	Slight pinprick to sole of foot causes leg to flex.	
Plantar (toe-grasping) reflex	Pressure applied against the ball of the foot elicits plantar flexion of the toes. Disappears by 12 months.	
Trunk incurvation (Galant reflex)	Stroking the spine of the prone newborn causes the pelvis to turn to the stimulated side.

Behavioral Capacities of the Newborn

Newborns have several behavioral capacities that assist them in adapting to extrauterine life. For example, **self-quieting ability** is the ability of newborns to use their own resources to quiet and comfort themselves. Their repertoire includes hand-to-mouth movements, sucking on a fist or tongue, and attending to external stimuli. Neurologically impaired newborns are unable to use self-quieting activities and require more frequent comforting from caregivers when stimulated. For example, drug-positive newborns often exhibit abnormal sleep and feeding patterns and irritability.

Habituation is the newborn's ability to process and respond to complex stimulation. For example, when a bright light is flashed into the newborn's eyes, the initial response is blinking, constriction of the pupil, and perhaps a slight startle reaction. However, with repeated stimulation the newborn's response repertoire gradually diminishes and

disappears. The capacity to ignore repetitious, disturbing stimuli is a newborn defense mechanism that is readily apparent in the noisy, well-lit nursery.

Sensory Capacities of the Newborn

Sensory capacities of the newborn include visual, auditory, olfactory, taste, and tactile capacities.

Visual Capacity

Orientation is the newborn's ability to be alert to, follow, and fixate on appealing and attractive, complex visual stimuli. The newborn prefers the human face and eyes and high-contrast objects and patterns. The newborn is nearsighted and has best vision at a distance of 8 to 15 inches. As the face or object comes into the line of vision, the newborn responds with bright, wide eyes as well as still limbs and a fixed stare. This intense visual involvement may last several minutes. During this time, the newborn is able to follow the stimulus from side to side. The newborn uses this sensory capacity to become familiar with family, friends, and surroundings.

Auditory Capacity

The newborn responds to auditory stimulation with a definite, organized behavioral repertoire. The stimulus used to assess auditory response should be selected to match the state of the newborn. A rattle is appropriate for light sleep, a voice for an awake state, and a clap for deep sleep. As the newborn hears the sound, the cardiac rate rises; a minimal startle reflex may be observed. If the sound is appealing, the newborn will become alert and search for the site of the auditory stimulus. Lack of auditory development is associated with an increased risk of sudden infant death syndrome. The CDC (2015c) currently recommends that newborns be screened for hearing loss no later than 1 month of age.

Olfactory Capacity

Newborns not only select their mother by smell, they apparently also can select other individuals by smell (Lehtonen, 2015). Newborns are able to distinguish their mothers' breast pads from those of other mothers as early as 1 week after birth.

Taste and Sucking

The newborn responds differently to varying tastes. Sugar, for example, increases sucking. Newborns fed with a rubber nipple versus the breast also show sucking pattern variations. When breastfeeding, the newborn sucks in bursts, with frequent regular pauses. The bottle-fed newborn, however, tends to suck at a regular rate, with infrequent pauses.

When awake and hungry, the newborn displays rapid searching motions in response to the rooting reflex. Once feeding begins, the newborn establishes a sucking pattern according to the method of feeding. Finger sucking is seen in utero as well as after birth. The newborn frequently uses nonnutritive sucking as a self-quieting activity, which assists in the development of self-regulation. For bottle-fed babies, there is no reason to discourage nonnutritive sucking with a pacifier. Pacifiers should be offered to breastfed babies only after breastfeeding is well established. If the pacifier is offered too soon, a phenomenon called "nipple confusion" may occur, in which the breastfed baby has difficulty learning to suck from the breast and will nurse less.

Tactile Capacity

The newborn is very sensitive to being touched, cuddled, and held. Often, a mother's first response to an upset or crying newborn is touching or holding. Swaddling, placing a hand on the abdomen, or holding the arms to prevent a startle reflex are other methods of soothing the newborn. The quieted newborn is then able to attend to and interact with the environment. Touch is also used to rouse a drowsy newborn, making him or her more alert for feeding.

Alterations of the Newborn Period

Neonatology is the field of medicine providing care for sick and premature neonates. Many levels of nursery care have evolved in response to increasing knowledge about at-risk newborns: special care, intensive care, and convalescent or transitional care. Along with the newborn's parents, the nurse is an important caregiver in all these settings. As a member of the multidisciplinary healthcare team, the nurse is a technically competent professional who contributes the high-touch, human care necessary in the high-tech perinatal environment.

Various factors influence the outcome of at-risk neonates, including the following:

- Birth weight
- Gestational age
- Type and length of illness
- Environmental factors
- Maternal factors
- Maternal-newborn separation.

An at-risk newborn is one susceptible to illness (morbidity) or even death (mortality) because of dysmaturity, immaturity, physical disorders, or complications during or after birth. In most cases, the neonate is the product of a pregnancy involving one or more predictable risk factors, including the following:

- Low socioeconomic level of the mother
- Limited access to healthcare or no prenatal care
- Exposure to environmental dangers, such as toxic chemicals and illicit drugs
- Preexisting maternal conditions, such as heart disease, diabetes, hypertension, hyperthyroidism, and renal disease
- Maternal factors, such as age and parity
- Medical conditions related to pregnancy and their associated complications
- Pregnancy complications, such as abruptio placentae, oligohydramnios, preterm labor, premature rupture of membranes, and preeclampsia.

Because these factors and the perinatal risks associated with them are known, the birth of at-risk newborns can often be anticipated. The pregnancy can be closely monitored, treatment can be started as necessary, and arrangements can be made for birth to occur at a facility with appropriate resources to care for both mother and baby.

Whether or not prenatal assessment indicates that the fetus is at risk, the course of labor and birth, as well as the newborn's ability to withstand the stress of labor, cannot

be predicted. Thus, the nurse's use of electronic fetal heart monitoring or fetal heart auscultation by Doppler plays a significant role in detecting stress or distress in the fetus. Immediately after birth, the Apgar score may help identify the at-risk newborn, but it is not the only indicator of possible long-term outcome.

The newborn classification and neonatal mortality risk chart is another useful tool for identifying newborns at risk. Before this classification tool was developed, birth weight of less than 2500 g was the sole criterion for determining prematurity. Healthcare providers then recognized that a newborn could weigh more than 2500 g and still be premature. Conversely, a newborn weighing less than 2500 g might be functionally at term or beyond. As a result, birth weight and gestational age together are now the criteria used to assess neonatal maturity, morbidity, and mortality risk.

According to the newborn classification and neonatal mortality risk chart, gestation (postmenstrual age) is divided as follows:

- **Preterm:** less than 37 (completed) weeks
- **Term:** 37–41 6/7 (completed) weeks
- **Postterm:** greater than 42 weeks.

Late preterm is an emerging classification that refers to subgroups of newborns between 34 and 37 weeks of gestation.

As shown in **Figure 33–64** », large-for-gestational-age newborns are those who plot above the 90th percentile curve

Source: From Oken, E., Kleinman, K. P., Rich-Edwards, J., & Gillman, M. W. (2003). A nearly continuous measure of birth weight for gestational age using a United States national reference. *BMC Pediatrics*, 3, 6. Figure 33–64 » Classification of newborns by birth weight and gestational age. Select reference percentiles for birth weight at each gestational age from 22 to 44 completed weeks for male and female singleton newborns: 10th, 50th, and 90th percentiles. Data from 3,423,215 male and 3,267,502 female newborns in the 1999–2000 U.S. Natality datasets.

on an intrauterine growth chart. Appropriate-for-gestational-age newborns are those who plot between the 10th percentile and 90th percentile growth curves. Small-for-gestational-age newborns are those that plot below the 10th percentile growth curve. A newborn is assigned to a category depending on birth weight, length, occipitofrontal head circumference, and gestational age. For example, a newborn classified as Pr SGA is preterm and small for gestational age. The term newborn whose weight is appropriate for gestational age is classified F AGA. It is important to note that intrauterine growth charts are influenced by altitude and by the ethnicity of the newborn population used to create the chart. Also, the assigned newborn classification may vary according to the intrauterine growth curve chart used; therefore, the chart used should correlate with the characteristics of the patient population.

Neonatal mortality risk is a baby's chance of death within the newborn period—that is, within the first 28 days of life. As indicated in **Figure 33–65** », the neonatal mortality risk decreases as both gestational age and birth weight increase. Neonates who are preterm and small for gestational age have the highest mortality risk. The previously high mortality rates for large-for-gestational-age newborns have decreased at most perinatal centers because of both improved management of diabetes in pregnancy and increased recognition of potential complications of these newborns.

Neonatal morbidity can be anticipated based on birth weight and gestational age. In Figure 33–65, the newborn's birth weight is located on the vertical axis, and the gestational age in weeks is found along the horizontal axis. The area where the two meet on the graph identifies common problems. This tool assists in determining the needs of particular newborns for special observation and care. For example, a newborn of 2000 g at 40 weeks of gestation should be carefully assessed for evidence of distress, hypoglycemia, congenital anomalies, congenital infection, and polycythemia.

Exemplar 33.E discusses care of the premature newborn. Common alterations seen in the newborn are described in *Alterations and Therapies: Newborn Care*.

» Go to **Pearson MyLab Nursing and eText** to see Chart 15: Potential Birth Injuries and Chart 16: Congenital Anomalies: Identification and Care in the Newborn Period.

Collaboration

The healthcare team, composed of members from various disciplines, works together to care for the newborn. The team commonly includes a pediatrician or neonatal specialist, a nurse, a lactation consultant, and an audiology specialist. The nurse's role is described in detail in the Nursing Process section that follows. Needs of the newborn differ dramatically in the 4-hour period following birth versus later time periods. Assessment and interventions involve all body systems as the neonate transitions from intrauterine to extrauterine life. As a result, care is divided into initial care, subsequent care, and preparation for discharge. Complications in the newborn may require referral to additional specialists.

NURSING PROCESS

As with any patient, the plan of care for the newborn is based on thorough and ongoing assessment. Thermoregulation and respiratory and cardiac function are the nurse's

Source: From *Contemporary Maternal-Newborn Nursing* 7th edition, by Patricia W Ladewig; Marcia L London; Michele Davidson. Published by Pearson Education © 2009.

Figure 33-65 » Neonatal morbidity by birth weight and gestational age.

primary concerns. These and other interventions are discussed in this section.

Initial Care of the Newborn

Immediately after birth, the provider places the newborn on the mother's abdomen or under the radiant heat unit. Placing the newborn on the maternal abdomen promotes attachment and bonding and gives the mother the opportunity to immediately interact with her baby. Placing the baby on the mother's chest also promotes early breastfeeding opportunities. Even though the baby may not breastfeed immediately, placement on the mother's chest enables the baby to smell, touch, and lick the mother's nipples. The newborn is maintained in a modified Trendelenburg position, which aids drainage of mucus from the nasopharynx and trachea by gravity. The newborn is dried immediately, and wet blankets

are removed. The nurse helps maintain the baby's warmth by placing warmed blankets over the newborn or by placing the newborn in skin-to-skin contact with the mother. If the newborn is under a radiant-heated unit, he or she is dried, placed on a dry blanket, and left uncovered under the radiant heat. Because radiant heat warms the outer surface of objects, a newborn wrapped in blankets will receive no benefit from radiant heat.

The newborn's nose and mouth are suctioned with a bulb syringe as needed. Most immediate care of the newborn can be accomplished while the newborn is in the parent's arms or under the radiant-heated unit. Many women request that their babies be left on their abdomens or chests while initial care is given. Unless a medical complication exists, the nurse should complete assessments in this position to promote parental attachment.

Alterations and Therapies

Newborn Care

ALTERATION	DESCRIPTION	THERAPIES
Growth		
Small for gestational age (SGA)	Less than the 10th percentile for birth weight; the newborn may be preterm, term, or postterm; often seen in women who smoke, have high blood pressure, or any condition that reduces blood flow to the fetus. Increased risk of perinatal asphyxia, perinatal mortality, polycythemia, and hypoglycemia.	<ul style="list-style-type: none"> Care is aimed at promoting growth. Requires ongoing screening for potential complications related to SGA, including polycythemia, cold stress, asphyxia, hypothermia, and hyperbilirubinemia. Assess parents and family members because SGA may be an expected finding if short stature runs in the family.
Very small for gestational age (VSGA)	Less than the third percentile for birth weight; the newborn may be preterm, term, or postterm.	<ul style="list-style-type: none"> Promote weight gain. Monitor blood sugar levels for hypoglycemia. Promote smoking cessation or substance abstinence if that is a factor in the newborn's VSGA status.
Large for gestational age (LGA)	Newborn's weight is at or above the 90th percentile; often associated with maternal diabetes, genetic predisposition, multiparous women, erythroblastosis fetalis, Beckwith-Wiedemann syndrome, or transposition of the great vessels.	<ul style="list-style-type: none"> Accurate estimation of gestational age is important to determining LGA status. Carefully assess for potential birth trauma, including effects of cephalopelvic disproportion and macrosomia, fractured clavicle or humerus, or damage to the brachial plexus nerves as a result of shoulder dystocia. Monitor for hypoglycemia, polycythemia, and hyperbilirubinemia.
Intrauterine growth restriction (IUGR)	Pregnancy circumstances of advanced gestation and limited fetal growth most commonly associated with lack of prenatal care, age extremes in the mother, low socioeconomic status, hypertension, multiple-gestation pregnancy, grand multiparity, and primiparity. Environmental factors such as excessive exercise, exposure to toxins, high altitudes, and maternal drug use have also been implicated.	<ul style="list-style-type: none"> Early identification is important to early intervention. If IUGR is unexplained, an in utero infection must be ruled out. Monitor newborn for hypoglycemia. Provide patient teaching to promote growth after discharge and participation in neonatal stimulation programs to promote neurologic function.
Conditions Present at Birth		
Newborn of a mother with diabetes	Babies born to mothers with diabetes are often LGA, macrosomic, ruddy in color, and have excessive adipose tissue, decreased total body water, edema, cardiomegaly, and often trouble regulating blood sugar levels initially because of higher-than-normal insulin production in utero to cope with the mother's elevated blood sugar levels.	<ul style="list-style-type: none"> Assess blood sugar levels frequently. Monitor for signs of hypoglycemia, including tremors, cyanosis, apnea, temperature instability, poor feeding, and hypotonia. Seizures may occur in severe cases. Assess lab results for hypocalcemia, hyperbilirubinemia, and polycythemia. Initial assessment should observe for birth trauma due to large size.
Postterm newborn	Newborn born after 42 weeks of gestation; most often seen in those of Australian, Greek, and Italian heritage. Most are normal size but large because they continued to grow in utero and face higher risk for morbidity, with a 2–3 times higher mortality rate. Potential complications include hypoglycemia, meconium aspiration, polycythemia, congenital anomalies, seizures, and cold stress.	<ul style="list-style-type: none"> Many postterm neonates will adapt well to extrauterine life. Monitor serum blood sugar. Assess respiratory status, especially in the presence of possible meconium aspiration. Maintain neutral thermal environment until newborn demonstrates temperature stability.

(continued on next page)

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPIES
Newborns with prenatal substance abuse exposure	Substance exposure may include tobacco, marijuana, prescription medications, narcotics, or any number of illegal substances.	<ul style="list-style-type: none"> Babies are at risk for IUGR, meconium aspiration, reduced birth weight, vomiting, seizures, or irritability depending on the substances the fetus was exposed to. Sedate newborns to decrease irritability and tremors. Provide IV fluid therapy for hydration. Possibly advise against breastfeeding. Care of newborns and infants with prenatal substance abuse is discussed in detail in the module on Addiction.
Newborns born to mothers with HIV/AIDS	HIV can be transmitted through the fetal circulation, but the mother who begins antiretroviral medications early in her pregnancy can reduce the risk to the newborn.	<ul style="list-style-type: none"> Advise mother that taking most HIV medications during pregnancy is safe. Neonates may be given prophylactic antiretroviral therapy to decrease risk of active infection. Advise against breastfeeding. This concept is discussed in detail in the exemplar on HIV and AIDS, in the module on Immunity.
Congenital heart defects	Any number of abnormalities can impact the heart during fetal development, increasing the challenge for newborn adaptation to extrauterine life.	<ul style="list-style-type: none"> One third of neonates born with congenital heart defects develop life-threatening symptoms in the first few days of life. Therapies range from palliative care to surgery. This topic is discussed in more detail in the exemplar on Congenital Heart Defects in the module on Perfusion.
Phenylketonuria (PKU)	Amino acid disorders, in which phenylalanine found in dietary protein cannot be converted to tyrosine, result in accumulation of phenylalanine in the blood, which, in turn, results in damage to brain tissue that leads to progressive mental retardation.	<ul style="list-style-type: none"> Collect routine screening blood sample before discharge (24–48 hours after first enteral feeding). Instruct parents that a second screening may be required if initial collection occurs before the initiation of enteral feedings. This follow-up screening often occurs between 7 and 14 days of life.
Maple syrup urine disease	Rapidly progressing and often fatal disease, when untreated, caused by enzymatic defect in the metabolism of the branched-chain amino acids leucine, isoleucine, and alloisoleucine.	<ul style="list-style-type: none"> Diagnosed by routine newborn screening and confirmed by plasma amino acid assay. Instruct parents on importance of obtaining second screening exam, as noted for PKU.
Galactosemia	An inborn error of carbohydrate metabolism in which the body is unable to use the sugars galactose and lactose. Enzyme pathways in liver cells normally convert galactose and lactose to glucose. In galactosemia, one step in that conversion pathway is absent because of the lack of either the enzyme galactose 1-phosphate uridyl transferase or the enzyme galactokinase. High levels of unusable galactose circulate in the blood, resulting in cataracts, brain damage, and liver damage.	<ul style="list-style-type: none"> Instruct parents on importance of routine newborn screening for inborn errors of metabolism.
Homocystinuria	Disorder caused by a deficiency of the enzyme cystathionine beta-synthase, which causes an elevated excretion of homocysteine and methionine.	<ul style="list-style-type: none"> Screening is included in the Recommended Uniform Screening Panel (RUSP) and is considered an amino acid disorder (U.S. Department of Health and Human Services, 2015). No symptoms are usually seen in the newborn period.
Birth-Related Stressors		
Asphyxia	Asphyxia can occur for a number of reasons, including, but not limited to, abruptio placentae, prolapsed cord, maternal hypoxia or death, difficult or prolonged labor, meconium in the amniotic fluid, intrapartum bleeding, maternal infection, prematurity, multiple births, or narcotic use during labor.	<ul style="list-style-type: none"> Promote oxygenation, airway clearance, and breathing to reduce newborn hypoxia, which often includes resuscitation. Monitor blood gas status. Support parents and family. Provide cardiorespiratory monitoring. Newborn is usually taken to the neonatal intensive care unit.

Alterations and Therapies *(continued)*

ALTERATION	DESCRIPTION	THERAPIES
Respiratory distress	May result from inadequate production of surfactant, prematurity, excessive airway secretions, narcotic administration to the mother during labor, meconium aspiration, or congenital anomalies, among other factors. Parenchymal damage results in hyaline membrane disease compounded by mechanical ventilation if required.	<ul style="list-style-type: none"> Continuous monitoring is conducted with a cardiorespiratory monitor. Continuous oxygen saturation monitoring is provided. Determine arterial blood gas levels frequently until stable. May require assistance with respiration in the form of mechanical ventilation, continuous positive airway pressure (CPAP), bilevel positive airway pressure (BiPAP), and/or oxygen administration. Parents and family members require emotional support because it can be very frightening to see a small baby who is so sick and who requires mechanical ventilation.
Transient tachypnea of the newborn	Of particular risk to the LGA and late-preterm neonate because of inadequate clearing of the airways; the newborn will display increased work of breathing 1–6 hours after birth, with rapid respirations, grunting, nasal flaring, and/or mild respiratory and metabolic acidosis. Improvement is usually seen after 24–48 hours.	<ul style="list-style-type: none"> Monitor newborn's respiratory adaptation to extrauterine life, and report any signs of distress immediately to primary healthcare provider. Administration of oxygen should be in conjunction with oxygen saturation monitoring to prevent complications related to oxygen toxicity. Promote parental attachment because a newborn requiring oxygen may not be able to feed or spend as much time with parents until breathing improves.
Meconium aspiration syndrome (MAS)	Meconium is passed in utero secondary to stress and/or hypoxia. This fluid may be aspirated into the tracheobronchial tree in utero or during the first few breaths taken by the newborn. Meconium causes chemical irritation and also forms small balls that become lodged in terminal airways, allowing some air to enter the alveoli but not allowing air to escape. As alveoli continue to expand, they eventually rupture. Complete respiratory collapse may be seen in severe cases.	<ul style="list-style-type: none"> Avoid positive end-expiratory pressure, which forces more air into the lungs and increases chance that alveoli might rupture. Mechanical ventilation may be inadequate, and oscillating ventilators that administer 300–400 breaths/minute in small waves of air may be required. Continuous cardiorespiratory and oxygen saturation monitoring is indicated. Reduce oxygen demands by keeping the baby quiet; sedation may be required. Hypoxic newborns should not be fed because oxygen is shunted from the gut; total parenteral nutrition may be administered to meet nutritional demands.
Cold stress	Results from inadequate temperature regulation; can progress to respiratory distress.	<ul style="list-style-type: none"> Thermoregulation is discussed in the Nursing Process section that follows and in detail in the module on Thermoregulation.
Hypoglycemia	Abnormally low blood sugar (40 mg/dL) can result from a number of conditions, including a mother with diabetes, prematurity, or cold stress.	<ul style="list-style-type: none"> If possible, feed the baby to raise blood sugar levels. If unable to feed, 10% dextrose in water (D₁₀W) may be administered intravenously. Observe for signs of hypoglycemia, including jitteriness, crying, or in severe cases, seizures.
Polycythemia	Abnormally high hemoglobin levels; can result from placental transfusion caused by delayed cord clamping or cord stripping, fetal asphyxia, or twin-to-twin blood transfusion in utero.	<ul style="list-style-type: none"> Encourage fluids. Monitor cardiorespiratory status for tachycardia or congestive heart failure, respiratory distress. Assess jaundice caused by increased red blood cell breakdown. May require patience with feeding because of feeding intolerance, poor feeding, and vomiting.

TABLE 33–18 The Apgar Scoring System

Sign	Score		
	0	1	2
Heart rate	Absent	Slow—below 100 beats/min	Above 100 beats/min
Respiratory effort	Absent	Slow—irregular	Good crying
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	None	Grimace	Vigorous cry
Color	Pale blue	Body pink, blue extremities	Completely pink

Source: Data from Apgar, V. (1966, August). The newborn (Apgar) scoring system, reflections and advice. *Pediatric Clinics of North America*, 13, 645.

Apgar Scoring System

The Apgar scoring system (**Table 33–18** ►) is used to evaluate the physical condition of the newborn at birth. The newborn is rated 1 minute after birth and again at 5 minutes and receives a total score (**Apgar score**) ranging from 0 to 10 based on the following assessments:

- **Heart rate** is auscultated or palpated at the junction of the umbilical cord and skin. This is the most important assessment. A newborn heart rate of less than 100 beats/min indicates the need for immediate resuscitation.
- **Respiratory effort** is the second most important Apgar assessment. Complete absence of respirations is termed apnea. A vigorous cry indicates adequate respirations.
- **Muscle tone** is determined by evaluating the degree of flexion and resistance to straightening of the extremities. A normal newborn's elbows and hips are flexed, with the knees positioned up toward the abdomen.
- **Reflex irritability** is evaluated by stroking the baby's back along the spine or by flicking the soles of the feet. A cry merits a full score of 2. A grimace is given 1 point, and no response is scored as 0.
- **Skin color** is inspected for cyanosis and pallor. Generally, newborns have blue extremities with a pink body, which merits a score of 1. This condition is termed acrocyanosis and is present in 85% of normal newborns at 1 minute after birth. A completely pink newborn scores a 2, and a totally cyanotic, pale neonate scores a 0. Newborns with darker skin pigmentation will not be pink in color. Their skin color is assessed for pallor and acrocyanosis, and a score is selected on the basis of the assessment.

A score of 7–10 indicates a newborn in good condition who requires only nasopharyngeal suctioning and, perhaps, some oxygen near the face (called “blow-by” oxygen). If the Apgar score is less than 7 at 5 minutes, the scoring should be repeated every 5 minutes up to 20 minutes (AAP & ACOG, 2012), and resuscitative measures may need to be instituted. Apgar scores of less than 3 at 5 minutes may correlate with neonatal mortality (Assuncao et al., 2012).

Clamping the Cord

If the healthcare provider has not placed some type of cord clamp on the newborn's umbilical cord, the nurse must do

so. Before applying the cord clamp, the nurse examines the cut end of the cord for the presence of two arteries and one vein. The umbilical vein is the largest vessel; the arteries are seen as smaller vessels. The number of vessels is recorded on the birth and newborn records. The cord is clamped approximately 1.3–2.5 cm (0.5–1 in.) from the abdomen to allow room between the abdomen and clamp as the cord dries. Abdominal skin must not be clamped, because this will cause necrosis of the tissue. The most common type of cord clamp is the plastic Hollister cord clamp (**Figure 33–66** ►). The Hollister clamp is removed in the newborn nursery approximately 24 hours after the cord has dried.

Evidence-based practice suggests that delayed clamping may yield more benefits than immediate cord clamping (ACOG, 2012a). Delaying cord clamping for at least 30–60 seconds produces increased blood volume, reduced need from blood transfusions, decreased incidence of intracranial hemorrhage, and a lower frequency of iron deficiency anemia (ACOG, 2012a). One concern with delayed clamping is

Figure 33–66 ► Hollister cord clamp. **A**, Clamp is positioned 1/2–1 in. from the abdomen and then secured. **B**, Cut cord. The one vein and two arteries can be seen. **C**, Plastic device for removing the clamp after the cord has dried. After the cord is cut, the nurse grasps the Hollister clamp on either side of the cut area and gently separates it.

polycythemia, which is benign. Other concerns include delayed resuscitation of the newborn and interfering with cord blood banking collection (ACOG, 2012a).

Banking Cord Blood

A growing number of parents are arranging for cord blood banking. Parents obtain a special container from the Cord Blood Registry, which they bring with them for the birth. Immediately after the newborn's umbilical cord is clamped and cut, the healthcare provider withdraws blood from the remaining umbilical cord by inserting a large-gauge needle into the umbilical vein. The needle allows the blood to be collected into the container. The nurse labels the specimen immediately and follows the directions required for storage and pickup. The collected cord blood can then be used to treat childhood cancers, rare genetic disorders, and cerebral palsy. There are both public and private cord blood banks. At private banks, the cord blood is stored for possible later use by the donor. Alternatively, cord blood may be donated to public banks for use by anyone in need, much like blood donations. Although cord blood can be donated at some hospital facilities, most hospitals do not have these services available. The main drawback of cord blood banking remains the cost.

Newborn Identification and Security

Identification bands typically come in a set of four, all preprinted with identical numbers. The nurse places two bands on the newborn—one on the wrist and one on the ankle. The newborn bands must fit snugly to prevent their loss. The nurse then gives the mother and partner each a band. The band number is documented in the maternal and newborn medical records. The bands allow access to the newborn care areas; they must not be removed until the newborn is discharged. In most facilities, as a security measure, only individuals with a band are given unlimited access to the newborn. Some facilities also include an umbilical clamp with a preprinted number identical to the number printed on the bands.

Although some institutions rely on an umbilical band system to ensure the safety of newborns, others attach an alarm to the ankle band (**Figure 33-67** ▶). The alarm is triggered if the device is tampered with or if the newborn is removed from the perimeters of the security field.

Additional hospital security measures are now commonplace in maternity settings. This includes mandating that all staff wear appropriate identification at all times. Parents are instructed that individuals without appropriate identification should not be allowed to remove their baby under any circumstances. The nurse also advises the parents to place their baby on the side of the bed away from the window and to have the baby returned to the nursery whenever the mother naps or showers and no other family member is present.

Although hospital newborn abductions are rare, they are catastrophic for the family, hospital, and community. Many abductors pose as medical personnel to gain access to the mother and baby. Women should be advised to ask all hospital personnel for proper identification. If the mother or family feels unsure of the individual, they should immediately use the call bell to alert the nurse and ask for other verification. If a woman is reluctant to allow a student nurse to transport her baby, the staff nurse should be asked to assist the student.

Figure 33-67 ▶ Newborn with security device in place on one ankle.

Assessment

Unlike the adult, the newborn communicates needs primarily by behavior. Because nurses are the most consistent professional observers of the newborn, they can translate this behavior into information about the newborn's condition and respond with appropriate nursing interventions.

Assessment of the newborn is a continuous process designed to evaluate development and adjustments to extra-uterine life. In the birth setting, the Apgar scoring procedure and careful observation form the basis of assessment and are correlated with information such as the following:

- Maternal prenatal care history
- Birthing history
- Maternal analgesia and anesthesia
- Complications of labor or birth
- Treatment instituted immediately after birth, in conjunction with determination of clinical gestational age
- Consideration of the classification of newborns by weight and gestational age and by neonatal mortality risk
- Physical examination of the newborn.

During the first 1–4 hours after birth, the nurse incorporates data from these sources with the assessment findings to formulate a plan for nursing intervention.

The various newborn assessments and the data obtained from them are valuable only to the degree to which they are shared with the parents. The parents must be included in the assessment process from the moment of their child's birth. The Apgar score and its meaning should be explained immediately to the family. As soon as possible, the parents should take part in the physical and behavioral assessments as well.

The nurse encourages the parents to identify the unique behavioral characteristics of their newborn and to learn nurturing activities. Attachment is promoted when parents

have an opportunity to explore their newborn in private and identify individual physical and behavioral characteristics themselves. It is essential that the nurse provide supportive responses to parents' questions and observations throughout the assessment process. The newborn physical examination is the beginning of newborn health surveillance and health education for the newborn's family that will continue beyond discharge.

Timing of Newborn Assessments

During the first 24 hours of life, the newborn makes the critical transition from intrauterine to extrauterine life. The risk of mortality and morbidity is statistically high during this period. Assessment of the newborn is essential to ensure that the transition proceeds successfully.

There are three major time frames for assessments of newborns while they are in the birth facility:

1. The first assessment is done in the birthing area immediately after birth to determine the need for resuscitation or other interventions. The stable newborn can stay with the family after birth in order to initiate early attachment. The newborn with complications is usually taken to the nursery for further evaluation and intervention.
2. A second assessment is done by the nursery nurse as part of routine admission procedures. During this assessment, the nurse carries out a brief physical examination to estimate gestational age and evaluate the newborn's adaptation to extrauterine life. No later than 2 hours after birth, the admitting nursery nurse should evaluate the newborn's status and any problems that place the newborn at risk (AAP & ACOG, 2012).
3. Before discharge, a CNM, physician, or nurse practitioner will carry out a behavioral assessment and a complete physical examination to detect any emerging or potential problems. A general assessment is also done at this time.

Initial Physical Assessment

The nurse performs an abbreviated but systematic physical assessment in the birthing area to detect any abnormalities (Table 33-19 >>). First, the nurse notes the size of the newborn as well as the contour and size of the head in relationship to the rest of the body. The newborn's posture and movements indicate tone and neurologic functioning.

TABLE 33-19 Initial Newborn Evaluation

Assess	Normal Findings
Respirations	30–60 breaths/min, irregular No retractions, no grunting
Apical pulse	110–160 beats/min, somewhat irregular
Temperature	Skin temp above 36.5°C (97.8°F)
Skin color	Body pink with bluish extremities
Umbilical cord	Two arteries and one vein
Gestational age	Should be 37–42 weeks to remain with parents for an extended time
Sole creases	Sole creases that involve the heel

The nurse inspects the skin for discoloration, presence of vernix caseosa and lanugo, and evidence of trauma and desquamation (peeling of skin). **Vernix caseosa** is a white, cheesy substance found normally on newborns. It is absorbed within 24 hours after birth. Vernix is abundant on preterm babies and absent on postterm newborns. **Lanugo** (fine hair) is seen on preterm newborns, especially on the shoulders, foreheads, backs, and cheeks. Desquamation of the skin is seen in postterm newborns.

In general, expect a scant amount of vernix on upper back, axilla, and groin; lanugo only on upper back; ears with incurving of upper two thirds of pinnae and thin cartilage that springs back from folding; male genitals—testes palpated in upper or lower scrotum; female genitals—labia majora larger, clitoris nearly covered.

In the following situations, the newborn may require stabilization by the nursing staff or the NICU team and may need to be temporarily removed from the birth area.

- Apgar score of less than 8 at 1 minute and less than 9 at 5 minutes or baby requires resuscitation measures
- Respirations below 30 or above 60 breaths/min, with retractions and/or grunting
- Apical pulse below 110 or above 160 beats/min, with marked irregularities
- Skin temperature below 36.5°C (97.8°F)
- Skin color pale blue or circumoral pallor
- Baby less than 37 weeks or more than 42 weeks of gestation
- SGA or LGA newborns
- Congenital anomalies involving open areas in the skin (meningomyelocele).

The nurse observes the nares for flaring and, as the newborn cries, inspects the palate for cleft palate. The nurse looks for mucus in the nose and mouth and removes it with a bulb syringe as needed. The nurse inspects the chest for respiratory rate and the presence of retractions. If retractions are present, the nurse assesses the newborn for grunting or stridor. A normal respiratory rate is 30–60 breaths/min. It is important to note that during the first few hours of life the newborn's respiratory rate may be as high as 80 breaths/min. The nurse auscultates the lungs bilaterally for breath sounds. Absence of breath sounds on one side could indicate a pneumothorax. Because a small amount of fluid may remain in the lungs, rales may be heard immediately after birth; this fluid will be absorbed. Rhonchi indicate aspiration of oral secretions. If there is excessive mucus or respiratory distress, the nurse suctions the newborn with a mucous trap or wall suction. The nurse notes and records elimination of urine or meconium on the newborn record.

Establishing Gestational Age

The nurse must establish the newborn's gestational age in the first 4 hours after birth so that careful attention can be given to age-related problems. Once learned, the procedure can be done in a few minutes. Clinical **gestational age assessment tools** have two components:

1. External physical characteristics
2. Neurologic or neuromuscular development.

Physical characteristics generally include sole creases, amount of breast tissue, amount of lanugo, cartilaginous development of the ear, and testicular descent and scrotal rugae or labial development. These objective clinical criteria are not influenced by labor and birth and do not change significantly within the first 12 hours after birth.

Neurologic examination facilitates assessment of functional or physiologic maturation in addition to physical development. However, the newborn's nervous system is unstable during the first 24 hours of life. Therefore, neurologic evaluation findings based on reflexes or assessments that are dependent on the higher brain centers may not be reliable. If the neurologic findings drastically deviate from the gestational age derived by evaluation of external characteristics, a second assessment is done in 24 hours.

The neurologic assessment components (excluding reflexes) can aid in assessing the gestational age of newborns of less than 34 weeks of gestation. Between 26 and 34 weeks, neurologic changes are significant, whereas significant physical changes are less evident. One significant neuromuscular change is that muscle tone progresses from extensor tone to flexor tone in the extremities because the neurologic system matures in a caudocephalad (tail-to-head) progression.

SAFETY ALERT It is essential for the nurse to wear gloves when assessing the newborn in the early hours after birth and before the first bath until amniotic fluid, as well as vaginal and bloody secretions, on the skin are removed.

Ballard et al. (1991) developed the estimation of gestational age by maturity rating, a simplified version of the well-researched **Dubowitz tool**. The Ballard tool omits some of the neuromuscular tone assessments, such as head lag, ventral suspension (difficult to assess in very ill newborns or those on respirators), and leg recoil. In the Ballard tool, each physical and neuromuscular finding is given a value, and the total score is matched to a gestational age. The maximum score on the Ballard tool is 50, which corresponds to a gestational age of 44 weeks.

Postnatal gestational age assessment tools can overestimate preterm gestational age and underestimate postterm gestational age. The tools have been shown to lose accuracy when newborns of less than 28 weeks or more than 43 weeks of gestation are assessed. Ballard et al. (1991), in the **New Ballard Score**, added criteria for more accurate assessment of the gestational age of newborns between 20 and 28 weeks of gestation and less than 1500 g. They suggest that the assessments should be made within 12 hours of birth to optimize accuracy, especially in newborns with a gestational age of less than 26 weeks. Also, the Ballard assessment may be overstimulating to neonates of less than 27 weeks of gestation. Some maternal conditions, such as preeclampsia, diabetes, and maternal analgesia and anesthesia, may affect certain gestational assessment components and warrant further evaluation. Maternal diabetes, although it appears to accelerate fetal physical growth, seems to retard maturation. Maternal hypertension states, which retard fetal physical growth, seem to speed maturation.

Newborns of women with preeclampsia have a poor correlation with the criteria involving active muscle tone and

edema. Maternal analgesia and anesthesia may cause respiratory depression in the baby. Babies with respiratory distress syndrome tend to be flaccid and edematous and to assume a "frog-like" posture. These characteristics affect the scoring of the neuromuscular components of the assessment tool used.

ASSESSING PHYSICAL MATURITY CHARACTERISTICS The nurse first evaluates observable characteristics without disturbing the baby. Selected physical maturity characteristics common to the Dubowitz and Ballard gestational assessment tools are presented in **Figure 33-68** » in the order in which they might be most effectively evaluated.

Other physical characteristics assessed by some gestational age scoring tools include the following:

- **Vernix** covers the preterm newborn. The postterm newborn has no vernix. After noting vernix distribution, the birthing area nurse (wearing gloves) dries the newborn to prevent evaporative heat loss, thus disturbing the vernix and potentially altering this gestational age criterion.
- **Hair** of the preterm newborn has the consistency of matted wool or fur and lies in bunches rather than in the silky, single strands of the term newborn's hair.
- **Skull firmness** increases as the fetus matures. In a term newborn, the bones are hard, and the sutures are not easily displaced. The nurse should not attempt to displace the sutures forcibly.
- **Nails** appear and cover the nail bed at about 20 weeks of gestation. Nails extending beyond the fingertips may indicate a postterm newborn.

ASSESSING NEUROMUSCULAR MATURITY CHARACTERISTICS The CNS of the fetus matures at a fairly constant rate. Tests have been designed to evaluate neurologic status as manifested by development of neuromuscular tone. As noted earlier, neuromuscular tone in the fetus develops in a caudocephalad direction, from the lower to the upper extremities.

The neuromuscular evaluation of the newborn requires more manipulation and disturbances than the physical evaluation. The neuromuscular evaluation is best performed when the newborn has stabilized. Selected neuromuscular maturity characteristics common to the Dubowitz and Ballard gestational assessment tools are presented in **Figure 33-69** ».

Other neuromuscular characteristics assessed by some gestational age scoring tools include the following:

- **Head lag** (neck flexor) is measured by pulling the newborn to a sitting position and noting the degree of head lag. Total lag is common in newborns up to 34 weeks of gestation, whereas postterm newborns (>42 weeks) hold their heads in front of their body lines. Full-term newborns can support their heads momentarily.
- **Ventral suspension** (horizontal position) is evaluated by holding the newborn prone on the nurse's hand. The position of the head and back and the degree of flexion in the arms and legs are noted. Some flexion of arms and legs indicates 36–38 weeks of gestation; fully flexed extremities, with the head and back even, are characteristic of a term newborn.

Physical Characteristics of Gestational Age**Skin**

Assess for thickness, transparency, and texture.

The preterm newborn's skin appears thin and transparent, and has visible blood vessels.

As the newborn approaches term, the skin is thicker and appears opaque because of increased subcutaneous tissue.

Disappearance of the protective vernix caseosa promotes skin desquamation; this is commonly seen in postmature neonates and those showing signs of placental insufficiency.

A. Preterm skin

B. Term skin

Source: Glenn Kraushar/Alamy Stock Photo.

C. Postterm skin

Lanugo

Assess for the quantity of lanugo, the fine soft hair covering the fetus during intrauterine development.

This hair begins to appear at approximately 19–20 weeks' gestation and is most prominent at 27–28 weeks' gestation.

Source: Vanessa Howell, RN, MSN.

D. Lanugo

It is mostly shed by 37 weeks' gestation. It first begins to thin over the lower back and then disappears last from the shoulders.

Plantar surfaces

Assess the number of sole creases over the bottom of the foot. They are reliable indicators of gestational age in the first 12 hours of life.

Plantar creases vary with ethnicity; in newborns of African descent, sole creases may be less developed at term.

A few creases appear on the anterior portion of the foot and the heel is smooth at approximately 34 weeks' gestation (**Ballard score 2**).

E. Plantar surface, 34 weeks gestation

By 36 weeks' gestation, a deeper network of creases cover the anterior two thirds of the foot and the heel is smooth (**Ballard score 3**).

F. Plantar surface, 36 weeks gestation

At term, deep creases cover the entire foot, including the heel (**Ballard score 4**).

G. Plantar surface, term

Breast

Assess the chest for visibility of the nipple and areola. Then assess the size of the breast bud when grasped between the thumb and forefinger. The extremely preterm neonate has no visible nipple and areola. The nipple and areola become more defined and raised by 34 weeks' gestation. A small breast bud appears by 36 weeks' gestation.

The nurse should not grasp the nipple firmly, because skin and subcutaneous tissue will prevent accurate estimation of size. The nurse must do this procedure gently to avoid causing trauma to the breast tissue.

At 38 weeks' gestation, the breast bud is 4 mm (**Ballard score 3**).

H. Breast bud, 38 weeks' gestation

At term, it grows to 5–10 mm (**Ballard score 4**).

I. Breast bud, term

As gestation progresses, the breast tissue mass and areola enlarge. However, a large breast tissue mass can occur as a result of specific conditions other than advanced gestational age or the effects of maternal hormones on the baby. In the LGA neonate, the accelerated development of breast tissue in a mother with diabetes is a reflection of subcutaneous fat deposits. SGA term or postterm newborns may have used subcutaneous fat, which would have been deposited as breast tissue, to survive in utero; as a result, their lack of breast tissue may indicate a gestational age of 34–35 weeks even though other factors indicate a term or postterm newborn.

Eyes and ears

Assess the eye opening. In extremely preterm neonates, the eyelids are examined with gentle flexion to determine the amount of fusion. Eye opening begins at 22 weeks, and the lids are completely unfused by 28 weeks' gestation.

Assess the formation of the ear cartilage and curving of the pinna. At earlier gestational ages the lack of cartilage allows the ear to fold easily and retain the fold. As gestational age increases, the resistance of the ear to folding increases and recoil is seen. In extremely preterm neonates the pinnae are flat. Incurving proceeds from the top down toward the lobes with advancing gestational age.

The ear of the newborn at approximately 36 weeks gestation shows incurving of the upper two thirds of the pinna (**Ballard score 2**).

J. Ear at 36 weeks gestation

Newborn at term shows well-defined incurving of the entire pinna (**Ballard score 3**).

K. Ear at term

The pinna is folded toward the face and released. If the auricle stays in the position in which it is pressed or returns slowly to its original position, it usually means the gestational age is less than 38 weeks.

Source: Vanessa Howell, RN, MSN.

L. Assessing the pinna

Male genitals

Assess for size of the scrotal sac, presence of rugae (wrinkles and ridges in the scrotum), and descent of the testes.

Before 36 weeks of gestation, the scrotum has few rugae, and the testes are palpable in the inguinal canal not within the scrotum (**Ballard score 2**).

M. Male genitals, preterm

By 36–38 weeks, the testes are in the upper scrotum, and rugae have developed over the anterior portion of the scrotum. By term, the testes are fully descended in the lower scrotum, which is pendulous and covered with rugae (**Ballard score 3**).

N. Male genitals, term

Female genitals

Assess labial development. Genital appearance depends in part on subcutaneous fat deposition and, therefore, relates to fetal nutritional status. The clitoris varies in size and, occasionally, is so swollen that it is difficult to identify the sex of the newborn. This swelling may be caused by adrenogenital syndrome, which causes the adrenals to secrete excessive amounts of androgen and other hormones.

At 32 weeks of gestation, the clitoris is prominent and the labia minora are flat (**Ballard score 1**).

O. Female genitals, 32 weeks gestation

By 36 weeks' gestation, the labia majora are larger and the clitoris is nearly covered (**Ballard score 2**).

P. Female genitals, 36 weeks' gestation

At term, the labia majora are well developed and cover both the clitoris and labia minora (**Ballard score 3**).

Source: Christine Anderson.

Q. Female genitals, term

Figure 33-68 » Physical characteristics of gestational age. (continued)

Neuromuscular Characteristics of Gestational Age**Resting posture**

Assess the posture that the supine newborn assumes at rest. The extremely preterm neonate will lie with arms and legs extended or in any position placed.

At approximately 31 weeks' gestation, the newborn has slightly more flexion in the arms and legs (**Ballard score 1 or 2**).

A. Resting posture, 31 weeks' gestation

At approximately 35 weeks' gestation, the newborn exhibits stronger flexion of the arms, hips, and thighs (**Ballard score 3**).

B. Resting posture, 35 weeks' gestation

At term, the newborn exhibits hyper-tonic flexion of all extremities with arms flexed to the chest, hands fisted, and legs flexed toward the abdomen (**Ballard score 4**).

C. Resting posture, term

Square window sign

Assess the angle of the wrist when the palm is flexed toward the forearm until resistance is felt. The angle formed at the wrist is measured. The extremely preterm neonate has no flexor tone and cannot achieve a 90-degree angle. The preterm neonate has poor flexion and is unable to flex the arm at the elbow more than 90 degrees.

At 28–32 weeks' gestation, the angle is 90 degrees (**Ballard score 0**).

D. Square window sign, 28–32 weeks' gestation

At 38–40 weeks' gestation, the angle is 30- to 40-degrees (**Ballard score 2 to 3**).

E. Square window sign, 38–40 weeks' gestation

A 0- to 15-degree angle occurs in newborns from 40–42 weeks' gestation (**Ballard score 4**).

Source: Vanessa Howell, RN, MSN.

F. Square window sign, 40–42 weeks' gestation

Recoil of extremities

Very preterm neonates do not resist extension. They respond with weak and delayed flexion in a small arc. Term newborns resist extension and briskly return their arms to the flexed position.

Arm recoil may be slower in healthy but fatigued newborns after birth; therefore, arm recoil is best elicited after the first hour postbirth, when the baby has had time to recover from the stress of the birth. The deep sleep state also decreases the arm recoil response. Assessment of arm recoil should be bilateral to rule out brachial palsy.

Assess the amount of arm flexion by flexing both arms at the elbows for 5 seconds. Then extend the arms at the elbows

G. Extend arms at elbows

Release the arms to see the amount of recoil

H. Release arms to see recoil

Because flexion first develops in the lower extremities, recoil generally is first tested in the legs. Place the newborn supine on a flat surface. With a hand on the newborn's knees, place the baby's legs in flexion and extend them parallel to each other and flat on the surface. The response to this maneuver is recoil of the newborn's legs. According to gestational age, they may not move or may return slowly or quickly to the flexed position. Preterm neonates have less muscle tone than term neonates, so preterm neonates have less recoil.

Figure 33–69 >> Neuromuscular characteristics of gestational age.

Popliteal angle

Assess the angle of the knee in the supine newborn. The angle formed is then measured.

Holding the pelvis flat, flex and hold the thigh to the abdomen while extending the leg at the knee until resistance is met

I. Popliteal angle

The newborn with more advanced gestational age has greater flexion. Results vary from no resistance in the very immature newborn to an 80-degree angle in the term newborn.

Scarf sign

Assess the newborn's resistance to pulling the arm across the chest toward the opposite shoulder. The newborn's elbow moves closer to the opposite shoulder with decreasing gestational age.

Until approximately 30 weeks' gestation, the elbow moves past the midline with no resistance (**Ballard score 1**).

At 36–40 weeks' gestation, the elbow is at midline (**Ballard score 2**).

The term newborn's elbow will not cross the midline of the chest (**Ballard score 4**).

J. Scarf sign, 30 weeks' gestation

K. Scarf sign, 36–40 weeks' gestation

Source: Vanessa Howell, RN, MSN.

L. Scarf sign, term

Heel-to-ear extension

Assess by placing the newborn in a supine position and then gently drawing the foot toward the ear on the same side until resistance is felt. Allow the knee to bend during the test and hold the buttocks down to keep from rolling the baby. Both the proximity of foot to ear and the degree of knee extension are assessed.

A preterm, immature newborn's leg will remain straight, and the foot will go to the ear or beyond (**Ballard score 0**).

M. Heel-to-ear extension

With advancing gestational age, the newborn demonstrates increasing resistance to this maneuver. Maneuvers involving the lower extremities of newborns who had frank breech presentation should be delayed to allow for resolution of leg positioning.

Ankle dorsiflexion

Assess by flexing the ankle on the shin. Use a thumb to push on the sole of the newborn's foot while the fingers support the back of the leg. Then, measure the angle formed by the foot and the interior leg.

A 45-degree angle indicates 32 to 36 weeks' gestation (**Ballard score 1**).

A 20-degree angle indicates 36–40 weeks' gestation (Ballard score 2 to 3). A 15- to 0-degree angle is common at 40 weeks or more of gestation (**Ballard score 4**).

Ankle dorsiflexion findings can be influenced by intrauterine position and congenital deformities.

N. Ankle dorsiflexion, 32–36 weeks' gestation.

O. Ankle dorsiflexion, 40 or more weeks' gestation.

Figure 33-69 » Neuromuscular characteristics of gestational age. (continued)

- **Major reflexes**, such as sucking, rooting, grasping, Moro, tonic neck, Babinski, and others, are evaluated during the newborn exam (see Table 33–17).

ADDITIONAL METHODS FOR ESTIMATING GESTATIONAL AGE A supplementary method for estimating gestational age (done by the physician or nurse practitioner) is to view the vascular network of the cornea with an ophthalmoscope. The nurse may need to delay administration of prophylactic eye ointment in preterm neonates until after this vascular eye exam has been done. The amount of vascularity present over the surface of the lens assists in identifying neonates with a gestational age of 27–34 weeks (Rosenberg, 2013).

When the gestational age determination and birth weight are considered together, the newborn can be identified as one whose growth is classified as SGA (below 10th percentile), AGA (between 10th and 90th percentile), or LGA (above 90th percentile) (see Figure 33–64).

This determination enables the nurse to anticipate possible physiologic problems and is used in conjunction with a complete physical examination to establish an appropriate plan of care for the individual newborn. For example, newborns who are SGA or LGA are at risk for hypoglycemia and therefore often require frequent glucose monitoring and early feedings started soon after birth.

The nurse also plots the gestational age against the newborn's length, head circumference, and weight on an appropriate growth chart to determine if these measurements fall within the average range—the 10th to 90th percentile for the corresponding gestational age. These correlations further document the level of maturity and appropriate category for the newborn. The comparison of the newborn's weight–length ratio further facilitates identification of SGA newborns as having symmetric or asymmetric growth restriction. Measuring weight and height often aggravates newborns and may alter their vital signs. For better accuracy, take the newborn's vital signs before weighing and measuring the neonate.

Subsequent Physical Assessment

Once the initial assessment process is complete and gestational age has been established, the nurse carries out a thorough, systematic assessment of the newborn. Completing the physical assessment in the presence of the parents provides an opportunity to acquaint them with their unique newborn. The examination is performed in a systematic, head-to-toe manner, and all findings are recorded. When assessing the physical and neurologic status of the newborn, the nurse should first consider general appearance and then proceed to specific areas.

GENERAL APPEARANCE The newborn's head is disproportionately large for its body. The neck looks short because the chin rests on the chest. Newborns have a prominent abdomen, sloping shoulders, narrow hips, and rounded chests. The center of the baby's body is the umbilicus rather than the symphysis pubis, as in the adult. The body appears long and the extremities short.

Newborns tend to stay in a flexed position similar to the one maintained in utero and will offer resistance to

straightening of the extremities. This flexed position contributes to the short appearance of the extremities. The hands are tightly clenched. After a breech birth, the feet are usually dorsiflexed, and it may take several weeks for the newborn to assume the typical newborn posture.

WEIGHT AND MEASUREMENT The normal, full-term newborn has an average birth weight of 3405 g (7 lb, 8 oz). Other factors that influence weight are age and size of the parents, health of the mother (smoking and malnutrition decrease birth weight), and the interval between pregnancies (short intervals, such as every year, result in lower birth weight). After the first week, and for the first 6 months, the baby's weight increases about 198 g (7 oz) weekly.

Approximately 70–75% of the newborn's body weight is water. During the initial newborn period (the first 3–4 days), term newborns have a physiologic weight loss of about 5–10% because of fluid shifts. For the term newborn, weight loss that is greater than 10% indicates the need for clinical appraisal. Large babies also tend to lose more weight because of greater fluid loss in proportion to birth weight. Factors contributing to weight loss include insufficient fluid intake resulting from delayed breastfeeding or a slow adjustment to the formula, increased volume of meconium excreted, and urination. Weight loss may be marked in the presence of temperature elevation (because of associated dehydration) or consistent chilling (because of nonshivering thermogenesis).

The length of the average newborn is difficult to measure because the legs are flexed and tensed. To measure length, the nurse should place newborns flat on their backs with their legs extended as much as possible. The average length is 50 cm (20 in.), and the range is 46–56 cm (18–22 in.). The newborn will grow approximately 2.5 cm (1 in.) a month for the next 6 months. This is the period of most rapid growth.

At birth, the newborn's head is one third the size of an adult's head. The circumference (biparietal diameter) of the newborn's head is 32–37 cm (12.5–14.5 in.). For accurate measurement, the nurse places the tape over the most prominent part of the occiput and brings it just above the eyebrows. The circumference of the newborn's head is approximately 2 cm (0.8 in.) greater than the circumference of the newborn's chest at birth and will remain in this proportion for the next few months. It is best to take another head circumference measurement on the second day if the newborn experienced significant head molding or developed a caput from the birth process.

The average circumference of the chest is 32 cm (12.5 in.) and ranges from 30 to 35 cm (12 to 14 in.). Chest measurements are taken with the tape measure placed at the lower edge of the scapulas and brought around anteriorly, directly over the nipple line. The abdominal circumference, or girth, may also be measured at this time by placing the tape around the newborn's abdomen at the level of the umbilicus, with the bottom edge of the tape at the top edge of the umbilicus.

TEMPERATURE Initial assessment of the newborn's temperature is critical; if no heat conservation measures are started, skin temperature decreases markedly within

10 minutes after exposure to room air. The newborn's temperature should stabilize within 8–12 hours.

Temperature is monitored when the newborn is admitted to the nursery and at least every 30 minutes until the newborn's status has remained stable for 2 hours. Thereafter, the nurse should assess temperature at least once every 8 hours, or according to institutional policy (AAP & ACOG, 2012). For neonates who have been exposed to Group B hemolytic streptococcus, more frequent temperature monitoring may be required.

Temperature can be assessed by the axillary skin method, a continuous skin probe, the rectal route, or a tympanic thermometer. Axillary temperatures are the preferred method and are considered to be a close estimation of the rectal temperature. Axillary temperature ranges from 36.5° to 37.0°C (97.7° to 98.6°F). Skin temperature is measured most accurately by means of a continuous skin probe, but this method generally is used only with small or sick newborns placed under radiant warmers or in isolettes. Normal skin temperature is 36°–36.5°C (96.8°–97.7°F). Rectal temperature is assumed to be the closest approximation to core temperature, but the accuracy of this method depends on the depth to which the thermometer is inserted. The rectal temperature is often measured during the initial newborn assessment to determine patency. This method is not recommended for routine use because of the risk of irritation to the rectal mucosa and increased chances of perforation (Blackburn, 2013). Normal rectal temperature is 36.6°–37.2°C (97.8°–99°F).

Temperature instability (a deviation of more than 1°C [2°F] from one reading to the next) or a subnormal temperature may indicate an infection. In contrast to an elevated temperature in older children, an increased temperature in a newborn may indicate a reaction to too many coverings, too hot a room, or dehydration. Dehydration, which tends to increase body temperature, occurs in newborns whose feedings have been delayed for any reason. Newborns may respond to overheating (temperature of >37.5°C [99.5°F]) by increased restlessness and, eventually, by perspiration after 35–40 minutes of exposure (Blackburn, 2013). The perspiration appears initially on the head and face and then on the chest.

SKIN CHARACTERISTICS Although the newborn's skin color varies with genetic background, all healthy newborns have a pink tinge to their skin. The ruddy hue results from increased RBC concentrations in the blood vessels and limited subcutaneous fat deposits.

Skin pigmentation is slight in the newborn period, so color changes may be seen even in darker-skinned babies. Caucasian newborns have a pinkish-red skin tone a few hours after birth, and African American newborns have pinkish-red to reddish-brown skin color. Hispanic and Asian newborns may have an olive skin tone (Vargo, 2014). Skin pigmentation deepens over time; therefore, variations in skin color indicating illness are more difficult to evaluate in African American and Asian newborns (Vargo, 2014). A newborn who is cyanotic at rest and pink only with crying may have choanal atresia (congenital blockage of the passageway between the nose and pharynx). If crying increases the cyanosis, heart or lung problems should be suspected. Very pale newborns may be anemic or have hypovolemia (low blood pressure) (see discussion of hypovolemia in the module on Fluids and Electrolytes) and should be evaluated for these problems.

Source: George Dodson/Pearson Education, Inc.

Figure 33-70 >> Newborn with acrocyanosis.

Acrocyanosis may be present in the first 24–48 hours after birth (**Figure 33-70** >>). This condition, bluish discoloration of the hands and feet, is caused by poor peripheral circulation, which results in vasomotor instability and capillary stasis, especially when the baby is exposed to cold. Blue hands and nails are a poor indicator of decreased oxygenation in a newborn. If the central circulation is adequate, the blood supply should return quickly (2–3 seconds) to the extremity after the skin is blanched with a finger. The nurse should assess the face and mucous membranes for pinkness that reflects adequate oxygenation.

Mottling (lacy pattern of dilated blood vessels under the skin) occurs as a result of general circulation fluctuations. It may last several hours to several weeks, or it may come and go periodically. Mottling may be related to chilling or prolonged apnea, sepsis, or hypothyroidism.

Harlequin sign (clown) color change is occasionally noted: A deep red color develops over one side of the newborn's body while the other side remains pale, so the skin resembles a clown's suit. This color change results from a vasomotor disturbance in which blood vessels on one side dilate while the blood vessels on the other side constrict. It usually lasts from 1 to 20 minutes. Affected newborns may have single or multiple episodes, but they are transient and clinically insignificant. The nurse should document each occurrence.

Jaundice is yellow pigmentation of body tissues caused by the presence of bile pigments. It is first detectable on the face (where skin overlies cartilage) and the mucous membranes of the mouth, and it has a head-to-toe progression (Vargo, 2014). Jaundice regresses in the opposite direction (from toe to head). It is evaluated by blanching the tip of the nose, the forehead, the sternum, or the gum line. This procedure must be carried out in appropriate lighting. If jaundice is present, the area will appear yellowish immediately after blanching. Another area to assess for jaundice is the sclera. Evaluation and determination of the cause of jaundice must be initiated immediately to prevent possibly serious sequelae. The jaundice may be related to breastfeeding (extremely rare), hematomas, immature liver function, or bruises from forceps, or it may be caused by blood incompatibility, oxytocin (Pitocin) augmentation or

Source: George Dodson/Pearson Education, Inc.

Figure 33-71 » Erythema toxicum on leg.

induction, or a severe hemolytic process. Any jaundice noted before a newborn is 24 hours of age should be reported to the physician or neonatal nurse practitioner.

Erythema toxicum is an eruption of lesions in the area surrounding a hair follicle that are firm, vary in size from 1 to 3 mm, and consist of a white or pale yellow papule or pustule with an erythematous base. It is often called “newborn rash” or “flea bite” dermatitis. The rash may appear suddenly, usually over the trunk and diaper area, and is frequently widespread (**Figure 33-71** »). The lesions do not appear on the palms of the hands or the soles of the feet. The peak incidence is at 24–48 hours of life. The condition rarely presents at birth or after 5 days of life. The cause is unknown, and no treatment is necessary. Some healthcare providers believe it may be caused by irritation from clothing. The lesions disappear in a few hours or days. If a maculopapular rash appears, a smear of the aspirated papule will show numerous eosinophils on staining; no bacteria will be cultured.

Milia (exposed sebaceous glands) appear as raised white spots on the face, especially across the nose (**Figure 33-72** »). No treatment is necessary, because they will clear spontaneously within the first month. Newborns of African heritage

Source: Jack Sullivan/Alamy Stock Photo.

Figure 33-72 » Facial milia.

have a similar condition called transient neonatal pustular melanosis (Silverman, 2012).

Skin turgor (the elasticity of the skin) is assessed to determine hydration status, the need to initiate early feedings, and the presence of any infectious processes. The usual place to assess skin turgor is over the abdomen, forearm, or thigh. Skin should be elastic and return rapidly to its original shape.

Forceps marks may be present after a difficult forceps birth. The newborn may have reddened areas over the cheeks and jaws. It is important to reassure the parents that these marks will disappear, usually within 1 or 2 days. Transient facial paralysis resulting from the forceps pressure is a rare complication. Vacuum extractor suction marks on the vertex of the scalp are often seen when vacuum extractors are used to assist with the birth; these marks are benign and do not indicate underlying brain lesions.

BIRTHMARKS Birthmarks are frequently a cause of concern and guilt for parents. The mother may be especially anxious, fearing that she is to blame (“Is my baby ‘marked’ because of something I did?”). Birthmarks should be identified and explained to the parents. By providing appropriate information about the cause and course of birthmarks, the nurse can relieve the fears and anxieties of the family. The nurse should note any bruises, abrasions, or birthmarks seen on admission to the nursery.

Telangiectatic nevi (stork bites) appear as pale pink or red spots and are frequently found on the eyelids, nose, lower occipital bone, and nape of the neck. These lesions are common in newborns with light complexions and are more noticeable during periods of crying. These areas have no clinical significance and usually fade by the second birthday.

Mongolian spots are macular areas of bluish-black or gray-blue pigmentation on the dorsal area and the buttocks (**Figure 33-73** »). They are common in newborns of Asian, Hispanic, and African descent and in any newborn with darker skin. They gradually fade during the first or second year of life. They may be mistaken for bruises and should be documented in the newborn’s chart.

Source: George Dodson/Pearson Education, Inc.

Figure 33-73 » Mongolian spots.

Nevus flammeus (port-wine stain) is a capillary angioma directly below the epidermis. It is a nonelevated, sharply demarcated, red-to-purple area of dense capillaries. In newborns of African descent, it may appear as a purple-black stain. The size and shape vary, but it commonly appears on the face. It does not grow in size, does not fade with time, and as a rule, does not blanch. The birthmark may be concealed by using an opaque cosmetic cream.

Nevus vasculosus (strawberry mark) is a capillary hemangioma. It consists of newly formed and enlarged capillaries in the dermal and subdermal layers. It is a raised, clearly delineated, dark red, rough-surfaced birthmark commonly found in the head region. Such marks usually grow (often rapidly) starting in the second or third week of life, and they may not reach their full size until about 6 months (Witt, 2015). They begin to shrink and start to resolve spontaneously several weeks to months after they reach peak growth. A pale purple or gray spot on the surface of the hemangioma signals the start of resolution. The best cosmetic effect is achieved when the lesions are allowed to resolve spontaneously.

HEAD The newborn's head is large (approximately one fourth of the body size), with soft, pliable skull bones. For most term neonates, the occipitofrontal circumference is 32–37 cm (12.6–14.6 in.).

The head may appear asymmetric in the newborn of a vertex birth. This asymmetry, called **molding**, is caused by overriding of the cranial bones during labor and birth. The degree of molding varies with the amount and length of pressure exerted on the head. Within a few days after birth, the overriding usually diminishes, and the suture lines become palpable. Because head measurements are affected by molding, a second measurement is indicated a few days after birth.

The heads of breech-born newborns and of those delivered by elective cesarean are characteristically round and well shaped because no pressure was exerted on them during birth. Any extreme differences in head size may indicate microcephaly (abnormally small head) or hydrocephalus (an abnormal buildup of fluid in the brain). Variations in the shape, size, or appearance of the head measurements may be caused by craniosynostosis (premature closure of the cranial sutures), which will need to be corrected through surgery to allow brain growth, and plagiocephaly (asymmetry caused by pressure on the fetal head during gestation) (Johnson, 2015).

Two fontanels (“soft spots”) may be palpated on the newborn's head. Fontanels, which are openings at the juncture of the cranial bones, can be measured with the fingers. Accurate measurement necessitates that the examiner's finger be measured in centimeters. The assessment should be carried out with the newborn in a sitting position and not crying. The diamond-shaped anterior fontanel is approximately 3–4 cm (1.2–1.6 in.) long by 2–3 cm (0.8–1.2 in.) wide. It is located at the juncture of the frontal and parietal bones. The posterior fontanel, smaller and triangular, is formed by the parietal bones and the occipital bone and is 0.5 by 1 cm. Because of molding, the fontanels are smaller immediately after birth than they are several days later. The anterior fontanel closes within 18 months, whereas the posterior fontanel closes within 8–12 weeks.

The fontanels are a useful indicator of the newborn's condition. The anterior fontanel may swell when the newborn cries or passes a stool or may pulsate with the heartbeat, which is normal. A bulging fontanel usually signifies increased intracranial pressure, and a depressed fontanel indicates dehydration (Vargo, 2014).

The sutures between the cranial bones should be palpated for the amount of overlapping. In newborns whose growth has been restricted, the sutures may be wider than normal, and the fontanels may also be larger because of impaired growth of the cranial bones. In addition to inspecting the newborn's head for degree of molding and size, the nurse should evaluate it for soft-tissue edema and bruising.

Cephalohematoma is a collection of blood resulting from ruptured blood vessels between the surface of a cranial bone (usually parietal) and the periosteal membrane (**Figure 33–74** >>). The scalp in these areas feels loose and slightly edematous. These areas emerge as defined hematomas between the first and second days. Although external

Figure 33–74 >> Cephalohematoma is a collection of blood between the surface of a cranial bone and the periosteal membrane. This is a cephalohematoma over the left parietal bone.

pressure may cause the mass to fluctuate, it does not increase in size when the newborn cries. Cephalohematomas may be unilateral or bilateral and do not cross suture lines. They are relatively common in vertex births and may disappear within 2 weeks to 3 months. They may be associated with physiologic jaundice because extra RBCs are being destroyed within the cephalohematoma. A large cephalohematoma can lead to anemia and hypotension.

Caput succedaneum is a localized, easily identifiable, soft area of the scalp, generally resulting from a long and difficult labor or vacuum extraction. The sustained pressure of the presenting part against the cervix results in compression of local blood vessels, and venous return is slowed. This results in an increase of tissue fluids, edematous swelling, and occasional bleeding under the periosteum. The caput may vary from a small area to a severely elongated head. The fluid in the caput is reabsorbed within 12 hours to a few days after birth. Caputs resulting from vacuum extractors are sharply outlined, circular areas up to 2 cm (0.8 in.) thick. They disappear more slowly than naturally occurring edema. It is possible to distinguish between a cephalohematoma and a caput because the caput overrides suture lines (**Figure 33-75** >>), whereas the cephalohematoma, because

of its location, never crosses a suture line. Also, caput succedaneum is present at birth, whereas cephalohematoma generally is not.

>> Go to **Pearson MyLab Nursing and eText** to see Chart 17: Comparison of Cephalohematoma and Caput Succedaneum.

FACE The newborn's face is well designed to help the newborn suckle. Sucking (fat) pads are located in the cheeks, and a labial tubercle (sucking callus) is frequently found in the center of the upper lip. The chin is recessed, and the nose is flattened. The lips are sensitive to touch, and the sucking reflex is easily initiated.

Symmetry of the eyes, nose, and ears is evaluated. Symmetry of facial movement should be assessed to determine the presence of facial palsy.

Facial paralysis appears when the newborn cries: The affected side is immobile, and the palpebral (eyelid) fissure widens. Paralysis may result from forceps-assisted birth or pressure on the facial nerve caused by the maternal pelvis during birth. Facial paralysis usually disappears within a few days to 3 weeks, although in some cases it may be permanent.

EYES The eyes of the newborn range from a blue- or slate-gray color to a dark brown color. Scleral color tends to be bluish white in all newborns because of its relative thinness. A blue sclera is associated with osteogenesis imperfecta. The infant's eye color is usually established at approximately 3 months, although it may change any time up to 1 year.

The eyes should be checked for size, equality of pupil size, reaction of pupils to light, blink reflex to light, and edema and inflammation of the eyelids. The eyelids are usually edematous during the first few days of life because of the pressure associated with birth.

Erythromycin is frequently used prophylactically to reduce risk from bacteria to which the neonate may have been exposed during the birth process. Erythromycin is preferred over the once-popular silver nitrate because erythromycin does not usually cause chemical irritation of the eye. The instillation of silver nitrate drops in the newborn's eyes may cause edema, and **chemical conjunctivitis** (irritation of the conjunctiva by chemicals used to treat the eyes, resulting in a purulent greenish yellow discharge exudate) may appear a few hours after instillation but disappears in 1–2 days. Tetracycline is still used in some institutions (AAP & ACOG, 2012).

If infectious conjunctivitis exists, the newborn has the same purulent discharge exudate as in chemical conjunctivitis, but it is caused by gonococcus, *Chlamydia*, staphylococci, or a variety of gram-negative bacteria. It requires treatment with ophthalmic antibiotics. Onset is usually after the second day. Edema of the orbits or eyelids may persist for several days until the newborn's kidneys can eliminate the fluid.

Small **subconjunctival hemorrhages** appear in approximately 10% of newborns and are commonly found on the sclera. These hemorrhages are caused by the changes in vascular tension or ocular pressure during birth. They will remain for a few weeks and are of no pathologic significance.

Figure 33-76 >> Transient strabismus may be present in the newborn because of poor neuromuscular control.

Parents need reassurance that the newborn is not bleeding from within the eye and that vision will not be impaired.

The newborn may demonstrate transient strabismus caused by poor neuromuscular control of eye muscles (**Figure 33-76** >>). It gradually dissipates in 3–4 months. The “doll’s-eye” phenomenon is also present for approximately 10 days after birth. As the newborn’s head position is changed to the left and then to the right, the eyes move to the opposite direction. “Doll’s eye” results from underdeveloped integration of head–eye coordination.

The nurse should observe the newborn’s pupils for opacities or whiteness and for the absence of a normal red retinal reflex. Red retinal reflex is a red-orange flash of color observed when an ophthalmoscope light reflects off the retina. In a newborn with dark skin color, the retina may appear paler or more grayish. Absence of red reflex occurs with cataracts. Congenital cataracts should be suspected in newborns of mothers with a history of rubella, cytomegalic inclusion disease, or syphilis. Brushfield spots (black or white spots on the periphery of the iris) can be associated with Down syndrome (Vargo, 2014).

The cry of the newborn is commonly tearless because the lacrimal structures are immature at birth and are not usually fully functional until the second month of life. However, some babies produce tears during the newborn period.

Although poor oculomotor coordination and absence of accommodation limit visual abilities, newborns have peripheral vision, can fixate on objects near (20.3–38.1 cm [8–15 in.]) and in front of their face for short periods, can accommodate to large objects (7.6 cm [3 in.] tall × 7.6 cm [3 in.] wide), and can seek out high-contrast geometric shapes. Newborns can perceive faces, shapes, and colors, and they begin to show visual preferences early. Newborns generally blink in response to bright lights, to a tap on the bridge of the nose (glabellar reflex), or to a light touch on the eyelids. Pupillary light reflex is also present. Examination of the eye is best accomplished by rocking the newborn from an upright position to the horizontal a few times or by other methods, such as dimming overhead lights, which elicit an opened-eye response.

NOSE The newborn’s nose is small and narrow. Babies are characteristically nose breathers for the first few months of life and generally remove obstructions by sneezing. Nasal patency is ensured if the newborn breathes easily with the mouth closed. If respiratory difficulty occurs, the nurse checks for choanal atresia (congenital blockage of the passageway between nose and pharynx). This can be done by observing the newborn feeding or by gently occluding each of the nares (Cavaliere & Sansoucie, 2014).

The newborn has the ability to smell after the nasal passages have been cleared of amniotic fluid and mucus. Newborns demonstrate this ability by the search for milk. Newborns turn their heads toward a milk source, whether bottle or breast. Newborns react to strong odors, such as alcohol, by turning their heads away or blinking.

MOUTH The lips of the newborn should be pink. A touch on the lips should produce sucking motions. Saliva is normally scant. The taste buds develop before birth, and the newborn can easily discriminate between sweet and bitter flavors.

The easiest way to examine the mouth completely is to stimulate the baby to cry by gently depressing the tongue, thereby causing the newborn to open the mouth fully. It is extremely important to examine the entire mouth to check for a cleft palate, which can be present even in the absence of a cleft lip. The examiner moves a gloved index finger along the hard and soft palate to feel for any openings. If the facility still provides gloves with powder, the glove powder should always be removed before examining the newborn’s mouth.

Occasionally, an examination of the gums will reveal precocious teeth over the area where the lower central incisors will erupt. If they appear loose, they should be removed by the provider to prevent aspiration. Gray-white lesions (inclusion cysts) on the gums may be confused with teeth. On the hard palate and gum margins, **Epstein pearls** (small, glistening, white specks [keratin-containing cysts] that feel hard to the touch) are often present. They usually disappear in a few weeks and are of no significance. **Thrush** may appear as white patches that look like milk curds adhering to the mucous membranes, and bleeding may occur when patches are removed. Thrush is caused by *Candida albicans*, often acquired from an infected vaginal tract during birth, antibiotic use, or poor hand washing when the mother handles her newborn. Thrush is treated with an oral preparation of nystatin (Mycostatin).

A newborn who has ankyloglossia (tongue tied) has a ridge of frenulum tissue attached to the underside of the tongue at varying lengths from its base, causing a heart shape at the tip of the tongue. “Clipping the tongue,” or cutting the ridge of tissue, is recommended only in severe cases. This ridge generally does not affect speech or eating, and cutting creates an entry for infection.

Transient nerve paralysis resulting from birth trauma may be manifested by asymmetric mouth movements when the newborn cries or by difficulty with sucking and feeding.

EARS The ears of the newborn are soft and pliable and should recoil readily when folded and released. In the

Figure 33-77 >> The position of the external ear may be assessed by drawing a line across the inner and outer canthus of the eye to the insertion of the ear. **A**, Normal position. **B**, True low-set position.

normal newborn, the top of the ear (pinna) should be parallel to the outer and inner canthus of the eye. The ears should be inspected for shape, size, firmness of cartilage, and position. Low-set ears (**Figure 33-77** >>) are characteristic of many syndromes. Although most often associated with Down syndrome, low-set ears may indicate other chromosomal abnormalities, intellectual disability, and internal organ abnormalities, especially bilateral renal agenesis. Preauricular skin tags may be present just in front of the ear. Visualization of the tympanic membrane typically is not done soon after birth because blood and vernix block the ear canal.

The first cry helps initiate hearing improvement as mucus from the middle ear is absorbed, the eustachian tube becomes aerated, and the tympanic membrane becomes visible. Newborns, especially when awake, should startle or respond to loud noise. Although this is not a completely accurate test, absence of this response requires further evaluation. This is one of the reasons why the AAP has endorsed universal newborn hearing screening before discharge from the birthing unit as the standard of care (AAP & ACOG, 2012; Johnson, 2015). If the birth occurs in the home or an alternative birthing center, referral for screening should be made within 1 month of birth. The current goal is to screen all babies by 1 month of age, confirm hearing loss with audiologic examination by 3 months of age, and treat with comprehensive early intervention services before 6 months of age (AAP & ACOG, 2012). Families need to be educated about appropriate interpretation of screening test results and the suitable steps for follow-up.

The newborn can discriminate the individual characteristics of the human voice and is especially sensitive to sound levels within the normal conversational range. The newborn in a noisy nursery may habituate to the sounds and not stir unless the sound is sudden or much louder than usual.

NECK A short neck, creased with skinfolds, is characteristic of the normal newborn. Because muscle tone is not well developed, the neck cannot support the full weight of the head, which rotates freely. The head lags considerably when

the newborn is pulled from a supine to a sitting position, but the prone newborn is able to raise the head slightly. The neck is palpated for masses and the presence of lymph nodes and is also inspected for webbing. Adequacy of range of motion and neck muscle function is determined by fully extending the head in all directions. Injury to the sternocleidomastoid muscle (congenital torticollis) must be considered in the presence of neck rigidity.

The nurse evaluates the clavicles for evidence of fractures, which occasionally occur during difficult births or in newborns with broad shoulders. The normal clavicle is straight. If it is fractured, a lump and a grating sensation (crepitus) during movements may be palpated along the course of the side of the break. The nurse also elicits the Moro reflex to evaluate bilateral equal movement of the arms. If the clavicle is fractured, the response will be demonstrated only on the unaffected side.

CHEST The thorax is cylindrical and symmetric at birth, and the ribs are flexible. The general appearance of the chest should be assessed. A protrusion at the lower end of the sternum, called the xiphoid cartilage, is frequently seen. It is under the skin and will become less apparent after several weeks as adipose tissue accumulates.

Engorged breasts occur frequently in both male and female newborns. This condition, which occurs by the third day, is a result of maternal hormonal influences and may last up to 2 weeks (**Figure 33-78** >>). A whitish secretion from the nipples may also be noted. The newborn's breast should not be massaged or squeezed, because this may cause a breast abscess. Extra, or supernumerary, nipples are occasionally noted below and medial to the true nipples. These harmless pink or (in dark-skinned newborns) brown spots vary in size and do not contain glandular tissue. Accessory nipples can be differentiated from a pigmented nevus (mole) by placing the fingertips alongside the accessory nipple and pulling the adjacent tissue laterally. The accessory nipple will appear dimpled. At puberty, the accessory nipple may darken.

Source: Michele Davidson.

Figure 33-78 >> Breast hypertrophy.

CRY The newborn's cry should be strong, lusty, and of medium pitch. A high-pitched, shrill cry is abnormal and may indicate neurologic disorders or hypoglycemia. Periods of crying usually vary in length after consoling measures are used. Babies' cries are an important method of communication; alerting caregivers to changes in a baby's condition and needs.

RESPIRATIONS Normal respiration for a term newborn is 30–60 breaths/minute and is predominantly diaphragmatic, with associated rising and falling of the abdomen during inspiration and expiration. The nurse notes any signs of respiratory distress, nasal flaring, intercostal or xiphoid retraction, expiratory grunt or sigh, seesaw respirations, or tachypnea (>60 breaths/minute). Hyperextension (chest appears high) or hypoextension (chest appears low) of the anteroposterior diameter of the chest should also be noted. The nurse auscultates both the anterior and posterior chest. Some breath sounds are heard best when the newborn is crying, but localizing and identifying breath sounds are difficult in the newborn. Upper airway noises and bowel sounds can be heard over the chest wall, making auscultation difficult. Because sounds may be transmitted from the unaffected lung to the affected lung, the absence of breath sounds may not be diagnosed. Air entry may be noisy in the first couple of hours until lung fluid resolves, especially after cesarean births. Brief periods of apnea (periodic breathing) occur, but no color or heart rate changes occur in healthy, term newborns. Sepsis should be suspected in term newborns experiencing apneic episodes.

HEART The nurse examines the heart for rate and rhythm, position of the apical impulse, and heart sound intensity. The pulse rate is variable and is influenced by physical activity, crying, state of wakefulness, and body temperature. The nurse auscultates the entire chest region (precordium) below the left axilla, and below the scapula. Auscultation for a full minute, preferably when the newborn is asleep, allows the nurse to obtain apical pulse rates.

A shift of heart tones in the mediastinal area to either side may indicate pneumothorax, dextrocardia (heart placement on the right side of the chest), or a diaphragmatic hernia. The nurse should auscultate heart sounds using both the bell and the diaphragm of the stethoscope. A slur or slushing sound (usually after the first sound) may indicate a murmur. Although 90% of all murmurs are transient and are considered to be normal, the nurse should document and report them. Many murmurs are secondary to closing of a patent ductus arteriosus or a patent foramen ovale, which should close 1–2 days after birth. A low-pitched, musical murmur just to the right of the apex of the heart is fairly common. Occasionally, significant murmurs are heard, such as the murmur of a patent ductus arteriosus, aortic or pulmonary stenosis, or small ventricular septal defect. Congenital cardiac defects are discussed in the module on Perfusion.

The nurse evaluates peripheral pulses (brachial, femoral, and pedal) to detect any lags or unusual characteristics.

Brachial pulses are palpated bilaterally for equality and compared with the femoral pulses. Femoral pulses are palpated by applying gentle pressure with the middle finger over the femoral canal (**Figure 33-79** **»**). Decreased or absent femoral pulses may indicate coarctation of the aorta or hypovolemia and require additional evaluation. A wide difference in blood pressure between the upper and lower extremities also indicates coarctation of the aorta.

The measurement of blood pressure is best accomplished by using a noninvasive blood pressure device. If a blood pressure cuff is used, the newborn's extremities must be immobilized during the assessment, and the cuff should cover two thirds of the upper arm or upper leg. Movement, crying, and inappropriate cuff size can give inaccurate measurements of the blood pressure.

A

B

Figure 33-79 **»** **A**, Bilaterally palpate the femoral arteries for rate and intensity of the pulses. Press fingertip gently at the groin as shown. **B**, Compare the femoral pulses to the brachial pulses by palpating the pulses simultaneously for comparison of rate and intensity.

SAFETY ALERT If possible, obtain blood pressure measurements during the quiet sleep or sleep state. Place the cuff on the neonate's arm or leg, and give the neonate time to quiet. Obtain an average of two to three measurements when making clinical decisions. Follow mean blood pressure to monitor changes, because the mean blood pressure is less likely to be erroneous. Noninvasive blood pressure may overestimate blood pressure in very-low-birth-weight neonates.

It is essential to measure blood pressure routinely for newborns who are in distress, premature, or suspected of having a cardiac anomaly (Vargo, 2014). Neonates who have birth asphyxia and are on ventilators have significantly lower systolic and diastolic blood pressures compared with healthy neonates. If a cardiac anomaly is suspected, blood pressure is measured in all four extremities. At birth, systolic values usually range from 70 to 50 mmHg and diastolic values from 45 to 30 mmHg. By the 10th day of life, blood pressure rises to 90/50 mmHg.

ABDOMEN The nurse can learn a great deal about the newborn's abdomen without disturbing the neonate. The abdomen should be cylindrical, protrude slightly, and move with respiration. A certain amount of laxness of the abdominal muscles is normal. A scaphoid (hollow-shaped) appearance suggests the absence of abdominal contents (often seen in diaphragmatic hernias). No cyanosis should be present, and few, if any, blood vessels should be apparent to the eye. There should be no gross distention or bulging. The more distended the abdomen, the tighter the skin becomes, with engorged vessels appearing. Distention is the first sign of many gastrointestinal abnormalities.

Before palpating the abdomen, the nurse should auscultate for the presence or absence of bowel sounds in all four quadrants. Bowel sounds may be present by 1 hour after birth. Palpation can cause a transient decrease in the intensity of bowel sounds.

The nurse palpates the abdomen systematically, assessing each of the four abdominal quadrants and moving in a clockwise direction until all four quadrants have been palpated for softness, tenderness, and the presence of masses. The nurse should place one hand under the newborn's back for support during palpation.

UMBILICAL CORD The umbilical cord initially appears white and gelatinous, with the two umbilical arteries and one umbilical vein readily apparent. Because a single umbilical artery is frequently associated with congenital anomalies, the nurse should count the vessels during the newborn assessment. The cord begins drying within 1 or 2 hours of birth and is shriveled and blackened by the second or third day. Within 7–10 days, it sloughs off, although a granulating area may remain for a few days longer.

Cord bleeding is abnormal and may result because the cord was inadvertently pulled or the cord clamp was loosened. Foul-smelling drainage is also abnormal and is generally caused by infection, which requires immediate treatment to prevent septicemia. If the newborn has a patent urachus (abnormal connection between the umbilicus and bladder),

Source: George Dodson/Pearson Education, Inc.

Figure 33–80 » Umbilical hernia.

moistness or draining urine may be apparent at the base of the cord. Another umbilical cord anomaly that can occur is umbilical cord hernia and associated patent omphalomesenteric duct (**Figure 33–80** »). Umbilical hernias are more common in newborns of African American descent than in Caucasian babies (Goodwin, 2015).

GENITALS For female neonates, the nurse examines the labia majora, labia minora, and clitoris and notes whether the size of each is appropriate for gestational age. A vaginal tag or hymenal tag is often evident and will usually disappear in a few weeks. During the first week of life, the female newborn may have a vaginal discharge composed of thick, whitish mucus. This discharge, which can become tinged with blood, is called pseudomenstruation and is caused by the withdrawal of maternal hormones. Smegma (a white, cheeselike substance) is often present between the labia. Removing it may traumatize tender tissue.

For male neonates, the nurse inspects the penis to determine whether the urinary orifice is positioned correctly. Possible alterations include *hypospadias*, which occurs when the urinary meatus is located on the ventral surface of the penis, and *epispadias*, in which the meatus is located on the dorsal surface of the glans. Hypospadias occurs most commonly among individuals of Western European descent. *Phimosis* is a condition in which the opening of the foreskin (prepuce) is small and the foreskin cannot be pulled back over the glans at all. This condition may interfere with urination, so the adequacy of the urinary stream should be evaluated.

The nurse then inspects the scrotum for size and symmetry. Scrotal color variations are especially prominent in African American, Indian, and Hispanic newborns (Vargo, 2014). Palpation allows the nurse to verify the presence of both testes and to rule out cryptorchidism (failure of testes to descend). The nurse palpates the testes separately between the thumb and forefinger, with the thumb and forefinger of the other hand placed together over the inguinal canal. Scrotal edema and discoloration are common in breech births. *Hydrocele* (a collection of fluid surrounding the testes in the scrotum) is common in newborns and should be identified. It usually resolves without intervention.

The nurse should report the presence of a discolored or dusky scrotum and solid testis, because this may indicate testicular torsion.

ANUS It is essential to inspect the anal area to verify that it is patent and has no fissure. Imperforate anus and rectal atresia may be ruled out by observation and through an initial rectal temperature. Digital examination, if necessary, is done by a physician or nurse practitioner. The nurse also notes the passage of the first meconium stool. Atresia of the gastrointestinal tract or meconium ileus with resultant obstruction must be considered if the newborn does not pass meconium in the first 24 hours of life.

EXTREMITIES The nurse assesses the newborn's extremities for gross deformities, extra digits or webbing, clubfoot, and range of motion. Normal newborn extremities appear short, are generally flexible, and move symmetrically. Abnormalities should be noted so that the plan of care may be created.

Nails extend beyond the fingertips in term newborns. The nurse should count fingers and toes. Polydactyly is the presence of extra digits on either the hands or the feet. Syndactyly refers to fusion (webbing) of fingers or toes. The hands are inspected for normal palmar creases; a single palmar crease, called a simian line (**Figure 33-81** >>), is frequently present in children with Down syndrome.

Brachial palsy, paralysis of portions of the arm, results from trauma to the brachial plexus during a difficult birth. It occurs commonly when strong traction is exerted on the head of the newborn in an attempt to deliver a shoulder lodged behind the symphysis pubis in the presence of shoulder dystocia. Brachial palsy may also occur during a breech birth if an arm becomes trapped over the head and traction is exerted.

The portion of the arm affected is determined by the nerves damaged. **Erb-Duchenne paralysis (Erb palsy)** involves damage to the upper arm (fifth and sixth cervical nerves) and is the most common type. Injury to the eighth

cervical and first thoracic nerve roots and the lower portion of the plexus produces the relatively rare lower arm injury. The whole-arm type results from damage to the entire plexus.

With Erb-Duchenne paralysis, the newborn's arm lies limply at the side. The elbow is held in extension, with the forearm pronated. The newborn is unable to elevate the arm. Lower arm injury causes paralysis of the hand and wrist; complete paralysis of the limb occurs with the whole-arm type.

The nurse carefully instructs the parents in the correct method of performing passive range-of-motion (ROM) exercises (to prevent muscle contractures and restore function) and arranges supervised practice sessions for the parents and referral to physical therapy follow-up within 2 weeks of discharge. In more severe cases, splinting of the arm is indicated until the edema decreases. The arm is held in a position of abduction and external rotation, with the elbow flexed 90 degrees; this is often called the "Statue of Liberty" position. The "Statue of Liberty" splint is commonly used, although similar results are obtained by attaching a strip of muslin to the head of the crib and tying the other end around the wrist, thereby holding the arm up.

Prognosis is related to the degree of nerve damage resulting from trauma and hemorrhage within the nerve sheath. With minimal trauma, complete recovery occurs within a few months. Moderate trauma may result in partial paralysis. With severe trauma, recovery is unlikely, and muscle wasting may develop.

The legs of the newborn should be of equal length, with symmetric skinfolds. However, they may assume a "fetal posture" secondary to position in utero, and it may take several days for the legs to relax into a normal position. To evaluate for hip dislocation or hip instability, the Ortolani and Barlow maneuvers are performed. The nurse (or, more commonly, the physician or nurse practitioner) performs the **Ortolani maneuver** to rule out the possibility of developmental dysplastic hip, also called congenital hip dysplasia (hip dislocatability). With the newborn relaxed, quiet, and on a firm surface, with hips and knees flexed at a 90-degree angle, the experienced nurse grasps the neonate's thigh with the middle finger over the greater trochanter and then lifts the thigh to bring the femoral head from its posterior position toward the acetabulum. With gentle abduction of the thigh, the femoral head is returned to the acetabulum. Simultaneously, the examiner feels a sense of reduction or a "clunk" as the femoral head returns. This reduction is palpable and may be heard. With the **Barlow maneuver**, the healthcare provider grasps and adducts the neonate's thigh and then applies gentle downward pressure. Dislocation is felt as the femoral head slips out of the acetabulum. The femoral head is then returned to the acetabulum using the Ortolani maneuver, confirming the diagnosis of an unstable or dislocatable hip (**Figure 33-82** >>).

The feet are then examined for evidence of a talipes deformity (clubfoot). Intrauterine position frequently causes the feet to appear to turn inward (**Figure 33-83** >>); this is termed a "positional" clubfoot. If the feet can easily be returned to the midline by manipulation, no treatment is indicated, and the nurse teaches ROM exercises to the family. Further evaluation is indicated when the foot will not turn

The baby's thigh is grasped and adducted (placed together) with gentle downward pressure. **C**, Dislocation is palpable as the femoral head slips out of the acetabulum. **D**, The Ortolani maneuver puts downward pressure on the hip and then inward rotation. If the hip is dislocated, this maneuver will force the femoral head back into the acetabular rim with a noticeable "clunk."

to a midline position or align readily. This is considered the most severe type of "true clubfoot," or talipes equinovarus.

BACK With the newborn prone, the nurse examines the back. The spine should appear straight and flat, because the lumbar and sacral curves do not develop until the newborn begins to sit. The base of the spine is examined for a dermal sinus. A nevus pilosus ("hairy mole") is occasionally found at the base of the spine. This is significant because it is frequently associated with spina bifida. A pilonidal dimple should be examined to ascertain that there is no connection to the spinal canal.

Assessing Neurologic Status

The nurse should begin the neurologic examination with a period of observation, noting the general physical

characteristics and behaviors of the newborn. Important behaviors to assess are the state of alertness, resting posture, cry, and quality of muscle tone and motor activity.

The usual position of the newborn is with partially flexed extremities, with the legs abducted to the abdomen. When awake, the newborn may exhibit purposeless, uncoordinated bilateral movements of the extremities. If these movements are absent, minimal, or obviously asymmetric, then neurologic dysfunction should be suspected.

Eye movements are observable during the first few days of life. An alert newborn is able to fixate on faces and brightly colored objects. Shining a bright light in the newborn's eyes elicits the blinking response.

The nurse evaluates muscle tone by moving various parts of the body while the head of the newborn is in a neutral position. The newborn is somewhat hypertonic; that is, there

should be resistance to extending the elbow and knee joints. Muscle tone should be symmetric. Diminished muscle tone and flaccidity require further evaluation.

Tremors or jitteriness (tremor-like movements) in the term newborn must be evaluated to differentiate the tremors from convulsions. Tremors may also be related to hypoglycemia, hypocalcemia, or substance withdrawal. Environmental stimuli may initiate tremors. Jitteriness may be distinguished from tonic-clonic seizure activity because it usually can be stopped by the baby's sucking on the extremity or by the nurse holding or flexing the involved extremity. A fine jumping of the muscle is likely to be a CNS disorder and requires further evaluation. Newborn seizures may consist of no more than chewing or swallowing movements, deviations of the eyes, rigidity, or flaccidity because of CNS immaturity. In contrast to tremors, seizures are not usually initiated by stimuli, and they cannot be stopped by holding.

Specific deep tendon reflexes can be elicited in the newborn but have limited value unless they are obviously asymmetric. The knee jerk is typically brisk; a normal ankle clonus may involve three or four beats. Plantar flexion is present.

The newborn's immature CNS is characterized by a variety of reflexes. Because the newborn's movements are uncoordinated, methods of communication are limited, and control of bodily functions is restricted, the reflexes serve a variety of purposes. Some are protective (blink, gag, and sneeze), some aid in feeding (rooting and sucking) and may not be very active if the newborn has eaten recently, and some stimulate human interaction (grasping). See Table 33-17 for commonly found reflexes in the normal newborn.

The nurse assesses CNS integration as follows:

1. The nurse inserts a gloved finger into the newborn's mouth to elicit a sucking reflex.
2. As soon as the newborn is sucking vigorously, the nurse assesses hearing and vision responses by noting changes in sucking in the presence of a light, a rattle, and a voice.
3. The newborn should respond to such stimuli with a brief cessation of sucking, followed by continuous sucking with repeated stimulation.

This CNS integration exam demonstrates auditory and visual integrity as well as the ability to conduct complex behavioral interactions.

As healthcare providers carry out the newborn physical and neurologic assessment, they are always on the alert to recognize possible alterations and possible injuries related to the birth process that require further investigation and intervention.

Assessing Newborn Behavior

The **Brazelton Neonatal Behavioral Assessment Scale** provides valuable guidelines for assessing the newborn's state changes, temperament, and individual behavioral patterns (Brazelton, 1984). It provides a way for the nurse, in conjunction with the parents (primary caregivers), to identify and understand the individual newborn's states and capabilities. Families learn which responses, interventions, or activities best meet the special needs of their newborn, and this understanding fosters positive attachment experiences.

The Brazelton assessment tool identifies the newborn's repertoire of behavioral responses to the environment and also documents the newborn's neurologic adequacy and capabilities. The examination usually takes 20–30 minutes and involves approximately 30 tests. Some items are scored according to the newborn's response to specific stimuli. Others, such as consolability and alertness, are scored as a result of continuous behavioral observations throughout the assessment. (For a complete discussion of all test items and maneuvers, see Brazelton & Nugent, 1995.)

Because the first few days after birth are a period of behavioral disorganization, the complete assessment should be done on the third day after birth. The nurse should make every effort to elicit the best response. This may be accomplished by repeating tests at different times or by testing during situations that facilitate the best possible response, such as when the parents are holding, cuddling, rocking, and/or singing to their baby.

Assessment of the newborn should be carried out initially in a quiet, dimly lighted room, if possible. The nurse should first determine the newborn's state of consciousness, because scoring and introduction of the test items are correlated with the sleep or waking state (discussed previously). The newborn's state depends on physiologic variables, such as the amount of time from the last feeding, positioning, environmental temperature, and health status; the presence of such external stimuli as noises and bright lights; and the sleep-wake cycle of the neonate. An important characteristic of the newborn period is the pattern of states, as well as the transitions from one state to another. The pattern of states is a predictor of the newborn's receptivity and ability to respond to stimuli in a cognitive manner. Babies learn best in a quiet, alert state and in an environment that is supportive and protective and that provides appropriate stimuli.

The nurse should observe the newborn's sleep-wake patterns, including the rapidity with which the newborn moves from one state to another, the newborn's ability to be consoled, and the newborn's ability to diminish the impact of disturbing stimuli. The following questions may provide the nurse with a framework for assessment:

- Does the newborn's response style and ability to adapt to stimuli indicate a need for parental interventions that will alert the newborn to the environment so that he or she can grow socially and cognitively?
- Are parental interventions necessary to lessen the outside stimuli, as in the case of the baby who responds to sensory input with intensity?
- Can the baby control the amount of sensory input that he or she must deal with?

The behaviors, and the sleep-wake states in which they are assessed, are categorized as follows:

- **Habituation.** The nurse assesses the newborn's ability to diminish or shut down innate responses to specific repeated stimuli, such as a rattle, bell, light, or pinprick to the heel.
- **Orientation to inanimate and animate visual and auditory assessment stimuli.** The nurse observes how often and where the newborn attends to auditory and visual stimuli. Orientation to the environment is determined by an ability to respond to clues given by others and by a natural ability to fix on and follow a visual object both horizontally and vertically. This capacity and the parental appreciation of it are important for positive communication between newborn and parents; the parents' visual (*en face*) and auditory (soft, continuous voice) presence stimulates their newborn to orient to them. Inability or a lack of response may indicate visual or auditory problems. It is important for parents to know that their newborn can turn to voices soon after birth or by 3 days of age and can become alert at different times with a varying degree of intensity in response to sounds.
- **Motor activity.** Several components are evaluated. Motor tone of the newborn is assessed in the most characteristic state of responsiveness. This summary assessment includes overall use of tone as the newborn responds to being
